18. Consensus

Consensus (sometimes called ‘reliable broadcast’ or ‘atomic broadcast’) is a fundamental building block for distributed systems. Informally, we say that several processes achieve consensus if they all agree on some value. Three obvious applications are:

Distributed transactions, where all the processes need to agree on whether a transaction commits or aborts. Each transaction needs a new consensus on its outcome.

Membership, where a set of processes cooperating to provide a highly available service need to agree on which processes are currently functioning as members of the set. Every time a process fails or starts working again there must be a new consensus.

ELECTING A LEADER OF A GROUP OF PROCESSES

State machines

There is a much more general way to use consensus, as the mechanism for implementing a highly available state machine. The way to get availability is to have either perfect components or redundancy. The simplest form of redundancy is replication: have several copies of each component, and make all the non-faulty components do the same thing. Since any computation can be expressed as a state machine, a replicated state machine can make any computation highly available.

Recall the basic idea of a replicated state machine:

If the transition relation is deterministic (in other words, is a function from (state, input) to (new state, output)), then several copies of the state machine that start in the same state and see the same sequence of inputs will do the same thing, that is, end up in the same state and produce the same outputs.

So if several processes are implementing the same state machine and achieve consensus on the values and order of the inputs, they will do the same thing. In this way it’s possible to replicate an arbitrary computation and thus make it highly available. Of course we can make the order a part of the value of the input by defining some total order on the set of possible inputs.\footnote{This approach was first proposed in a classic paper by Leslie Lamport: Time, clocks, and the ordering of events in a distributed system, \textit{Comm. ACM} 21, 7, July 1978, pp 558-565. This paper is better known for its analysis of the partial ordering of events in a distributed system, which is too bad.} We have already seen one application of this replicated state machine idea, in the implementation of transactional services; there the replication takes the form of redoing a sequence of actions that is remembered in a log.

In many applications the inputs are requests from clients to the replicated service. Typically different clients generate their requests independently, so it’s necessary to agree not only on what the requests are, but also on the order in which to serve them. The simplest way to do this is to number them with consecutive integers, starting at 1. This is what is done in ‘primary copy’ replication, since it’s easy for one place (the primary) to assign consecutive numbers.

The literature contains many other schemes for achieving consensus on the order of requests when their total order is not derived from consecutive integers. These schemes label each input with some label from a totally ordered set (for instance, (client UID, timestamp) pairs) and then devise some way to be certain that you have seen all the inputs that can ever exist with labels smaller than a given value. They are complicated, and of doubtful utility.\footnote{For details, see F. Schneider, Implementing fault-tolerant services using the state-machine approach: A tutorial, \textit{ACM Computing Surveys} 22 (Dec 1990). This paper is reprinted in the book \textit{Distributed Systems}, 2nd edition, ed. S. Mullender, Addison-Wesley, 1993, pp 169-197.}

The section on leases at the end of this handout explains practical methods for minimizing the number of times you need to use consensus in implementing a reliable state machine.

**Specification for consensus**

Here is the specification for consensus; we have seen it already in handout 8 on history and prophecy variables. There is an \textit{outcome} variable initialized to \textit{nil}, and an action \textit{Allow(v)} that can be invoked any number of times. There is also an action \textit{Outcome} to read the outcome variable; it must return either \textit{nil} or a \textit{v} which was the argument of some \textit{Allow} action, and it must always return the \textit{same} \textit{v}.

More precisely, we have two requirements:

\begin{itemize}
  \item \textbf{Agreement:} Every non-\textit{nil} result of \textit{Outcome} is the same.
  \item \textbf{Validity:} A non-\textit{nil} \textit{outcome} equals some allowed value.
\end{itemize}

Validity means that the outcome can’t be any arbitrary value, but must be a value that was allowed. Consensus is reached by choosing some allowed value and assigning it to \textit{outcome}. This spec makes the choice on the fly as the allowed values arrive.

\begin{verbatim}
MODULE Consensus [V] EXPORT Allow, Outcome = % data Value to agree on
VAR outcome : (V + Null) := nil
APROC Allow(v) = << outcome = nil => outcome := v [] SKIP >>
APROC Outcome() -> (V+Null) = << RET outcome [] RET nil >>
END Consensus
\end{verbatim}

Note that \textit{Outcome} is allowed to return \textit{nil} even after the choice has been made. This reflects the fact that in an implementation with several replicas, \textit{Outcome} is often implemented by talking to just one of the replicas, and that replica may not yet have learned about the choice.

If only one \textit{Allow} action occurs, there’s no need to choose a \textit{v}, and the implementation’s only problem is to ensure termination. An algorithm that does so is said to implement ‘reliable’ or ‘atomic’ broadcast; there is only one sender, and either everyone or no one gets the message. The
This is usually too strong for a distributed implementation. It means that a process may not be able to respond to an `Outcome` request, since it can’t return a value if it doesn’t know the outcome yet, and it can’t return `nil` if anyone else has already returned a value.

### Facts about consensus

In this section we summarize the most important facts about when consensus is possible and what it costs. You can learn more about this in Nancy Lynch’s course on distributed algorithms, 6.852J, or in her book cited in handout 2.

#### Fault models

To devise an implementation of `Consensus` we need a precise model for the general setting of processes connected by links that can communicate messages from one process to another. In particular, the model must define what faults are possible. There are lots of ways to do this, and we have space to describe only the models that are most popular and closest to reality.

There are two broad classes of models:

- **Synchronous**, in which a non-faulty component makes its state transitions within a known amount of time. Usually this is implemented by using a timeout, and declaring a component faulty if it fails to perform within the specified time.
- **Asynchronous**, in which nothing is known about the relative rate of progress of different components. In particular, a process can take an arbitrary amount of time to make a transition, and a link can take an arbitrary amount of time to deliver a message.

In general a process can send a message only to certain other processes; this “can send message” relation defines a graph whose edges are the links. The graph may be directed (it’s possible that `A` can talk to `B` but `B` can’t talk to `A`), but we will assume that communication is full-duplex so that the graph is undirected. Links are either working or faulty; a faulty link delivers no messages. Even a working link may lose messages, and in some models may lose any number of messages; it’s helpful to think of such a system as one with totally asynchronous communication.

Processes are either working or faulty. There are two models for a faulty process:

- **Stopping** faults: a faulty process stops making transitions and doesn’t start again. In an asynchronous model this isn’t very interesting, since there’s no way to distinguish a stopped process or link from one that is simply very slow.
- **Byzantine** faults: a faulty process makes arbitrary transitions; these are named after the Byzantine Empire, famous for treachery. The motivation for this model is usually not fear of treachery, but ignorance of the ways in which a process might fail. Clearly Byzantine failure is an upper bound on how bad things can be.

#### Is consensus possible (will it terminate)?

A consensus algorithm terminates when the outcome variables of all non-faulty processes equal some allowed value. Here are the basic facts about consensus in some of these models.
• There is no consensus algorithm that is guaranteed to terminate in an asynchronous system with perfect links and even one process that has a stopping fault. This startling result is due to Fischer, Lynch, and Paterson. It holds even if the communication system provides reliable broadcast that delivers each message either to all the non-faulty processes or to none of them. Real systems get around it by using timeout to make the system synchronous.

• Even in a synchronous system with perfect processes there is no consensus algorithm that is guaranteed to terminate if an unbounded number of messages can be lost (that is, if communication is effectively asynchronous). The reason is that the last message sent must be pointless, since it might be lost. So it can be dropped to get a shorter algorithm. Repeat this argument to drop all the messages. But clearly an algorithm with no messages can’t achieve consensus. The simplest case of this problem, with just two processes, is called the “two generals problem”.

• In a system with both synchronous processes and synchronous communication, consensus is possible. If \( f \) faults are allowed, then:
  
  For processes with stopping faults, consensus requires \( f+1 \) processes and an \( f+1 \)-connected network (that is, at least one good process and a connected subnet of good processes after all the allowed faults have happened). Even if the network is fully connected, it takes \( f+1 \) rounds to reach consensus in the worst case.

  For processors with Byzantine faults, consensus requires \( 3f+1 \) processes, a \( 2f+1 \)-connected network, at least \( f+1 \) rounds of communication, and \( 2^f \) bits of data communicated.

  For processors with Byzantine faults and digital signatures (so that a process can present unforgeable evidence that another process sent it a message), consensus requires \( f+1 \) processes. Even if the network is fully connected, it takes \( f+1 \) rounds to reach consensus in the worst case.

The amount of communication required depends on the number of faults, the complexity of the algorithm, etc. Randomized algorithms can achieve better results with arbitrarily high probability.

Warning: In many applications the model of no more than \( f \) faults may not be realistic if the system is allowed to do the wrong thing when the number of faults exceeds \( f \). It’s often more important to do either the right thing or nothing.

### The simplest consensus algorithms

There are two simple and popular algorithms for consensus. Both have the problem that they are not very fault-tolerant.

• A fixed ‘leader’, ‘master’, or ‘coordinator’ process that works like the Consensus spec: it gets all the Allow actions, chooses the outcome, and tells everyone. If it fails, you are out of luck. The abstraction function is just the identity on the leader’s state; TermConsensus.done is true iff everyone has gotten the outcome (or failed permanently). Standard two-phase commit for distributed transactions works this way.

• Simple majority voting. The abstraction function for outcome is the value that has a majority, or nil if there isn’t one. This fails if you don’t get a majority, or if enough members of a majority fail that it isn’t a majority any more. In the latter case you can’t determine the outcome. Example: a vote for ab and c vote for d, and b fails. Now all you can see is one vote for 11 and one for 12, so you can’t tell that 12 had a majority.

#### The Paxos algorithm: The idea

In the rest of this handout, we describe Lamport’s Paxos algorithm for implementing consensus; Liskov and Oki independently invented this algorithm as part of a replicated data storage system. Its heart is the best asynchronous algorithm known, which is run by a set of leader processes that guide a set of agent processes to achieve consensus, correct no matter how many simultaneous leaders there are and no matter how often leader or agent processes fail and recover or how slow they are, and guaranteed to terminate if there is a single leader for a long enough time during which each member of a majority of the agent processes is up for long enough, but possibly non-terminating if there are always too many leaders (fortunate, since we know that guaranteed termination is impossible).

To get a complete consensus algorithm we combine this with a sloppy timeout-based algorithm for choosing a single leader. If the sloppy algorithm leaves us with no leader or more than one leader for a time, the consensus algorithm may not terminate during that time. But if the sloppy algorithm ever produces a single leader for long enough the algorithm will terminate, no matter how messy things were earlier.

Paxos is the way to do consensus if you want a high degree of fault-tolerance, don’t have any real-time requirements, and can’t tightly control the time to transmit and process a message. There isn’t any simpler algorithm that has the same fault-tolerance. There are lots of implemented consensus schemes that don’t work.

The grand plan of the algorithm is to have a sequence of rounds, each with a single leader. This attacks the problem with simple majority voting, which is that a single attempt to get a majority

---

4 A graph is connected if there is a path (perhaps traversing several links) between any two nodes, and disconnected otherwise. It is \( k \)-connected if \( k \) is the smallest number such that removing \( k \) links can leave it disconnected.

may fall victim to failure. Each Paxos round is a distinct attempt to get a majority. In each round the leader

queries the agents to learn their state for past rounds,

chooses a value $v$ and commands the agents, trying to get a majority to accept $v$, and

if successful, distributes $v$ as the outcome to everyone.

The outcome is the value accepted by a majority in some round. The tricky part of the algorithm is to ensure that there is only one such value, even though there may be lots of rounds.

The agents do not make any decisions; they do whatever a leader requests, unless they have already done something inconsistent with that. In fact, an agent can be implemented by a memory that has a compare-and-swap operation, as we shall see later. Of course, the leaders and agents can run on the same machine, and even in the same process. This is usually the way it’s implemented, but the algorithm with separate leaders and agents is easier to explain.

It takes a total of 21/2 round trips for a successful round. If there’s only one leader that doesn’t fail, Paxos reaches consensus in one round. If the leader fails repeatedly, or several leaders fight it out, it may take many rounds to reach consensus.

The rounds are numbered (not necessarily consecutively), and the numbers determine a total ordering on the rounds. Each round has a single value, which starts out $\text{nil}$ and then may change to one of the allowed values; we write $v_n$ for the value of round $n$. In each round an agent starts out $\text{neutral}$, and it can only change to $v_n$ or $\text{no}$. A $v_n$ or $\text{no}$ state can’t change. Note that different rounds can have different values. A round is dead if a majority has state $\text{no}$, and successful if a majority has state $v_n$. If a round is successful, that round’s value is the outcome.

The state of Paxos that contributes to the abstraction function to \text{LateConsensus} is

\begin{verbatim}
MODULE Paxos[  
  V,  
  L WITH [*=: (L, L)->Bool],  
  A WITH [majority : SET A->Bool] ]  

TYPE I = Int  
N = [i, l] WITH [*=:LEqN]  
S = (ENUM[no, neutral] + V)  
Z = A -> N -> S

VAR agents : Z ::= [*->[*->neutral]}  
outcome : A -> (V+Null) ::= [*->nil]  
allowed : L -> SET V ::= [*->[]]}  

% Agreement: ( EXISTS v | outcome.rng <= (v, nil) )
% Validity: outcome.rng <= (+ : allowed.rng) + [nil]

Paxos ensures that a round has a single value by having at most one leader process per round, and making the leader’s identity part of the round number. So $N = [i, l]$, and leader $l$ chooses $(i, l)$ for $n$, where $i$ is an $i$ that $l$ has not used before, for instance, a local clock. The leader keeps $v_n$ in a volatile variable; rather than resuming an old round after a crash, it just starts a new one.

To understand why the algorithm works, it’s useful to have the notion of a stable predicate on the state, a predicate that once true, remains true henceforth. Since the non-$\text{nil}$ value of a round can’t change, "$v_n = v$" is stable. Since a state value once set can’t change, $\text{agents}(a)(n) = v$ and $\text{agents}(a)(n) = \text{no}$ are stable; hence "round $n$ is dead" and "round $n$ is successful" are stable as well.

Here is a more complex stable predicate:

\begin{align*}
\text{round } n \text{ is anchored } & = (\forall n' | n' \leq n \implies n' \text{ is dead } \lor v_n = v_n') \\
\text{lateConsensus } & = (\forall n | v_n = v_n')
\end{align*}

In other words, if you look back at rounds before $n$, skipping dead rounds, you see the same value as $n$. If all preceding rounds are dead, round $n$ is anchored no matter what its value is. For this to be well-defined, we need an ordering on $N$, and for it to be useful we need a total ordering. We get this as the lexicographic ordering on the $N = [i, l]$ pairs. This means that we need a total ordering on the leaders $L$.

With these preliminaries, we can give the abstraction function from Paxos to \text{LateConsensus}. For allowed it is just the union of the leaders’ allowed sets. For outcome it is the value of a successful round.

\begin{verbatim}
ABSTRACTION FUNCTION
LateConsensus.allowed = + : allowed.rng
LateConsensus.outcome = (n | Successful(n) | Value(n)).choose

FUNC Successful(n) -> Bool = RET {a | agents(a)(n) IS V}.majority
FUNC Value(n) -> (V+Null) = IF VAR a, v | agents(a)(n) = v => RET v [*] RET nil FI

For this to be an abstraction function, we need an invariant:

(1) Every successful round has the same value.

It’s easy to see that this follows from a stronger invariant: If round $n'$ is successful, then any later round’s value is the same or $\text{nil}$.

(2) (ALL n', n | n'<=n /\ n' is successful) => v_n = nil \/= v_n'

This in turn follows easily from something with a weaker antecedent:

(3) (ALL n', n | n'<=n /\ n' is not dead) => v_n = nil \/= v_n'

For validity, we also need to know that every round’s value is allowed:

(4) (ALL n | v_n = nil \/= v_n IN (+ : allowed.rng))

Initially all the $v_n$ are $\text{nil}$ so that (3) holds trivially. The Paxos algorithm maintains (3) by choosing the $v$ value of a round so that the round is anchored. To accomplish this, the leader chooses a new $n$ and queries all the agents to learn their state in all rounds with numbers less than $n$. Before an agent responds, it changes any neutral state for a round earlier than $n$ to $\text{no}$.

Handout 18. Consensus

7
Responses to this query from a majority of agents give the leader enough information to make round \( n \) anchored, as follows:

It looks back from \( n \), skipping over rounds with no \( \nu \) state, since these must be dead (remember that the reported state is a \( \nu \) or \( \text{no} \)). When it comes to a round \( n' \) with \( \nu \), in some agent in the majority, it chooses \( \nu \) as \( \nu \). Since \( n' \) is anchored by (13), and all the rounds between \( n' \) and \( n \) are dead, \( n \) is also anchored.

If all previous rounds are dead, the leader chooses any allowed value for \( \nu \). In this case \( n \) is certainly anchored.

Because ‘anchored’ and ‘dead’ are stable properties, no state change can invalidate this choice.

Another way of looking at this is that because a successful round is not dead and can never become dead, it forms a barrier that the leader can’t get past in choosing a value that will make a later round anchored. Thus the successful round forces the leader of the later round to choose the same value. A later round can choose differently from an earlier one only if the earlier one is dead.

An example may help to clarify the idea. Assume the allowed set is \{\( x, y, z \}\}. Given the following two sets of states in rounds 1 through 3, with three agents \( a, b, \) and \( c \), the leader’s possible choices for round 4 are as indicated. In the right-hand column there is a majority for \( z \) in round 2.

<table>
<thead>
<tr>
<th>Value, agents</th>
<th>( a )</th>
<th>( b )</th>
<th>( c )</th>
<th>Value, agents</th>
<th>( a )</th>
<th>( b )</th>
<th>( c )</th>

<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Note that only the latest \( \nu \) state is of interest, so only that state actually has to be transmitted.

Now in a second round trip the leader \textit{commands} everyone for round \( n \). Each agent that is still neutral in round \( n \) (because it hasn’t answered the query of a round later than \( n \)) \textit{accepts} by changing its state to \( \nu \), in round \( n \); in any case it reports its state to the leader. If the leader collects \( \nu \), reports from a majority of agents, then it knows that round \( n \) has succeeded, takes \( \nu \) as the agreed outcome of the algorithm, and sends this fact to all the processes in a final half round. Thus the entire process takes five messages or 2\( \frac{1}{2} \)round trips.

When a round succeeds, that is, what action simulates the \textit{agree} action of the spec? It succeeds at the instant that some agent forms a majority by accepting its value, \textit{even though} no agent or leader knows at the time that this has happened. In fact, it’s possible for the round to succeed without the leader knowing this fact, if some agents fail after accepting but before getting their reports to the leader, or if the leader fails. In this case, some leader will have to run another round, but it will have the same value as the invisibly successful round.

When does Paxos terminate? If no leader starts another round until after an existing one is successful, then the algorithm definitely terminates as soon as the leader succeeds in both querying and commanding a majority. It doesn’t have to be the same majority for both, and the agents don’t all have to be up at the same time. Therefore we want a single leader, who runs one round at a time. If there are several leaders, the one running the biggest round will eventually succeed, but if new leaders keep starting bigger rounds none may ever succeed. This is fortunate, since we know from the Fischer-Lynch-Paterson result that there is no algorithm that is guaranteed to terminate.

It’s easy to keep from having two leaders at once if there are no failures for a while, the processes have clocks, and the maximum time to send, receive, and process a message is known:

Every potential leader that is up broadcasts its name.

You become the leader one round-trip time after doing a broadcast unless you have received the broadcast of a bigger name.

The algorithm makes minimal demands on the properties of the network: lost, duplicated, or reordered messages are OK. Because nodes can fail and recover, a better network doesn’t make things much simpler. We model the network as a broadcast medium from leader to agents; in practice this is usually implemented by individual messages to each agent. We describe continuous retransmission; in practice agents retransmit only in response to the leader’s retransmission.

A process acting as a leader uses messages to communicate with the same process acting as an agent, so we describe the two roles of each process completely independently. In fact, the leader need not be an agent at all.
The next section gives the algorithm in detail. You can skip this, but be sure to read the section on optimizations, which has important remarks about using Paxos in practice.

### The Paxos algorithm: The details

We give a straightforward version of the algorithm in detail, and then describe encodings that reduce the information stored and transmitted to small fixed-size amounts. The first set of types and variables is copied from the earlier declarations.

numbers, which we are calling $\nu$’s, are not the same as the Paxos round numbers, the $n$’s; each action has its own instance of Paxos and therefore its own set of round numbers. In this application, the leader is usually called the primary. The following trick allows us to do the first round trip only once after a new primary starts up: interpret the report messages for action $k$ as applying not just to consensus on $a_k$, but to consensus on $a_j$ for all $j \geq k$.

As long as the same process continues to be leader, it can keep track of the current $k$ in its private state. A new leader needs to learn the first unused $k$. If it tries to get consensus using a number that’s too small, it will discover that there’s already an outcome for that action. If it uses a number that’s too big, however, it can get consensus. This is bad, since it leads to a gap in the action numbers that might later be filled by some other leader, with disastrous consequences. We want to maintain the invariant that if outcome $k$ is decided, then either $k=0$ or outcome $k-1$ is decided as well. So a new leader must find the first unused $k$ for its first action $a$. A clumsy way to do this is to start at $k=0$ and try to get consensus on successive $a_k$’s until you get consensus on $a$.

You might think that this is silly. Why not just poll the agents for the largest $k$ for which one of them knows the outcome? This is a good start, but it’s possible that consensus was reached on the last $a_k$ (that is, there’s a majority for it among the agents) but the outcome was not published before the leader crashed. Or it was not published to a majority of the agents, and all the ones that saw it have also failed. So after finding that $k$ is the largest $k$ with an outcome, the leader may still discover that the consensus on $a_{k+1}$ is not for its action $a$, but for some earlier action whose successful outcome was never broadcast. If leaders follow the rule of not starting consensus on $k+1$ until a majority knows the outcome for $k$, then this can happen at most once. It may be convenient for a new leader to start by getting consensus on a SKIP action in order to get this complication out of the way before trying to do real work.

Further optimizations are possible in distributing the actions already agreed, and handout 28 on primary copy replication describes some of them.

Note that since a state machine is completely general, one of the things it can do is to change the agent state. A leader needs to learn the first unused $k$. If it tries to get consensus using a number that’s too small, it will discover that there’s already an outcome for that action. If it uses a number that’s too big, however, it can get consensus. There are several variations:

- If you issue the lease to some known set of processes, you can revoke it provided they all acknowledge the revocation.
- If you know the maximum transmission time for a message, you can get by with clocks that have known differences in running rate rather than known differences in absolute time.

The most common application is to give some set of processes the right to cache some part of the state, for instance the contents of a cache line or of a file, without having to worry about the possibility that it might change. If you don’t have a lease, you have to do an expensive state machine action to get a current result; otherwise you might get an old result from some replica that isn’t up to date. Of course, you could settle for a result as of action \(k\), rather than a current one. Then you would need neither a lease nor a state machine action, but the client has to interpret the \(k\) that it gets back along with the result it wanted. Usually this is too complicated for the client.

If the only reason for running consensus is to issue a lease, you don’t need stable state in the agents. If an agent fails, it can recover with empty state after waiting long enough that any previous lease has expired. This means that the consensus algorithm can’t reliably tell you the owner of such a lease, but you don’t care because it has expired anyway. Schemes for electing a leader usually depend on this observation to avoid disk writes.

You might think that an exclusive lease allows the process that owns it to change the leased state as well, as with ‘owner’ access to a cache line or ownership of a multi-ported disk. This is not true in general, however, because the state is replicated, and at least a majority of the replicas have to be changed. There’s no reliable way to do this without running consensus. In spite of this, leases are not completely irrelevant to updates. With a lease you can use a simple read-write memory as an agent for consensus, since it allows you do the necessary read-modify-write operation automatically under the lease’s mutual exclusion. For this to work, you have to be able to bound the time that the write takes, so you can be sure that it completes before the lease expires. Actually, the requirement is weaker: a read must see the atomic effect of any write that is started earlier than the read. This ensures that if the write is started before the lease expires, a reader that starts after the lease expires will see the write.

This observation is of great practical importance, since it lets you run a replicated state machine where the agents are ‘dual-ported’ disk drives that can be accessed from more than one machine. One of the machines becomes the master by taking out a lease, and it can then write state changes to the disks.

### Compare-and-swap agents

An alternative to using simple memory and leases is to use memory that implements a compare-and-swap or conditional store operation. The spec for compare-and-swap is

\[
\text{APROC CAS}(a, \text{old: D, new: D}) \rightarrow D =
\]

\[
<< \text{IF } m(a) = \text{old} \Rightarrow m(a) := \text{new}; \text{RET old} [\ast] \text{ RET m(a) FI} >>
\]

Many machines, including the IBM 370 and the DEC Alpha, have such an operation (for the Alpha, you have to program it with Load Locked and Store Conditional, but this is easy and cheap).

To use a \(\text{CAS}\) memory as an agent, we have to code the state so that we can do the query and command actions as single \(\text{CAS}\) operations. Recall that the coded state of an agent is \(y = (v_{\text{last}}, \text{last}, \text{next})\), representing the value \(v_{\text{last}}\) for round \(\text{last}\), no for all rounds strictly between \(\text{last}\) and \(\text{next}\), and \(\text{neutral}\) for all rounds starting at \(\text{next}\). A query for round \(\text{next}\) changes the state to \((v_{\text{last}}, \text{last}, \text{next})\) provided \(\text{next} < \text{next}\). A command for round \(n\) changes the state to \((v_{\text{last}}, n, n)\) provided \(\text{next} = n\). So we need a representation that allows us to atomically test the current value of \(\text{next}\) and change the state in one of these ways. This is possible if an \(N\) fits in a single memory cell that \(\text{CAS}\) can read and update atomically. We can store the rest of the triple in a data structure on the side that is indexed by \(\text{next}\). If each possible leader has its own piece of this data structure, they won’t interfere with each other when they are updating it.

Since this is hard concurrency, the details of such a representation are tricky.

### Complex updates

The actions of a state machine can be arbitrarily complex. For example, they can be complete transactions. In a replicated state machine the replicas must agree on the sequence of actions, and then each replica must do each action atomically. In handouts 19 and 20, on sequential and concurrent transactions, we will see how to make arbitrary actions atomic using redo recovery and locking. So in a general state machine each agent will write a redo log, in which each committed transaction corresponds to one action of the state machine. The agents must reach consensus on the complete sequence of actions that makes up the transaction. In practice, this means that each agent logs all the updates, and then they reach consensus on committing the transaction. When an agent recovers from a failure, it runs redo recovery in the usual way. Then it has to find out from other agents about any actions that they agreed on while it was down.

Of course, if several leaders are trying to run transactions at the same time, you have to make sure that the log entries don’t get mixed up. Usually this is done by funneling everything through a single master called the primary; this master also acts as the leader for consensus.

Another way of doing this is to use a single master with passive agents that just implement simple memory; usually these are disk drives that record redundant copies of the log. The previous section on leases explains how to run Paxos with such passive agents. When a master fails, the new one has to sort out the consensus on the most recent transaction as part of recovery.
