This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal's standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Interdigitated conducting tetraphiafulvalene-based coordination networks

Damien Bechu, Lilia S. Xie, Noëwenn Le Breton, Sylvie Choua, Mircea Dincă, Mir Wais Hosseini and Stéphane A. Baudron

Assembly of a novel ethylenedithio-tetraphiafulvalene (EDT-TTF) derivative bearing two adjacent 4-thiopyridyl groups with M(NCS)$_2$ nodes (M = Fe, Co) leads to two isostructural 1D coordination polymers showing an enhancement of their electronic conductivity by six orders of magnitude (10$^4$ vs 10$^{12}$ S/cm), upon surface oxidation by iodine and subsequent generation of EDT-TTF-based radicals.

Owing to their crystallinity and porosity, Metal-Organic Frameworks (MOFs) and Coordination Polymers (CPs) have emerged as an interesting class of hybrid materials with development in diverse fields such as gas sorption and storage, catalysis or sensing. Interdigitated architectures by stacking of hard metal cations with a poor orbital overlap and thus no favourable pathway for charge transport. Therefore, the vast majority of MOFs consists of electrically insulating frameworks. The quest for conducting architectures thus represents a current challenge that has triggered intense research, fuelled by potential electrochemical or energy-related applications. Three main mechanisms have been identified and promoted to prepare such conducting porous coordination polymers: by introduction of guest molecules/dopants or through-space or through-bond conduction. In the latter case, charge delocalization occurs via an appropriate overlap of the organic components of the network. In this context, the choice of redox-active ligands and the control of their relative arrangement while retaining porosity of the crystalline material are essential. Recently, a particular emphasis has been put on the use of tetraphiafulvalene (TTF) derivatives for the construction of MOFs, in light of their capacity to reversibly form a stable radical cation and to be readily functionalized by coordinating groups. This has led to the development of some conducting MOFs showing a favourable stacking of the partially oxidized sulfur-rich moieties. However, design strategies to obtain MOFs featuring an organization of the red-oxide core akin to the one observed in reported metallic and superconducting TTF-based charge transfer salts, to promote a transport pathway, while forming porous networks, remain to be fully developed and exploited. Whereas interpenetration has been explored to favour a closer packing of organic fragments of MOFs within crystals, interdigitation appears as an appealing alternative approach that has not been pursued in the development of electron conducting systems, to the best of our knowledge. Indeed, one can envision that coordination networks of lower dimensionality (1 or 2D) bearing pendant redox-active fragments known to stack may result in a 3D arrangement in the crystal featuring an organization of the electro-oxide moieties adequate for conductivity upon oxidation, along with potential porosity. For example, as proposed herein, disymmetrical ligands comprising, on one hand, coordinating units, and, on the other hand, an extended sulfur-rich core are expected to form 1D coordination networks bearing peripheral TTF cores prone to interdigitation in the crystalline state (Fig. 1). It is foreseen that partial oxidation of the crystalline networks may lead to the promotion of a charge transport pathway and hence to conducting materials.

We report here on the successful application of this strategy using ligand 1 (Fig. 2) and its assembly with M(NCS)$_2$ (M = Fe, Co) nodes to form interdigitated architectures by stacking of TTFs. The conductivity of these materials has been studied in both their native - as synthesized - form and upon oxidation with iodine, showing a dependence on the doping of the crystals.
Ligand 1 (Fig. 2) has been designed to incorporate an ethylenedithio-tetrathiafulvalene core (EDT-TTF) functionalized by two adjacent 4-thiopyridine groups. The choice of the EDT-TTF moiety and of sulfur-bridged peripheral units was motivated by the enhanced capacity of such species to stack upon increasing the number of sulfur atoms. The two coordinating groups were introduced on the same side of the molecule to favour the formation of coordination networks bearing pendant redox-active fragments, as desired.

Compound 1 was prepared in 28 % yield by cross coupling with P(OEt)3 of dithiolone 2 with dithiolthione 3 (Fig. 2). The compound was characterized in solution by 1H- and 13C-NMR and UV-visible spectroscopies, by high-resolution mass spectrometry and single-crystal X-ray diffraction (Monoclinic, P21/c) (see ESI for details). The electrochemical properties of 1 were characterized by cyclic voltammetry in CHCl3 solution (Fig. ESI 4). As expected for such an EDT-TTF derivative, two reversible oxidation processes could be observed (E1/2 = 0.20 V and E1/2 = 0.55 V vs Fc/Fc+). Upon slow diffusion of an EtOH solution of M(NCS)2 into a CHCl3 solution of 1, crystals of the two isostructural networks (1)M(NCS)3(CHCl3)2 (M = Co, 4; Fe, 5) were obtained (Monoclinic, space group C2/c). The structure of the Co network 4 is presented in Fig. 3. The metal cation is in an octahedral environment, bound to two thiocyanate anions in apical positions (dM-N = 2.078(3) Å for 4, 2.110(3) Å for 5) while four pyridine groups belonging to four different bridging molecules of 1 occupy the square base (dM-N = 2.201(3), 2.205(3) Å for 4, 2.241(3), 2.250(3) Å for 5). This leads to a one-dimensional coordination network along the c axis, with metal cations separated by 10.10 Å within the chain (Fig. 3). The CC and CS bond distances within the central TTF core are similar to the ones observed in the structure of free 1 (dC-C = 1.345(2) for 1; 1.337(4) for 4; 1.333(4) Å for 5) and the EDT moiety is more bent with respect to the central TTF unit in the networks than in the free ligand (12.91° for 1 vs 34.27 and 34.36° for 4 and 5 respectively). This suggests that the electro-active core is neutral in the networks, as confirmed by EPR (vide infra).

Interestingly, in the crystals, the networks interdigitate by stacking of the sulfur-rich cores along the b axis with distances varying from 3.513(1) to 3.598(1) Å for 4 and from 3.530(1) to 3.600(1) Å for 5 (Fig. 3). These contacts between consecutive TTFs involve alternatively the sulfur atoms of two central cores or of the thiopyridyl groups and the central unit (Fig. 3). The stacking results in the formation of 1D channels along the b axis, occupied by CHCl3 molecules, thus separating TTF stacks. Our initial attempts at investigating the porosity of the materials have showed a decomposition upon thermal activation at 80°C, resulting in a small specific surface (6 m²/g, BET). While the organization of the electro-active cores within the crystals for 4 and 5 (Fig. 3c) is analogous to what is observed in TTF-based charge transfer salts, the presence of oxidized TTFs in radical form is also a prerequisite to conductivity in these systems. The EPR signature of radical cation 1•+ was obtained by exposure of a powder sample of compound 1 to I2 vapour and consists in a signal centred at 350 mT and with giso = 2.006.
(Fig. 4a) as expected for such species.\textsuperscript{22} EPR spectra collected on native networks 4 or 5 showed only the EPR signature of the Co and Fe coordination polymers (see Fig. ESI 6 and 7), thus emphasizing the absence of the EPR signal of the cation radical \(1^+\). This contrasts with reports on TTF-based MOFs for which the solvothermal conditions used for the synthesis induced a partial oxidation of the ligands and hence the presence of organic radicals.\textsuperscript{10} It may be explained by the softer crystallization conditions employed here (liquid-liquid diffusion at room temperature) as well as by the nature of the TTF derivative itself; EDT-TTFs are harder to oxidize than tetraphenyl-appended TTF species.\textsuperscript{23}

The post-synthetic formation of radicals in the materials was then explored. As for the free ligand, iodine was considered as oxidant, since it is compatible with the redox characteristics of 1 and it has been used in the literature for the oxidation of other TTF- and dithiolene-based MOFs.\textsuperscript{24} While exposure of crystals of 4 and 5 to \(I_2\) vapour led to the appearance of the EPR signature of radical \(1^{++}\), a loss of crystallinity of the materials could be observed. Oxidation in solution was therefore considered as an alternative. Crystals of 4 and 5 were left to stand in a CHCl\(_3\) solution of \(I_2\) \([0.05 \text{ M}]\) for several hours leading to a darkening of the crystal faces (see Fig. ESI 5 for photographs of the crystals throughout the oxidation process). Once again, partial oxidation was confirmed by the presence of the EPR signature of \(1^{++}\) (Fig. 4b for 4 and Fig. ESI 7b for 5).

Powder X-ray diffraction indicated that the samples remained crystalline with retention of the original structure throughout the oxidation process (Fig. 5). Data collection on single crystals of network 4 exposed to \(I_2\) \([0.05 \text{ M}]\) for 3 hours could be performed, allowing the structure determination of the oxidized samples. Interestingly, in the channels formed by stacking of the coordination polymers, the presence of CHCl\(_3\) was observed but residues associated with iodoide-based anions could not be clearly identified. A similar phenomenon has been recently reported for a TTF/TCNQ based MOF where no inclusion of iodine could be observed.\textsuperscript{13h} This suggests that formation of radicals is taking place solely at the surface of the materials. This has been confirmed by EDX analysis with a SEM demonstrating the presence of iodine in a uniform fashion at the surface of oxidized crystals of 4 and 5 (Fig. ESI 8 and 9).

Conductivity measurements were performed on pressed-pellets and single-crystals of networks 4 and 5, in both their native and oxidized forms (Fig. ESI 10-12). For both as-synthesized materials, a room-temperature conductivity below \(10^{-13} \text{ S/cm}\) indicating an insulating behaviour was measured in either form (single-crystal and pressed pellets). Upon exposure to \(I_2\), the conductivity measured on single-crystals reached \(10^{-6} - 10^{-7} \text{ S/cm}\) highlighting the positive effect of the formation of radicals. Surprisingly, no orientation effect could be observed. The value of conductivity was indeed similar, when measured along the stacking direction of the TTF cores or perpendicularly. Slightly higher conductivities were measured on pressed pellet samples \(\bar{\sigma} = 1.1 \times 10^{-6} \text{S/cm for 4}\). This may be explained by the larger surface area/volume ratio of the samples used for the pellet measurements. Indeed, since the pellets are composed of smaller particles on average than for the single-crystal studies, there may be more iodine incorporation and a higher doping level with a doping limited to the surface.

In conclusion, the assembly of a novel EDT-TTF derivative bearing two adjacent 4-thiopyridyl groups with M(NCS)\(_2\) nodes (M = Fe, Co) has led to two isostructural 1D coordination polymers featuring a stacking of the pendant sulfur-rich cores. While the as-synthesized materials include neutral TTFs as demonstrated by EPR measurements and are insulating, treatment with iodine in solution resulted in surface oxidation and hence appearance of organic radicals inducing an enhancement of the electronic conductivity by six orders of magnitude \((10^6 \text{ vs } 10^{-12} \text{ S/cm})\). The foregoing results show that interdigitation/stacking of coordination of networks of lower dimensionality followed by post-synthetic oxidation is an effective approach for the elaboration of conducting systems. Future work will aim at exploring other TTF derivatives, modulating their acceptor character and stacking by modification of the EDT moiety, as well as the elaboration of porous materials.
