Model Predictive Control and Reinforcement Learning: A Unified Framework Based on Dynamic Programming

Abstract: In this paper we describe a new conceptual framework that connects approximate Dynamic Programming (DP), Model Predictive Control (MPC), and Reinforcement Learning (RL). This framework centers around two algorithms, which are designed largely independently of each other and operate in synergy through the powerful mechanism of Newton’s method. We call them the off-line training and the on-line play algorithms. The names are borrowed from some of the major successes of RL involving games; primary examples are the recent (2017) AlphaZero program (which plays chess, [SHS17], [SSS17]), and the similarly structured and earlier (1990s) TD-Gammon program (which plays backgammon, [Tes94], [Tes95], [TeG96]). In these game contexts, the off-line training algorithm is the method used to teach the program how to evaluate positions and to generate good moves at any given position, while the on-line play algorithm is the method used to play in real time against human or computer opponents. Significantly, the synergy between off-line training and on-line play also underlies MPC (as well as other major classes of sequential decision problems), and indeed the MPC design architecture is very similar to the one of AlphaZero and TD-Gammon. This conceptual insight provides a vehicle for bridging the cultural gap between RL and MPC, and sheds new light on some fundamental issues in MPC. These include the enhancement of stability properties through rollout, the treatment of uncertainty through the use of certainty equivalence, the resilience of MPC in adaptive control settings that involve changing system parameters, and the insights provided by the superlinear performance bounds implied by Newton’s method.

1. INTRODUCTION

We will describe a conceptual framework for approximate DP, RL, and their connections to MPC, which was first presented in the author’s recent books [Ber20] and [Ber22a]. The present paper borrows heavily from these books, the course textbook [Ber23], the overview papers [Ber21a], [Ber22c], as well as recent research by the author and his collaborators.

Our framework is very broadly applicable thanks to the generality of the DP methodology on which it rests. This generality allows arbitrary state and control spaces, thus facilitating a free movement between continuous-space infinite-horizon formulations (such as those arising in control system design and MPC), discrete-space finite-horizon problem formulations (such as those arising in games and integer programming), and mixtures thereof that involve both continuous and discrete decision variables.

1 Special thanks are due to Yuchao Li for extensive helpful interactions relating to many of the topics discussed in this paper. Early discussions on MPC with Moritz Diehl were greatly appreciated. The suggestions of Manfred Morari and James Rawlings, as well as those of the reviewers, were also very much appreciated.

To present our framework, we will first focus on a class of deterministic discrete-time optimal control problems, which underlie typical MPC formulations. In subsequent sections, we will indicate how the principal conceptual components of our framework apply to problems that involve stochastic as well as set membership uncertainty, and how they impact the effectiveness of MPC for indirect adaptive control.

1.1 An MPC Problem Formulation

The theory and applications of MPC has undergone extensive development, since the early days of optimal control, thanks to research efforts from several scientific communities. The early papers by Clarke, Mohtadi, and Tuffs

2 The idea underlying MPC is on-line optimization with a truncated rolling horizon and a terminal cost function approximation. This idea has arisen in several contexts, motivated by different types of applications. It has been part of the folklore of the optimal control and operations research literature, dating to the 1960s and 1970s. Simultaneously, it was used in important chemical process control applications, where the name “model predictive control” (or “model-based predictive control”) and the related name “dynamic matrix control” were introduced. The term “predictive” arises often in this

The cost function of \mu, starting from an initial state \x_0 is

J_\mu(x_0) = \lim_{N \to \infty} \sum_{k=0}^{N-1} \alpha^k g(x_k, \mu(x_k)),

where \alpha \in (0, 1) is a discount factor, and

\alpha g(x, u) \geq 0, \quad \forall x \in X, u \in U(x).

We also assume that there is a cost-free and absorbing termination state \tau \{ i.e., \ g(t, u) = 0 and f(t, u) = \tau \ for all \ u \in U(t) \}; e.g., the origin in typical optimal regulation settings in control. The optimal cost function is defined by

J^*(x) = \min_{\mu \in \mathcal{M}} J_\mu(x), \quad \forall x \in X,

where \mathcal{M} is the set of all admissible policies, and our objective is to find an optimal policy \mu^*, i.e., one that satisfies \mu^* = J^*(x) for all \{ x \}.

This is a typical MPC problem formulation, and it includes the classical linear-quadratic problems where \( X = \mathbb{R}^n, U = \mathbb{R}^m, f, g \) is linear, \( g \) is positive definite quadratic, and the termination state \( \tau \) is the origin of \( \mathbb{R}^n \). Note that our formulation makes no assumptions on the nature of the state and control spaces \( X \) and \( U \); they can be arbitrary.

However, the problem and its computational solution have been analyzed at the level of generality used here in the author’s paper [Ber17b], which can serve as a foundation for mathematical results and analysis that we will use somewhat casually in this paper.

Fig. 1. Illustration of approximation in value space with one-step lookahead.

Stability of policies is of paramount importance in MPC. In particular, the issue of stability was addressed theoretically by Keerthi and Gilbert [KeG88], and stability issues have been discussed in detail in the overview paper by Mayne et al. [MR00]. A stability analysis with discrete constraint sets was given by Rawlings and Risbeck [RaL17]. The paper by Krener [Kre19] considers methods to estimate the optimal cost function for use as terminal cost function, aiming to achieve stabilization with MPC lookahead that is as small as possible.

In the context of the present paper, however, because \( X \) and \( U \) can be arbitrary sets, it is necessary to use a more general line of analysis and a nontraditional definition of stability. In particular, we say that a policy \( \mu \) is stable if \( J_\mu(x) < \infty \), \( \forall x \in X \).

For problems where \( \alpha = 1 \), this definition of stability is qualitatively similar to traditional definitions of stability in control theory/MPC contexts, including linear-quadratic problems (to be used later for visualization purposes). Our subsequent discussion of stability implicitly assumes such a context, and may not be meaningful in other contexts, such as games, discrete optimization, cases where \( \alpha < 1 \), etc. Note that \( J^*(x) \) is finite for all \( x \) if there exists at least one stable policy, which we will assume in this paper.

1.2 Approximation in Value Space - MPC and RL

It is known that \( J^* \) satisfies the Bellman equation

\[ J^*(x) = \min_{u \in U(x)} \{ g(x,u) + \alpha J^* (f(x,u)) \}, \quad \forall x \in X, \]

and that if \( \mu^*(x) \) attains the minimum above for all \( x \), then \( \mu^* \) is an optimal policy. Moreover for a policy \( \mu \), we have

\[ J_\mu(x) = g(x, \mu(x)) + \alpha J_\mu \{ f(x, \mu(x)) \}, \quad \forall x \in X. \]

These are results that are generally accepted in the optimal control literature. Their rigorous mathematical proofs at the level of generality considered here are given in the paper [Ber17b], which relies on the general theory of abstract DP problems with nonnegative cost, developed in the paper [Ber77] and extensively discussed in the books [BeS78], [BeC78]; see also Ch. 3 of the thesis [Li23] for a related discussion.

A major RL approach, which we call \emph{approximation in value space}, is to replace \( J^* \) with an approximating real-valued function \( \tilde{J} \), and obtain a suboptimal policy \( \tilde{\mu} \) with the minimization

\[ \tilde{\mu}(x) = \arg \min_{u \in U(x)} \{ g(x,u) + \alpha \tilde{J} (f(x,u)) \}, \quad \forall x \in X; \]

see Fig. 1. We assume that the minimum above is attained for all \( x \in X \), and refer to \( \tilde{\mu} \) as the \emph{one-step lookahead policy}.

There is also an \ell-step lookahead version of the preceding approach, which involves the solution of an \ell-step DP

path breaking literature, and generally refers to taking into account the system’s future, while applying control in the present. Related ideas appeared independently in the computer science literature, in contexts of search (A* and related), planning, and game playing.
Several RL methods are available for computing suitable terminal cost approximations $\hat{J}$ by using some form of learning from data, thus circumventing the solution of Bellman’s equation. The approximation in value space approach has also received a lot of attention in the MPC literature, but in the early days of MPC there was little consideration of learning that involves training of neural networks and other approximation architectures, as practiced by the RL community.

1.3 Rollout with a Stable Policy

An important cost function approximation approach is rollout, where $\hat{J}$ is the cost function $J_\mu$ of a stable policy $\mu$, i.e., one for which $J_\mu(x) < \infty$ for all $x \in X$. We discuss this approach in this section, together with associated stability issues.

In the MPC context it is often critical that the policy $\hat{\mu}$ obtained by one-step and $\ell$-step lookahead is stable. It can be shown that $\hat{\mu}$ is stable if $\hat{J}$ satisfies the following version of a Lyapunov condition:

$$J(x) \geq \min_{u \in U(x)} \{ g(x, u) + \alpha \hat{J}(f(x, u)) \}, \quad \forall x \in X;$$

see [Ber17b], [Ber20]. In particular, if $\hat{J} = J_\mu$ for some stable policy $\mu$, then $J_\mu$ is real-valued and satisfies the preceding Lyapunov condition. To see this, note that from Bellman’s equation we have,

$$J_\mu(x) = g(x, \mu(x)) + \alpha J_\mu(f(x, \mu(x))),$$

so that

$$J_\mu(x) \geq \min_{u \in U(x)} \{ g(x, u) + \alpha J_\mu(f(x, u)) \},$$

for all $x \in X$. Thus $J_\mu$ satisfies the Lyapunov condition, implying that $\hat{\mu}$ is stable when $\hat{J} = J_\mu$. In this case we call $\mu$ the base policy, and we call $\hat{\mu}$ the rollout policy that is based on $\mu$.

Rollout is a major RL approach, which is simple and very reliable, based on extensive computational experience. It is closely connected to the MPC design philosophy, as has been discussed in the author’s early overview paper [Ber05a] and recent books. An important conceptual point is that rollout consists of a single iteration of the fundamental DP method of policy iteration, whose connection with Newton’s method in the context of linear-quadratic problems [BeK65], [Kle68], and other Markov decision problems [PoA67], [PuB78], [PuB79] is well known.

The main difficulty with rollout is that computing the required values of $J_\mu(f(x, \mu(x)))$ on-line may require time consuming simulation. This is an even greater difficulty for the $\ell$-step lookahead version of rollout, where the required number of base policy values increases exponentially with $\ell$. In this case, approximate versions of rollout may be used, such as simplified rollout, truncated rollout, and multiagent rollout; see the books [Ber19], [Ber20], [Ber22a], [Ber23], and the subsequent discussion.

3 Note that if $\mu$ is unstable, then $J_\mu$ is not real-valued and does not qualify for use as $\hat{J}$ in the one-step lookahead scheme.
1.4 Off-Line Training and On-line Play

Implicit in approximation in value space is a conceptual separation between two algorithms:

(a) The off-line training algorithm, which designs the cost function approximation \( \hat{J} \), and possibly other problem components (such as for example a base policy for rollout, or a target/safety tube of states where the system must stay at all times).

(b) The on-line training algorithm, which implements the policy \( \hat{\mu} \) in real-time via one-step or \( \ell \)-step lookahead minimization, cf. Fig. 2.

An important point is that the off-line training and on-line play algorithms can often be designed independently of each other. In particular, approximations used in the on-line lookahead minimization need not relate to the methods used for construction of the terminal cost approximation \( \hat{J} \). Moreover, \( \hat{J} \) can be simple and primitive, particularly in the case of multistep lookahead, or it may be based on sophisticated off-line training methods involving neural networks.

Alternatively, \( \hat{J} \) may be computed off-line with a problem approximation approach, as the optimal or nearly optimal cost function of a simplified optimization problem, which is more convenient for computation (e.g., a linear-quadratic problem approximation, following linearization of nonlinear dynamics of the original problem). Problem simplifications may include exploiting decomposable structure, reducing the size of the state space, neglecting some of the constraints, and ignoring various types of uncertainties.

We note that the off-line training/on-line play separation does not explicitly appear in early MPC frameworks, but it is often used in more recent MPC proposals, noted earlier, where \( \hat{J} \) may involve the training of neural networks with data. On the other hand, the off-line training/on-line play division is common in RL schemes, as well as game programs such as computer chess and backgammon, which we discuss in the next section.

1.5 AlphaZero and TD-Gammon

The development of the AlphaZero program by DeepMind Inc, as described in the papers [SHS17], [SSS17], is perhaps the most impressive success story in reinforcement learning (RL) to date. AlphaZero plays Chess, Go, and other games, and is an improvement in terms of performance and generality over the earlier AlphaGo program [SHM16], which plays the game of Go only. AlphaZero plays chess and Go as well or better than all competitor computer programs, and much better than all humans.

The AlphaZero program is remarkable in several other ways. In particular, it has learned how to play without human instruction, just data generated by playing against itself. In RL this is called self-learning, and can be viewed as a form of the classical DP method of policy iteration, adapted to off-line training with self-generated data. Moreover, AlphaZero learned how to play chess very quickly; within hours, it played better than all humans and computer programs (with the help of awesome parallel computation power, it must be said).

The architecture of AlphaZero is described in Fig. 3. A comparison with Fig. 2 shows that the architectures of AlphaZero and MPC are very similar. They both involve optimization over a truncated rolling horizon with a terminal cost approximation. In AlphaZero, the cost function approximation takes the form of a position evaluator, which uses a deep neural network, trained off-line with an immense amount of chess data. The neural network training process also yields a player that can select a move “instantly” at any given chess position, and can be used to assist the on-line lookahead process.

The success of the AlphaZero design framework was replicated by other chess programs such as LeelaChess and Stockfish. It is presently believed that the principal contributor to their success is long lookahead, which uses an efficient on-line play algorithm that involves various forms of tree pruning. The off-line trained position evaluator and player have also contributed to success, although likely to a lesser extent.

The principles of the AlphaZero design have much in common with the earlier TD-Gammon programs of Tesaur\footnote{Two successful applications of problem approximation exploiting decomposable structures, where the author was personally involved, are described in the papers [KGB82] and [MLW24]. Another type of problem approximation, involving the use of some type of certainty equivalence, will be discussed in Section 3.} 5. Note that AlphaZero is trained to select moves assuming that it plays against an adversarial opponent. Its design philosophy would be more closely aligned to MPC, if it were to play against a known and fixed opponent, whose moves can be perfectly predicted at any given position.

Policy Improvement

TD-Gammon performs on-line a policy improvement, which is not degraded by neural network approximation.

An important lesson from AlphaZero and TD-Gammon is that the performance of an off-line trained policy can be greatly improved by on-line approximation in value space, with long lookahead (involving minimization or rollout with the off-line policy, or both), and terminal cost approximation that is obtained off-line. This performance enhancement is often dramatic and is due to a simple fact, which is couched on algorithmic mathematics and is a focal point of the present paper:

1.6 An Overview of our Framework

In the next section, we will aim to illustrate the principal ideas of our framework. These are the following:

(a) One-step lookahead is equivalent to a step of Newton’s method for solving Bellman’s equation.

(b) \(\ell\)-step lookahead is equivalent to a step of a Newton/SOR method, whereby the Newton step is preceded by \(\ell - 1\) SOR steps (a form of DP/value iterations; SOR stands for successive over-relaxation in numerical analysis terminology).

(c) There is a superlinear relation between the approximation error \(\|J - J^*\|\) and the performance error \(\|J_\tilde{\mu} - J^*\|\), owing to the preceding Newton step interpretation. As a result, within the region of convergence of Newton’s method, the performance error \(\|J_\tilde{\mu} - J^*\|\) is small and often negligible. In particular, the MPC policy \(\tilde{\mu}\) is very close to optimal if \(\tilde{J}\) lies within the region of superlinear convergence of Newton’s method.

(d) The region of convergence of Newton’s method expands as the length \(\ell\) of the lookahead minimization increases. Thus the performance of the MPC policy \(\tilde{\mu}\) improves as \(\ell\) increases, and is essentially optimal if \(\ell\) is sufficiently large regardless of the quality of the

*position evaluations, effectively expands the length of the lookahead.*

Thus in summary:

(a) The on-line player of AlphaZero plays much better than its extensively trained off-line player. This is due to the beneficial effect of policy improvement with long lookahead minimization, which corrects for the inevitable imperfections of the neural network-trained off-line player, and position evaluator/terminal cost approximation.

(b) The TD-Gammon player that uses long rollout with a policy plays much better than TD-Gammon without rollout. This is due to the beneficial effect of the rollout, which serves as a substitute for long lookahead minimization.

A striking empirical observation is that while the neural network used in AlphaZero was trained extensively, the player that it obtained off-line is not used directly during on-line play (it is too inaccurate due to approximation errors that are inherent in off-line neural network training). Instead a separate on-line player is used to select moves, based on multistep lookahead minimization, a limited form of rollout, and a terminal position evaluator that was trained using experience with the off-line player (cf. Fig. 5). The on-line player performs a form of policy improvement, which is not degraded by neural network approximations. As a result, it greatly improves the performance of the off-line player.

Similarly, TD-Gammon performs on-line a policy improvement step using one-step or two-step lookahead minimization, which is not degraded by neural network approximations. Note that the lookahead minimization in computer backgammon is short, because its lookahead tree of moves and countermoves expands very quickly to take into account the stochastic dice rolls. However, rollout with a base policy, aided by a trained neural network that provides

6 The name “rollout” was coined by Tesauro [TeG96] in the context of backgammon. It refers to simulating/“rolling out” and averaging the scores of many backgammon games, starting from the current position and using the one-step lookahead player that is based on the position evaluator.
terminal cost approximation $\tilde{J}$. Indeed, for finite state and control spaces, discount factor $\alpha < 1$, and a long enough lookahead, it can be shown that $\tilde{J}$ is an optimal policy, regardless of the size of the approximation error $||\tilde{J} - J^*||$; see Appendix A.4 of the book [Ber22a] and Prop. 2.3.1 of the book [Ber22b].

(e) The region of stability, i.e., the set of $\tilde{J}$ for which $\tilde{J}_p(x) < \infty$ for all $x \in X$, is closely connected to the region of convergence of Newton’s method.

(f) The region of stability is also enlarged by increasing the length of the rollout horizon, as long as the base policy that is used for rollout is stable.

(g) Rollout with a stable policy $\mu$ (i.e., $\tilde{J} = J_p$) guarantees that the lookahead policy $\tilde{\mu}$ is also stable, regardless of the length $\ell$ of lookahead.

In the next section, we will illustrate the preceding points through the use of a simple one-dimensional linear-quadratic problem, for which the Bellman equation can be defined through a one-dimensional Riccati equation. We note, however, that all the insights obtained through the Riccati equation survive intact to far more general problems, involving abstract Bellman equations where cost functions are defined over an arbitrary state space.\footnote{In this more general setting, the Bellman equation does not have the differentiability properties required to define the classical form of Newton’s method. However, Newton’s method has been extended to nondifferentiable operator equations through the work of many researchers starting in the late 70s, and in a form that is perfectly adequate to support theoretically the DP/RL/MPC setting; see Joseph [Jos79], Robinson [Rob80], [Rob88], [Rob11], Kojima and Shindo [Ko86], Kummer [Kum88], [Kum00], Pan [Pan90], Qi and Sun [Qi93], [Qi93], Facchinei and Pang [Fa03], Ito and Kunisch [ItK03], Bolte, Daniilidis, and Lewis [BDL09]. A convergence analysis of the nondifferentiable form of Newton’s method, together with a discussion of superlinear performance bounds that relate to MPC, is given in Appendix A of the book [Ber22a].}

In Section 3, we will briefly discuss stochastic extensions, where the system equation involves stochastic disturbances $w_k$:

$$x_{k+1} = f(x_k, u_k, w_k), \quad k = 0, 1, \ldots$$

The primary difficulty with stochastic problems is the increase of the computation required for both off-line training and on-line play, which may now involve Monte-Carlo simulation of $w_k$. This computation can be effectively mitigated with the use of certainty equivalence, i.e., by replacing the stochastic disturbances $w_k$ with typical values $\mu_k$ (such as for example the expected values $E\{w_k\}$). However, it is essential that when performing the $\ell$-step lookahead minimization, we use certainty equivalence only for the time steps $k+1, \ldots, k+\ell-1$, after the first step. This is necessary in order to maintain the Newton step character of the on-line play process.

In Section 4, we will comment on connections of the MPC/AlphaZero framework with adaptive control. An additional benefit of on-line policy generation by approximation in value space, not observed in the context of indirect adaptive control, which uses rollout in place of policy reoptimization. This one-dimensional case admits a convenient and visually insightful analysis of the algorithmic issues that are central for our purposes. However, the analysis fully generalizes to multidimensional linear-quadratic problems. It also extends to general DP problems, including those involving arbitrary state and control spaces, stochastic or set membership uncertainty, as well as multiplicative/risk-sensitive cost functions. At this level of generality, the analysis requires a more demanding mathematical treatment that is based on the machinery of abstract DP; see the books [Ber20], [Ber22b].

2. OFF-LINE TRAINING AND ON-LINE PLAY

SYNERGY THROUGH NEWTON’S METHOD

We will now aim to understand the character of approximation in value space as it relates to the Bellman equation, and to the principal algorithms for its solution. To this end we will focus on the one-dimensional version of the classical linear-quadratic problem, where the system has the form

$$x_{k+1} = ax_k + bu_k.$$ 

Here the state $x_k$ and the control $u_k$ are scalars, and the coefficients $a$ and $b$ are also scalars, with $b \neq 0$. The cost function has the form

$$\sum_{k=0}^{\infty} (qx_k^2 + r\mu_k^2),$$

where $q$ and $r$ are positive scalars, and we assume no discounting ($\alpha = 1$).

This one-dimensional case admits a convenient and visually insightful analysis of the algorithmic issues that are central for our purposes. However, the analysis fully generalizes to multidimensional linear-quadratic problems. It also extends to general DP problems, including those involving arbitrary state and control spaces, stochastic or set membership uncertainty, as well as multiplicative/risk-sensitive cost functions. At this level of generality, the analysis requires a more demanding mathematical treatment that is based on the machinery of abstract DP; see the books [Ber20], [Ber22b].

2.1 The Riccati Equation

Let us summarize the main analytical and computational results that we will need (all of these are well known and can be found in many sources, including nearly all textbooks on MPC and optimal control). The optimal cost function is quadratic of the form

$$J^*(x) = K^* x^2,$$

where the scalar $K^*$ is the unique positive solution of Riccati equation

$$K = F(K) = \frac{a^2 r K}{r + b^2 K} + q.$$

Moreover, the optimal policy is linear of the form

$$\mu^*(x) = L^* x,$$

where $L^*$ is the scalar given by

$$L^* = -\frac{abK^*}{r + b^2 K^*}.$$

The Riccati equation is simply the Bellman equation restricted to quadratic functions $J(x) = K x^2$ with $K \geq 0$. Both the Riccati and the Bellman equations can be viewed as fixed point equations, and can be graphically interpreted and solved graphically as indicated in Fig. 5.
Fig. 5. Graphical solution of the Riccati equation. The optimal cost function is $J^*(x) = K^*x^2$. The scalar $K^*$ solves the fixed point equation $K = F(K)$. It can be found graphically as the positive value of $K$ that corresponds to the point where the graphs of the functions $K$ and $F(K)$ meet. A similar interpretation can be given for the solution of the general Bellman equation, which however cannot be visually depicted for problems involving more than one or two states; see the books [Ber20], [Ber22a], and [Ber22b].

We can also characterize graphically the cost function of a policy $\mu$ that is linear of the form $\mu(x) = Lx$, and is also stable, in the sense that the scalar $L$ satisfies $|a + bL| < 1$, so that the corresponding closed-loop system $x_{k+1} = (a + bL)x_k$ is stable. Its cost function has the form

$$J_\mu(x) = K_Lx^2,$$

where $K_L$ solves the equation $K = F_L(K) = (a + bL)^2K + q + rL^2$.

The graphical solution of this equation is illustrated in Fig. [6] The function $F_L(K)$ is linear, with slope $(a + bL)^2$ that is strictly less than 1. In particular, $K_L$ corresponds to the point where the graphs of the functions $K$ and $F_L(K)$ meet.

If $\mu(x) = Lx$ is unstable, in the sense that the scalar $L$ satisfies $|a + bL| > 1$, then its cost function is given by $J_\mu(x) = \infty$ for all $x \neq 0$ and $J_\mu(0) = 0$. In this case the graphs of the functions $K$ and $F_L(K)$ meet at a negative value of $K$, which has no meaning in the context of the linear-quadratic problem.

2.2 Iterative Solution by Value and Policy Iteration

The classical DP algorithm of Value Iteration (VI for short) produces a sequence of cost functions $\{J_k\}$ by applying the Bellman equation operator repeatedly, starting from an initial nonnegative function $J_0$. For our linear-quadratic problem it takes the form

$$J_{k+1}(x) = \min_{u \in \mathbb{R}} \left\{ qx^2 + ru^2 + J_k(ax + bu) \right\}.$$ 

Sometimes this equation is called the “Lyapunov equation” in the control theory literature. In this paper, we will refer to it as the “Riccati equation for linear policies.”

Fig. 6. Graphical solution of the Riccati equation for a linear policy $\mu(x) = Lx$. When $\mu$ is stable, its cost function is $J_\mu(x) = K_Lx^2$, where $K_L$ corresponds to the point where the graphs of the functions $K$ and $F_L(K)$ meet.

Fig. 7. Graphical illustration of VI. It has the form $K_{k+1} = F(K_k)$, where $F$ is the Riccati operator,

$$F(K) = \frac{a^2rK}{r + b^2K} + q.$$ 

The algorithm converges to $K^*$ starting from any $K_0 \geq 0$.

When $J_0$ is quadratic of the form $J_0(x) = K_0x^2$ with $K_0 \geq 0$, it can be seen that the VI iterates $J_k$ are also quadratic of the form $J_k(x) = K_kx^2$, where

$$K_k = F(K_{k-1}).$$

Then the VI algorithm becomes a fixed point iteration that uses the Riccati operator $F$. The algorithm is illustrated in Fig. [7] As can be seen from the figure, when starting from any $K_0 \geq 0$, the algorithm generates a sequence $\{K_k\}$ of nonnegative scalars that converges to $K^*$.

Another major algorithm is Policy Iteration (PI for short). It produces a sequence of stable policies $\{\mu^k\}$, starting with some stable policy $\mu^0$. Each policy has improved cost function over the preceding one, i.e., $J_{\mu^{k+1}}(x) \leq J_{\mu^k}(x)$ for all $k$ and $x$, and the sequence of policies $\{\mu^k\}$ converges to the optimal. Policy iteration is of major importance in RL, since most of the successful algorithmic RL schemes
use explicitly or implicitly some form of approximate PI. We will discuss PI and its relation with rollout later, and we will provide visual interpretations based on their connection with Newton’s method.

2.3 Visualizing Approximation in Value Space

The use of Riccati equations allows insightful visualization of approximation in value space. This visualization, although specialized to linear-quadratic problems, is consistent with related visualizations for more general infinite horizon problems. In particular, in the books [Ber20] and [Ber22a], Bellman operators, which define the Bellman equations, are used in place of Riccati operators, which define the Riccati equations.

We will first show that approximation in value space with one-step lookahead can be viewed as a Newton step for solving the Riccati equation; see Fig. 8. In particular, let us consider a quadratic cost function approximation of the form $\tilde{J}(x) = Kx^2$, where $K \geq 0$. We will show that:

(a) An iteration of Newton’s method for solving the Riccati equation $K = F(K)$, starting from a value $\tilde{K}$ yields the quadratic cost coefficient $K_\ell$ of the cost function $J_\ell$ of the one-step lookahead policy $\tilde{\mu}$, which is linear of the form $\tilde{\mu}(x) = \tilde{L}x$ and has cost function $J_\ell(x) = K_\ell x^2$.

(b) As a result of (a), the quadratic cost coefficients $\tilde{K}$ and $K_\ell$ satisfy the quadratic convergence relation

$$\frac{|K_\ell - K^*|}{|K - K^*|^2} < \infty.$$  

(c) As a result of (b), for $\tilde{K}$ within the region of convergence of Newton’s method, the one-step lookahead policy cost function $J_\ell$ tends to be closer to $J^*$ than $\tilde{J}$, and for $\tilde{J}$ close to $J^*$, the policy $\tilde{\mu}$ is very close to optimal.

These facts admit a simple proof for the linear-quadratic case, but qualitatively hold in general generality, i.e., for arbitrary state and control spaces, for finite and infinite horizon problems, and in the presence of stochastic and

set-membership uncertainty. The reason for this generality is the universal character of the corresponding mathematical proof arguments, which rely on the theory of abstract DP.

For the case of multistep lookahead minimization, which typically underlies the MPC architecture, we will also show that the Newton step property holds. Indeed, this property is enhanced, because the region of convergence of Newton’s method is enlarged by longer lookahead, as we will argue graphically later. The extension of the Newton step interpretation is not surprising because, as noted earlier, we may view $\ell$-step lookahead as a one-step lookahead where the cost function approximation is the optimal cost function of an $(\ell - 1)$-stage DP problem with a terminal cost $\tilde{J}(x_{k+\ell})$ on the state $x_{k+\ell}$ obtained after $\ell - 1$ stages; see Fig. 9.

Indeed, let us first consider one-step lookahead minimization with any terminal cost function approximation of the form $\tilde{J}(x) = Kx^2$, where $K \geq 0$. The one-step lookahead control at state $x$, which we denote by $\tilde{\mu}(x)$, is obtained by minimizing the right side of Bellman’s equation when $J(x) = Kx^2$:

$$\tilde{\mu}(x) \in \arg\min_{u \in \mathbb{R}} \{ qx^2 + ru^2 + K(ax + bu)^2 \}.$$  

We can break this minimization into a sequence of two minimizations as follows:

$$F(K)x^2 = \min_{L \in \mathbb{R}} \{ qx^2 + ru^2 + K(ax + bu)^2 \}$$  

$$= \min_{L \in \mathbb{R}} \{ q + bL + K(a + bL)^2 \} x^2$$  

$$= \min_{L \in \mathbb{R}} F_L(K)x^2,$$

where the function $F_L(K)$ is the Riccati equation operator for the generic linear policy $\mu(x) = Lx$. Figure 10 illustrates the two-step minimization of the preceding equation, and shows how the graph of the Riccati operator
F can be obtained as the lower envelope of the linear operators \( F_L \), as \( L \) ranges over the real numbers.

Let us now fix the terminal cost function approximation to some \( K x^2 \), where \( K \geq 0 \), and consider the corresponding one-step lookahead policy \( \tilde{\mu} \). Figure 11 illustrates the corresponding linear cost function \( F_L \) of \( \tilde{\mu} \), and shows that its graph is a tangent line to the graph of \( F \) at the point \( \tilde{K} \) (cf. Fig. 10).

Thus the function \( F_L \) can be viewed as a linearization of \( F \) at the point \( \tilde{K} \), and defines a linearized problem: to find a solution of the equation

\[
K = F_L(K) = q + b\tilde{L}^2 + K(a + b\tilde{L})^2.
\]

The important point now is that the solution of this equation, denoted \( \tilde{K}_L \), is the same as the one obtained from a single iteration of Newton’s method for solving the Riccati equation, starting from the point \( \tilde{K} \). This is illustrated in Fig. 11.

To elaborate, let us note that the classical form of Newton’s method for solving a fixed point problem of the form \( y = T(y) \), where \( y \) is an \( n \)-dimensional vector, operates as follows: At the current iterate \( y_k \), we linearize \( T \) and find the solution \( y_{k+1} \) of the corresponding linear fixed point problem. Assuming \( T \) is differentiable, the linearization is obtained by using a first order Taylor expansion:

\[
y_{k+1} = T(y_k) + \frac{\partial T(y_k)}{\partial y}(y_{k+1} - y_k),
\]

where \( \partial T(y_k)/\partial y \) is the \( n \times n \) Jacobian matrix of \( T \) evaluated at the vector \( y_k \). For the linear quadratic problem, \( T \) is equal to the Riccati operator \( F \), and is differentiable. However, there are extensions of Newton’s method that are based on solving a linearized system at the current iterate, but relax the differentiability requirement to piecewise differentiability, and/or component concavity (here the role of the Jacobian matrix is played by subgradient operators). The quadratic or similarly fast superlinear convergence property is maintained in these extended forms of Newton’s method; see the monograph [Ber22a] (Appendix A) and the paper [Ber22c], which provide a convergence analysis and discussion related to the DP/MPC context.

The preceding argument can be extended to \( \ell \)-step lookahead minimization to show that a similar Newton step interpretation is possible (Fig. 12 depicts the case \( \ell = 2 \)). Indeed in this case, instead of linearizing \( F \) at \( \tilde{K} \), we
2.4 Region of Stability of Approximation in Value Space

It is useful to define the region of stability of approximation in value space as the set of $K \geq 0$ such that

$$[a + bL_K] < 1,$$

where $L_K$ is the linear coefficient of the one-step lookahead policy corresponding to $K$. It can be seen that the region of stability is also closely related to the region of convergence of Newton’s method: the set of points $K$ starting from which Newton’s method, applied to the Riccati equation $K = F(K)$, converges to $K^*$ asymptotically.

Note that for our one-dimensional linear-quadratic problem, the region of stability is the interval $(K_S, \infty)$ that is characterized by the single point $K_S$ where $F$ has derivative equal to 1; see Fig. [13]. For multidimensional problems, the region of stability may not be characterized as easily. Still, however, it is generally true that the region of stability is enlarged as the length of the lookahead increases. Moreover, substantial subsets of the region of stability may be conveniently obtained. Results of this type are known within the MPC framework under various conditions (see the papers by Mayne at al. [MRR00], Maggi et al. [MDM01], and the MPC book [RMD17]).

In this connection, it is interesting to note that with increased lookahead, the effective starting point $F^{t-1}(K)$ is pushed more and more within the region of stability, and approaches $K^*$ as $t$ increases. In particular, it can be seen that for any given $K \geq 0$, the corresponding $t$-step lookahead policy will be stable for all $t$ larger than some threshold; see Fig. [12]. The book [Ber22a], Section 2.4, contains a broader discussion of the region of stability and the role of multistep lookahead in enlarging it.

2.5 Rollout and Policy Iteration

Let us return to the linear quadratic problem and the rollout algorithm starting from a stable linear base policy $\mu$. It obtains the rollout policy $\tilde{\mu}$ by using a policy improvement operation, which by definition, yields the one-step lookahead policy that corresponds to terminal cost approximation $J_{\mu}$. Figure 14 illustrates the rollout algorithm. It can be seen from the figure that the rollout policy is in fact an improved policy, in the sense that $J_{\tilde{\mu}}(x) \leq J_{\mu}(x)$ for all $x$, something that is true in general (not just for linear-quadratic problems). Among others, this implies that the rollout policy is stable.

Since the rollout policy is a one-step lookahead policy, it can also be described using the formulas that we developed earlier in this section. In particular, let the base policy have the form

$$\mu^0(x) = L_0x,$$

where $L_0$ is a scalar. We require that $\mu^0$ is stable, i.e., $[a + bL_0] < 1$. From our earlier calculations, we have that the cost function of $\mu^0$ is

$$J_{\mu^0}(x) = K_0x^2,$$

where

$$K_0 = \frac{q + rL_0^2}{1 - (a + bL_0)^2}.$$

Moreover, the rollout policy $\mu^1$ has the form $\mu^1(x) = L_1x$, where

$$L_1 = -\frac{abK_0}{r + b^2K_0}.$$

We can similarly describe the policy iteration (PI) algorithm. It is simply the repeated application of rollout, and generates a sequence of stable linear policies $\{\mu^k\}$. By replicating our earlier calculations, we see that these policies have the form

$$\mu^k(x) = L_kx, \quad k = 0, 1, \ldots,$$
where $L_k$ is generated by the iteration

$$L_{k+1} = -\frac{abK_k}{r + b^2 K_k},$$

with $K_k$ given by

$$K_k = \frac{q + r L_k}{1 - (a + b L_k)^2}.$$

The corresponding cost functions have the form

$$J_{k,x}(x) = K_k x^2.$$

A favorable characteristic that enhances the performance of rollout and PI is that the graph of $F(K)$ is relatively “flat” for $K > K^*$. This is due to the concavity of the Riccati operator. As a result, the cost improvement due to the Newton step is even more pronounced, and is relatively insensitive to the choice of base policy. This feature generalizes to multidimensional problems with or without constraints; see the computational study [LKL23].

Part of the classical linear-quadratic theory is that $J_{k,x}$ converges to the optimal cost function $J^*$, while the generated sequence of linear policies $\{\mu^k\}$, where $\mu^k(x) = L_k x^2$, converges to the optimal policy, assuming that the initial policy is linear and stable. The convergence rate of the sequence $\{K_k\}$ is quadratic, as is typical of Newton’s method. This result was proved by Kleinman [Kle68] for the continuous-time multidimensional version of the linear quadratic problem, and it was extended later to more general problems. In particular, the corresponding discrete-time result was given by Hewer [Hew71], and followup analysis, which relates to policy iteration with approximations, was given by Feitza and Hyllqvist [FHS89] and Hyllqvist [Hyl11]. Kleinman gives credit to Bellman and Kalaba [Bek65] for the one-dimensional version of his results. Applications of approximate PI in the context of MPC have been discussed in Rosolia and Borrelli [RoB18], and Li et al. [LJM21], among others.

It is important to note that rollout, like policy iteration, can be applied universally, well beyond the linear-quadratic/MPC context that we have discussed here. In fact, the main idea of rollout algorithms, obtaining an improved policy starting from some other suboptimal policy, has appeared in several DP contexts, including games; see e.g., Abramson [Abr90], and Tesauro and Galperin [TeG99]. The adaptation of rollout to discrete deterministic optimization problems and the principal results relating to cost improvement were given in the paper by Bertsekas, Tsiatsiklis, and Wu [BTW97], and were also discussed in the neuro-dynamic programming book [BeT96]. Rollout algorithms for stochastic problems were further formalized in the papers by Bertsekas [Ber97], and Bertsekas and Castañón [BeC99]. Extensions to constrained rollout were given in the author’s papers [Ber05a], [Ber05b]. Rollout algorithms were also proposed in nontruncated form within the MPC framework; see De Nicolao, Magni, and Scattolin [DMS98], [MaS04], and followup works.

A noteworthy extension, highly relevant to MPC as well as other contexts, is multiagent rollout, which deals successfully with the acute computational difficulties arising from the large (Cartesian product) control spaces that are typical of multiagent problems. The author’s book [Ber20] and paper [Ber21a] discuss this research, and give references to supportive computational studies in multi-

---

**Fig. 15.** Illustration of the $m$-step truncated rollout algorithm with one-step lookahead. Starting with a linear stable base policy $\mu(x) = L x$, it generates a rollout policy $\tilde{\mu}$. The quadratic cost coefficient of $\tilde{\mu}$ is obtained with a Newton step, after approximating of the quadratic cost coefficient $K_L$ of $\mu$ with $m = 4$ value iterations that start from $\tilde{K}$. Compare with the nontruncated rollout Fig. 14.

Finally, we note that the author’s books [Ber20], [Ber21a], [Ber23] provide extensive references to the journal literature, which includes a large number of computational studies. These studies discuss variants and problem-specific adaptations of rollout algorithms and consistently report favorable computational experience. The size of the cost improvement over the base policy is often impressive, evidently owing to the fast convergence rate of Newton’s method that underlies rollout.

### 2.6 Truncated Rollout

An $m$-step truncated rollout scheme with a stable linear base policy $\mu(x) = L x$, one-step lookahead minimization, and terminal cost approximation $\tilde{J}(x) = \tilde{K} x^2$ is obtained by starting at $\tilde{K}$, executing $m$ VI steps using $\mu$, followed by a one-step lookahead minimization/Newton step. It is visually interpreted as in Fig. 15 where $m = 4$.

Thus the difference with (nontruncated) rollout is that we use $m$ VI steps starting from $\tilde{K}$ to approximate the cost function $K_L x^2$ of the base policy. Truncated rollout makes little sense in linear-quadratic problems where $K_L$ can be easily computed by solving the Riccati equation. However, it is useful in more general problem settings, as it may save significantly in computation, relative to obtaining exactly $J_\mu$ (which requires an infinite number of VI steps).

Some interesting points regarding truncated rollout schemes are the following:

(a) Lookahead by truncated rollout may be an economic substitute for lookahead by minimization, in the sense that it may achieve a similar performance at significantly reduced computational cost; see e.g., [LiB24].
(b) Lookahead by \( m \)-step truncated rollout with a stable policy has an increasingly beneficial effect on the stability properties of the lookahead policy, as \( m \) increases.

These statements are difficult to establish analytically in some generality. However, they can be intuitively understood in the context with our one-dimensional linear quadratic problem, using geometrical constructions like the one of Fig. 13. They are also consistent with the results of computational experimentation. We refer to the monograph [Ber22a] for further discussion.

2.7 Double Rollout

We noted that rollout with a base policy \( \mu \) amounts to a single policy iteration starting with \( \mu \), to produce the (improved) rollout policy \( \hat{\mu} \). The process can now be continued to apply a second policy iteration. This results in a double rollout policy, i.e., a second rollout policy that uses the first rollout policy \( \hat{\mu} \) as a base policy. For deterministic problems, the needed rollout policy costs can be computed recursively on-line, with computation that may be tractable, thanks to rollout truncation or special simplifications that take advantage of the deterministic character of the problem. Parallel computation, for which rollout is well suited, can also be very helpful in this respect.

Triple and higher order rollout, which amount to multiple successive policy iterations, are possible. However, the on-line computational costs quickly become overwhelming, despite the potential use of truncation and other simplifications, or parallel computation.

For further discussion of double rollout, see Section 2.3.5 of the book [Ber20] and Section 6.5 of the book [Ber22], and for computational experimentation results, see the recent paper by Li and Bertsekas [LiB24], which deals with special inference contexts in hidden Markov models. Policy iteration/double rollout has also been discussed by Yan et al. [YDR04] in the context of the game of solitaire, and by Silver and Barredo [SIB22] in the context of a broader class of search methods.

2.8 Double Newton Step - Rollout on Top of Approximation in Value Space

Given a quadratic cost coefficient \( \tilde{K} \) that defines the policy \( \mu(x) = L_{\tilde{K}} x \), it is natural and convenient to consider rollout that uses \( \tilde{\mu} \) as a base policy. This can be viewed as rollout that is built on top of approximation in value space. We call this algorithm double Newton step, because it consists of two Newton steps: a first step that maps \( K x \) to \( J_{\mu}(x) \) and a second step that maps \( J_{\mu}(x) \) to the cost function \( J_{\tilde{\mu}}(x) \) of the rollout policy \( \tilde{\mu} \) that is produced when the base policy is \( \mu \); see Fig. 16.

The double Newton step is much more powerful than the algorithm that performs approximation in value space with two-step lookahead starting from \( \tilde{K} \). In particular, both algorithms involve multiple steps for solving the Riccati equation starting from \( \tilde{K} \). However, the former algorithm amounts to a Newton step followed by a Newton step, while the latter algorithm amounts to a value iteration followed by a Newton step (cf. Fig. 12). For this statement to be correct, \( \tilde{K} \) should lie within the region of stability. Such \( \tilde{K} \) may obtained by using multiple value iterations, as in the case where a multistep lookahead minimization is performed, i.e. \( \ell > 1 \) (cf. Fig. 12).

Note that it is also possible to consider variants of rollout on top of approximation in value space, such as truncated and simplified versions. An important example of the truncated version is the TD-Gammon architecture, where the terminal cost function approximation is constructed off-line by using a neural network.

2.9 The Importance of the First Step of Lookahead

The Newton step interpretation of approximation in value space leads to an important insight into the special character of the initial step in \( \ell \)-step lookahead implementations. In particular, it is only the first step that acts as the Newton step, and needs to be implemented with precision; cf. Fig. 9. The subsequent \( \ell - 1 \) steps consist of a sequence of value iterations with starting point \( \alpha \tilde{J} \), and only serve to enhance the quality of the starting point of the Newton step. As a result, their precise implementation is not critical; this is a major point in the narrative of the author’s book [Ber22a].

This idea suggests that we can simplify (within reason) the lookahead steps after the first with small (if any) performance loss for the multistep lookahead policy. An important example of such a simplification is the use of certainty equivalence, which will be discussed in the next section. Other possibilities include various ways of “pruning” the lookahead tree; see [Ber23], Section 2.4. On the other hand, pruning the lookahead tree at the first stage of lookahead, as is often done in Monte Carlo Tree Search, can have a serious detrimental effect on the quality of the MPC policy.

In practical terms, simplifications after the first step of the multistep lookahead can save a lot of on-line computation, which can be fruitfully invested in extending the length
of the lookahead. This insight is supported by substantial computational experimentation, starting with the paper by Bertsekas and Castaño [BeC98], which verified the beneficial effect of certainty equivalence (after the first step) as a rollout simplification device for stochastic problems. On the other hand, implementing imprecisely the minimization of the first step can adversely impact the performance of the multistep lookahead policy. This point is often missed in the design of approximate lookahead minimization schemes, such as Monte Carlo Tree Search.

2.10 Newton Step Interpretation of Approximation in Value Space in General Infinite Horizon Problems

The interpretation of approximation in value space as a Newton step, and related notions of stability that we have discussed in this section admit a broad generalization. The key fact in this respect is that our DP problem formulation allows arbitrary state and control spaces, both discrete and continuous, and can be extended even further to general abstract models with a DP structure; see the abstract DP book [Ber22b].

Within this more general context, the Riccati operator is replaced by an abstract Bellman operator and the quadratic terminal cost function \( \ell \) is replaced by an abstract Bellman operator and the computational experimentation, starting with the paper by Bertsekas and Castaño [BeC98], which verified the beneficial effect of certainty equivalence (after the first step) as a rollout simplification device for stochastic problems. On the other hand, implementing imprecisely the minimization of the first step can adversely impact the performance of the multistep lookahead policy. This point is often missed in the design of approximate lookahead minimization schemes, such as Monte Carlo Tree Search.

2.11 How Approximation in Value Space Can Fail and What to Do About It

Practice has shown that MPC is a reliable methodology that can be made to work, assuming (as we have in this section) that a system model is available in either analytical form or in simulator form, and that this model is not changing over time. Still, however, even under these favorable circumstances, failure is possible, in the sense that the \( \ell \)-step lookahead MPC policy is performing poorly. Typically the reason for failure is that the terminal cost approximation \( \tilde{J} \) lies outside the region of convergence of the Newton step. This region depends on \( \ell \) (see the discussion near the end of Section 2.4), as well as the truncated rollout scheme, which effectively modifies the starting point of the Newton step (see the discussion of Section 2.6) [9].

For an example of broad interest, let us assume that \( \tilde{J} \) is obtained by training with data a neural network (e.g., as in AlphaZero and TD-Gammon). Let us also focus on the case of one-step lookahead with no truncated rollout. In this case there are three components that determine the approximation error \( \tilde{J} - J^* \):

(a) The power of the neural network architecture, which roughly speaking is a measure of the error that would be obtained if infinite data were available and used optimally to obtain \( J \) by training the given neural network.
(b) The additional error degradation due to limited availability of training data.
(c) The additional error degradation due to imperfections in the training methodology.

Thus if the architecture is not powerful enough to bring \( \tilde{J} - J^* \) within the region of convergence of Newton’s method, approximation in value space with one-step lookahead will likely fail, no matter how much data is collected and how effective the associated training method is.

In this case, there are two potential practical remedies:

1. Use a more powerful architecture/neural network for representing \( J \), so it can be brought closer to \( J^* \).
2. Extend the combined length of the lookahead minimization and truncated rollout in order to bring the effective value of \( \tilde{J} \) within the region of convergence of Newton’s method.

The first remedy typically requires a deep neural network or transformer, which uses more weights and requires more expensive training. [10] The second remedy requires longer on-line computation and/or simulation, which may run to difficulties because of some practical implementation limits. Parallel computation and sophisticated multistep lookahead methods may help to mitigate these requirements (see the corresponding discussions in the books [Ber22a] and [Ber23]).

3. THE TREATMENT OF STOCHASTIC UNCERTAINTY THROUGH CERTAINTY EQUIVALENCE

The main ideas of our framework extend to the case of a stochastic system of the form [11]

\[
x_{k+1} = f(x_k, u_k, w_k), \quad k = 0, 1, \ldots
\]

where \( w_k \) is random with given probability distribution that depends only on the current state \( x_k \) and control \( u_k \).

[10] For a recent example of implementation of a grandmaster-level chess program with one-step lookahead and a huge-size (270M parameters) neural network position evaluator, see Ruoss et al. [RDM24].

[11] In this section we restrict ourselves to stochastic uncertainty. For a parallel development relating to set-membership uncertainty and a minimax viewpoint, we refer to the books [Ber22a], Section 6.8, [Ber22b], Chapter 5, and [Ber23], Section 2.12. The paper [Ber21b] addresses the challenging issue of convergence of Newton’s method, applied to the Bellman equation of sequential zero-sum Markov games and minimax control problems. The zero-sum game structure differs in a fundamental way from its one-player optimization counterpart: its Bellman equation mapping need not be concave, and this complicates the convergence properties of Newton’s method. The paper [Ber21b] proposes new PI algorithms for discounted infinite horizon Markov games and minimax control, which are globally convergent, admit distributed asynchronous implementations, and lend themselves to the use of rollout and other RL methods.
and not on earlier states and controls. The cost per stage also depends on \( w_k \) and is \( g(x_k, u_k, w_k) \).

The cost function of \( \mu \), starting from an initial state \( x_0 \) is

\[
J_\mu(x_0) = \lim_{N \to \infty} E \left\{ \sum_{k=0}^{N-1} \alpha^k g(x_k, \mu(x_k), w_k) \right\},
\]

where \( E\{\cdot\} \) denotes expected value. The optimal cost function

\[
J^*(x) = \min_{\mu \in \mathcal{M}} J_\mu(x),
\]

again satisfies the Bellman equation, which now takes the form

\[
J^*(x) = \min_{w \in \mathcal{E}(x)} E \left\{ g(x, u, w) + \alpha J^* (f(x, u, w)) \right\}, \quad x \in X.
\]

Furthermore, if \( \mu^* (x) \) attains the minimum above for all \( x \), then \( \mu^* \) is an optimal policy.

Similar to the deterministic case, approximation in value space with one-step lookahead replaces \( J^* \) with an approximating function \( \tilde{J} \), and obtains a suboptimal policy \( \tilde{\mu} \) with the minimization

\[
\tilde{\mu}(x) \in \arg \min_{w \in \mathcal{E}(x)} E \left\{ g(x, u, w) + \alpha \tilde{J} (f(x, u, w)) \right\}, \quad x \in X.
\]

It is also possible to use \( \ell \)-step lookahead, with the aim to improve the performance of the policy obtained through approximation in value space. This, however, can be computationally expensive, because the lookahead graph expands fast as \( \ell \) increases, due to the stochastic character of the problem. Using certainty equivalence (CE for short) is an important approximation approach for dealing with this difficulty, as it reduces the search space of the \( \ell \)-step lookahead minimization. Moreover, CE mitigates the excessive simulation because it reduces the stochastic variance of the lookahead calculations at each stage.

In the pure but somewhat flawed version of the CE approach, when solving the \( \ell \)-step lookahead minimization problem, we simply replace all of the uncertain quantities \( w_k, w_{k+1}, \ldots, w_{k+\ell-1}, \ldots, w_{N-1} \) by some fixed nominal values, thus making that problem fully deterministic. Unfortunately, this affects significantly the character of the approximation: when \( w_k \) is replaced by a deterministic quantity, the Newton step interpretation of the underlying approximation in value space scheme is lost to a great extent.

Still, we may largely correct this difficulty, while retaining substantial simplification, by using CE after the first stage of the \( \ell \)-step lookahead. We can do this with a CE scheme whereby at state \( x_k \), we replace only the uncertain quantities \( w_{k+1}, \ldots, w_{N-1} \) by deterministic values, while we treat the first, i.e., \( w_k \), as a stochastic quantity.\(^{12}\)

This type of CE approach, first proposed and tested in the paper by Bertsekas and Castaño [BeC99], has an important property: it maintains the Newton step character of the approximation in value space scheme. In particular, the cost function \( J_\mu \) of the \( \ell \)-step lookahead policy \( \tilde{\mu} \) is generated by a Newton step, applied to the function obtained by the last \( \ell - 1 \) minimization steps (modified by CE, and applied to the terminal cost function approximation); see the monograph [Ber20] and Sections 1.6.7, 2.7.2, 2.8.3, of the textbook [Ber23] for a discussion. Thus the benefit of the fast convergence of Newton’s method is restored. In fact based on insights derived from this Newton step interpretation, it appears that the performance penalty for the CE approximation is often small. At the same time the \( \ell \)-step lookahead minimization involves only one stochastic step, the first one, and hence potentially much “thinner” lookahead graph, than an \( \ell \)-step minimization that does not involve any CE-type approximations.

## 4. MPC AND ADAPTIVE CONTROL

Our discussion so far dealt with problems with a known mathematical model, i.e., one where the system equation, cost function, control constraints, and probability distributions of disturbances are perfectly known. The mathematical model may be available through explicit formulas and assumptions, or through a computer program that can emulate all of the mathematical operations involved in the model, including Monte Carlo simulation for the calculation of expected values.\(^{13}\) In practice, however, it is common that the system parameters are either not known exactly or can change over time, and this introduces potentially enormous complications.\(^{14}\)

Let us also note that unknown problem environments are an integral part of the artificial intelligence view of RL. In particular, to quote from the popular book by Sutton and Barto [SuB18], “learning from interaction with the environment is a foundational idea underlying nearly all theories of learning and intelligence” while RL is described as “a computational approach to learning from interaction with the environment.” The idea of learning from interaction with the environment is often connected with the idea of exploring the environment to identify its characteristics.

In control theory this is often viewed as part of the system identification methodology, which aims to construct mathematical models of dynamic systems. The system identification process is often combined with the control process to deal with unknown or changing problem parameters, in a framework that is sometimes called dual control.\(^{15}\)

---

\(^{12}\) Variants of the CE approach, based on less drastic simplifications of the probability distributions of the uncertain quantities, which involve multiple representative scenarios, are given in the author’s books [Ber17a], Section 6.2.2, and [Ber19a], Section 2.3.2. Related ideas have also been suggested in MPC contexts; see e.g., Lucia, Finkler, and Engell [LFE13].

\(^{13}\) The term “model-free” is often used to describe the latter situation, but in reality there is a mathematical model that is hidden inside the simulator, so the ideas of present section apply in principle.

\(^{14}\) The difficulties introduced by a changing environment complicate the balance between off-line training and on-line play. It is worth keeping in mind that as much as learning to play high quality chess is a great challenge, the rules of play are stable; they do not change unpredictably in the middle of a game! Problems with changing system parameters can be far more challenging!

\(^{15}\) The dual control framework was introduced in a series of papers by Feldbaum, starting in 1960 with [Fel60]. These papers emphasized the division of effort between system estimation and control, now more commonly referred to as the exploration-exploitation tradeoff. In the last paper of the series [Fe63], Feldbaum prophetically concludes as follows: “At the present time, the most important problem for the immediate future is the development of approximate solution methods for dual control theory problems, the formulation of sub-optimal strategies, the determination of the numerical value
is one of the most challenging areas of stochastic optimal and suboptimal control, and has been studied intensively since the early 1960s, with several textbooks and research monographs written: Aström and Wittenmark [AsW94], Aström and Hagglund [AsH06], Bodson [Bo20], Goodwin and Sin [GoS84], Ioannou and Sun [IoS96], Jiang and Jiang [Ji17], Krstic, Kanellakopoulos, and Kokotovic [KKK95], Kumar and Varaiya [KuV86], Liu, et al. [LWW17], Lavretsky and Wise [LaW13], Narendra and Annaswamy [NaA12], Sastry and Bodson [SaB11], Slotine and Li [SiL91], and Vrabie, Vanvoudakis, and Lewis [VVL13]. These books describe a vast array of methods spanning 60 years, and ranging from adaptive and model-free approaches, to self-tuning regulators, to simultaneous or sequential control and identification, to time series models, to extremum-seeking methods, to simulation-based RL techniques, etc.

In this section, we will briefly review some of the most commonly used approaches for dealing with unknown parameters, such as robust control, PID control, and indirect adaptive control. We will also suggest a simplified version of indirect adaptive control that uses rollout (possibly truncated and supplemented with terminal cost approximation) in place of policy reoptimization.

4.1 Robust Control

Given a controller design that has been obtained assuming a nominal DP problem model, one possibility is to simply ignore changes in problem parameters. We may then try to investigate the performance of the current design for a suitable range of problem parameter values, and ensure that it is adequate for the entire range. This is sometimes called a robust controller design.

A simple time-honored robust/adaptive control approach for continuous-state problems is PID (Proportional-Integral-Derivative) control. The control theory and practice literature contains extensive accounts. In particular, PID control aims to maintain the output of a single-input single-output dynamic system around a set point or to follow a given trajectory, as the system parameters change within a relatively broad range. In its simplest form, the PID controller is parametrized by three scalar parameters, which may be determined by a variety of methods, some of them manual/heuristic. PID control is used widely and with success, although its range of application is mainly restricted to single-input, single-output continuous-state control systems.

4.2 Dealing with Unknown Parameters Through System Identification and Reoptimization - On-Line Replanning

In PID control, no attempt is made to maintain a mathematical model and to track unknown model parameters as they change. A more ambitious form of suboptimal control is to separate the control process into two phases, a system identification phase and a control phase. In the first phase the unknown parameters are estimated, while the control takes no account of the interim results of estimation. The final parameter estimates from the first phase are then used to implement an optimal or suboptimal policy in the second phase. This alternation of estimation and control phases may be repeated several times during any system run in order to take into account subsequent changes of the parameters. Moreover, it is not necessary to introduce a hard separation between the identification and the control phases. They may be going on simultaneously, with new parameter estimates being introduced into the control process, whenever this is thought to be desirable; see Fig. 17. This approach is often called on-line replanning and is generally known as indirect adaptive control in the adaptive control literature, see e.g., Aström and Wittenmark [AsW94].

Unfortunately, there is still another difficulty with this type of on-line replanning: it may be hard to recompute an optimal or near-optimal policy on-line, using a newly identified system model. In particular, it may be impossible to use time-consuming methods that involve for example the training of a neural network or discrete/integer control constraints. A simpler possibility is to use approximation in value space that uses rollout with some kind of robust base policy. We discuss this approach next.

4.3 Adaptive Control by Rollout

We will now consider dealing with unknown or changing parameters by means of an approximate form of on-line replanning that is based on rollout. Let us assume that some problem parameters change and the current controller becomes aware of the change “instantly” (i.e., very quickly, before the next control needs to be applied). The method by which the problem parameters are reestimated or become known is immaterial for the purposes of the

According to Wikipedia, “a formal control law for what we now call PID or three-term control was first developed using theoretical analysis, by Russian American engineer Nicolas Minorsky” in 1922 [Min22].
The purpose of the example is to illustrate how rollout with a policy that is optimal for a nominal set of problem parameters works well when the parameters change from their nominal values. This property is not practically useful in linear-quadratic problems because when the parameters change, it is possible to calculate the new optimal policy in closed form, but it is indicative of the performance robustness of rollout in other contexts.

Consider the deterministic one-dimensional undiscounted infinite horizon linear-quadratic problem involving the linear system

\[ x_{k+1} = x_k + bu_k, \]

and the quadratic cost function

\[ \lim_{N \to \infty} \sum_{k=0}^{N-1} (x_k^2 + ru_k^2). \]

The optimal cost function is given by

\[ J^*(x) = K^* x^2, \]

where \( K^* \) is the solution to the Riccati equation

\[ K = \frac{rK}{r + b^2K^*} + 1. \]

The optimal policy has the form

\[ \mu^*(x) = L^* x, \]

where

\[ L^* = -\frac{bK^*}{r + b^2K^*}. \]

We will consider the nominal problem parameters \( b = 2 \) and \( r = 0.5 \). We can then verify that for these parameters, the corresponding optimal cost and optimal policy coefficients are

\[ K = \frac{2 + \sqrt{6}}{4}, \quad L = -\frac{2 + \sqrt{6}}{5 + 2\sqrt{6}}. \]

We will now consider changes of the values of \( b \) and \( r \) while keeping \( L \) constant, and we will compare the quadratic cost coefficient of the following cost functions as \( b \) and \( r \) vary:

(a) The optimal cost function \( K^* x^2 \).
(b) The cost function \( K_L x^2 \) that corresponds to the base policy \( \mu_L(x) = L x \). From our earlier discussion, we have

\[ K_L = \frac{1 + rL^2}{1 - (1 + bL)^2}. \]

(c) The cost function \( \tilde{K}_L x^2 \) that corresponds to the rollout policy \( \tilde{\mu}_L(x) = \tilde{L} x \), obtained by using the policy \( \mu_L \) as base policy. Using the formulas given earlier, we have

\[ \tilde{L} = -\frac{bK_L}{r + b^2K_L}, \]

and

\[ \tilde{K}_L = \frac{1 + r \tilde{L}^2}{1 - (1 + b\tilde{L})^2}. \]
The difference $K_L - K^*$ is indicative of the robustness of the policy $\mu_L$, i.e., the performance loss incurred by ignoring the values of $b$ and $r$, and continuing to use the policy $\mu_L$, which is optimal for the nominal values $b = 2$ and $r = 0.5$, but suboptimal for other values of $b$ and $r$. The difference $\tilde{K}_L - K^*$ is indicative of the performance improvement due to using on-line replanning rather than using optimal replanning. Finally, the difference $K_L - \tilde{K}_L$ is indicative of the performance improvement due to on-line replanning using rollout rather than keeping the policy $\mu_L$ unchanged.

It can be seen that the rollout policy performance is very close to the one of the exactly reoptimized policy, while the base policy yields much worse performance. This is a consequence of the superlinear convergence rate of Newton’s method that underlies rollout:

$$\lim_{J \to J^*} \frac{\tilde{J}(x) - J^*(x)}{J(x) - J^*(x)} = 0,$$

where for a given initial state $x$, $\tilde{J}(x)$ is the rollout cost, $J^*(x)$ is the optimal cost, and $J(x)$ is the base policy cost.

5. CONCLUDING REMARKS

We have argued that the connections between the MPC and RL fields are strong, and that the most successful design architectures of the two fields share important characteristics, which relate to Newton’s method. Indeed, in the author’s view, a principal theoretical reason for the successes of the two fields is the off-line training/on-line play synergism that rests upon the mathematical foundations of Newton’s method.

Still the cultures of MPC and RL have different starting points and have grown in different directions. One of the primary reasons is the preference for continuous state and control spaces in MPC, which stems from the classical control theory tradition. Thus stability and safety/reachability issues have been of paramount importance in MPC, but they are hardly ever considered in RL. The main reason is that stability does not arise mathematically or practically in the discrete state and control contexts of games, Markovian decision problems, and more recently large language models that are favored in RL. At the same time, the ideas of learning from data are not part of the control theory tradition, and they have only been addressed relatively recently in a systematic way.

The framework that we have presented in this paper also aims to support a trend of increased use of machine learning methods in MPC. The fact that at their foundation, MPC and RL share important principles suggests that this trend will continue and accelerate in the future.
