Supporting Information

ABSTRACT: The reaction of MnCl$_2$ with 2,5-disulfhydrylbenzene-1,4-dicarboxylic acid (H$_4$DSBDC), in which the phenol groups in 2,5-dihydroxybenzene-1,4-dicarboxylic acid (H$_4$DOBDC) have been replaced by thiophenol units, led to the isolation of Mn$_2$(DSBDC), a thiolated analogue of the Mn$_2$(DOBDC) series of metal–organic frameworks (MOFs). The sulfur atoms participate in infinite one-dimensional Mn–S chains, and Mn$_2$(DSBDC) shows a high surface area and high charge mobility similar to that found in some of the most common organic semiconductors. The synthetic approach to Mn$_2$(DSBDC) and its excellent electronic properties provide a blueprint for a potentially rich area of exploration in microporous conductive MOFs with low-dimensional charge transport pathways.

Myriad applications have been found or proposed for microporous metal–organic frameworks (MOFs), yet those that require electron transport or conductivity in combination with permanent porosity still lag behind because the vast majority of microporous MOFs are electrical insulators. However, recent inroads in this area have suggested that judicious choice of the metal and organic components can lead to crystalline porous materials with promising conductivity or charge mobility properties. One of the most iconic examples is the series of materials with the formula Mn$_2$(DOBDC) (M = Mg, Mn, Fe, Co, Ni, Zn; H$_4$DOBDC = 2,5-dihydroxybenzene-1,4-dicarboxylic acid). The SBUs in these MOFs are (−M−O−)$_\infty$ chains where each pair of metal atoms is bridged by one phenolate group. We surmised that replacing the phenol groups by thiophenol functionalities would give rise to isomorphous materials with linear (−M–S−)$_\infty$ units and high charge mobility (Figure 1). Herein we show that 2,5-disulfhydrylbenzene-1,4-dicarboxylic acid (H$_4$DSBDC), the thiolated analogue of H$_4$DOBDC, generates Mn$_2$(DSBDC), a new material with permanent porosity and high charge mobility. To our knowledge, the new MOF has the highest surface area among MOFs that display electron delocalization, improving the previous record by almost 50% and reinforcing the idea that high surface area and charge delocalization can indeed coexist in crystalline hybrid materials.

The ligand precursor H$_4$DSBDC was synthesized starting from hydroquinone in five steps and 19% overall yield according to Scheme S1 in the Supporting Information (SI). Heating a degassed mixture of H$_4$DSBDC and anhydrous MnCl$_2$ in a dry and and methanol (10:1 by volume) at 120 °C under a nitrogen
atmosphere for 1 day generated yellow crystals of \([\text{Mn}_2(\text{DSBDC})(\text{DMF})_2] \cdot 0.2\text{DMF}\) (as-synthesized 1) and an unidentified orange powder. Single-crystal X-ray diffraction (XRD) analysis of 1 revealed a structure consisting of infinite Mn\(^{2+}\) chains bridged by both carboxylate groups and thiophenoxide groups of anionic DSBDC\(^{4-}\) ligands (Figure 2). Although related to the structure of M\(_2\)(DOBDC), the structure of 1 is different because two crystallographically independent Mn\(^{2+}\) ions are present in the asymmetric unit, whereas only one is present in M\(_2\)(DOBDC). In 1, one Mn\(^{2+}\) ion is coordinated by four carboxylate oxygen atoms and two thiophenoxide groups, while another is coordinated by two carboxylate oxygen atoms, two thiophenoxide groups and two cis-oriented DMF molecules.

Importantly, 1 contains infinite \((-\text{Mn}-\text{S}-)_\infty\) chains defined by Mn\(^{2+}\)-thiophenoxide linkages wherein the sulfur atoms at both crystallographic Mn sites are oriented trans to each other, with Mn–S distances of 2.493(1) and 2.632(1) Å, respectively. This indicates that the S atoms interact with the same d orbital of Mn, an important symmetry requirement for charge delocalization along the \((-\text{Mn}-\text{S}-)_\infty\) chain. Bridging in each pair of neighboring Mn atoms is completed by one oxygen atom from carboxylate groups and \(\mu\)-carboxylate linkages. Neighboring chains are connected by DSBDC\(^{4-}\) ligands that together define a three-dimensional framework containing hexagonal 1D pores with a van der Waals diameter of \(\sim 16\) Å (for fully activated 1). As expected on the basis of the longer Mn–S and C–S distances relative to Mn–O and C–O, respectively, this is \(\sim 2.4\) Å larger than that found in M\(_2\)(DOBDC) analogues\(^{12c}\) and is much larger than those found in previous conductive MOFs,\(^3\) suggesting potential applications in donor–acceptor studies.

Attempts to eliminate the unidentified secondary orange product led us to increase the methanol content of the solvent mixture. Although gradually increasing the methanol content visibly decreased the amount of undesired orange product, it also decreased the crystal size of 1. Pure 1 was obtained as a microcrystalline yellow material when the DMF/methanol ratio reached 2:1. Its identity and purity were verified by powder XRD (PXRD), which revealed a pattern corresponding to that simulated from the single-crystal X-ray structure (Figure 3).

Thermogravimetric analysis (TGA) of as-synthesized 1 exhibited a gradual weight loss of 31.8% between 50 and 365 °C (Figure S1 in the SI), which matched well with the expected...
loss of 2.2 DMF molecules, including both guest and bound DMF molecules. A second weight loss observed above 400 °C likely corresponds to ligand and framework decomposition. A better-defined TGA trace was obtained when the guest and bound DMF molecules were exchanged with lower-boiling methanol. To achieve this, as-synthesized 1 was subjected to a Soxhlet extraction with freshly dried and deaerated methanol for 2 days, during which the material (methanol-exchanged 1) acquired a green hue. The replacement of DMF by methanol was tested by IR spectroscopy, which confirmed the absence of the strong DMF C=O stretch at 1647 cm⁻¹, previously prominent in as-synthesized 1, and the appearance of a methanol C=O stretch at 1005 cm⁻¹ (Figure S3). TGA of methanol-exchanged 1 showed a rapid weight loss below ~100 °C and a stable plateau between 150 and 400 °C (Figure S2). Accordingly, activation of Mn₂(DSBDC) was achieved by heating methanol-exchanged 1 at 150 °C under high vacuum (3 mTorr) for 2 days to obtain activated 1. The structural integrity of activated 1 was verified by PXRD (Figure 3). The absence of guest and bound methanol was confirmed by IR spectroscopy, and the purity of the sample was confirmed by C, H, and S microanalysis. Upon activation, Mn₂(DSBDC) adsorbed ~240 cm³ of N₂/g at 77 K and exhibited a type-I isotherm (Figure 3 inset). The corresponding Brunauer–Emmett–Teller (BET) surface area of 978 m²/g (329 m²/g) is comparable with those reported for M₂(DOBDC) (287–416 m²/g).12c,d

The charge mobilities of methanol-exchanged 1 and activated 1 were evaluated by flash-photolysis time-resolved microwave conductivity (FP-TRMC) measurements. FP-TRMC is a contactless technique that utilizes high-frequency (GHz) microwaves to probe the laser-induced transient conductivity increase, giving information on charge transport on the multi-nanometer length scale. It is particularly informative in measurements of anisotropic crystalline materials because it eliminates perturbations related to grain boundaries, defects, impurities, contact resistance, and high electric fields that can affect the results obtained by the more common direct-current time-of-flight (TOF) and field-effect-transistor measurements, thereby revealing the intrinsic charge mobility of a material.14a FP-TRMC experiments were performed on films made from poly(methyl methacrylate) and the above two Mn₂(DSBDC) materials, which were mixed in 1:1 weight ratios. The films were inserted into a resonant microwave cavity and irradiated with 355 nm laser light. We obtained time-dependent values of the transient conductivity ϕΣμ, where ϕ is the quantum efficiency for the generation of charge carriers upon one-photon absorption and Σμ is the sum of the electron and hole mobilities. The FP-TRMC profiles of methanol-exchanged and activated 1 were virtually identical, displaying maximum ϕΣμ values of 2 × 10⁻⁵ cm² V⁻¹ s⁻¹ (Figure 4a). The values of ϕ were estimated by a TOF transient current integration method (Figure 4b). The TOF-derived ϕ values for methanol-exchanged 1 and activated 1 were 9.7 × 10⁻⁴ and 1.4 × 10⁻³, respectively.

The combination of FP-TRMC and TOF results revealed excellent charge mobilities of 0.02 and 0.01 cm² V⁻¹ s⁻¹ for methanol-exchanged and activated Mn₂(DSBDC), respectively. The similarity between the two values suggests that the charge transport pathway, presumably the Mn–S chain, is not greatly affected by the presence of solvent. On the basis of the observed charge mobility values and the frequency of the microwave field (9.1 GHz), the displacement length of charge carriers (defined as the distance that charge carriers can move in one period of the microwave radiation) in these two Mn₂(DSBDC) materials is 2–3 nm, corresponding to charge delocalization over 8–12 Mn–S units.15 This short displacement length of charge carriers confirms that the results indeed reveal the intrinsic charge mobility of the materials. As shown in Figure 4b, the photocurrent transients are principally dispersive ones; some inflection points are detectable to give mean flight times of charge carriers (Figure S5). The estimated values of the mobility are 0.001 cm² V⁻¹ s⁻¹ (E = 0 V/cm) according to the TOF results, which are 1 order of magnitude lower than those obtained by FP-TRMC and reflect long-range translational motion of charge carriers. An alternative charge transport pathway may involve transfer through the benzene ring of the 1,4-benzenedithiol moiety.16 Experiments to probe this possibility are currently underway.

Importantly, the charge mobility values observed for Mn₂(DSBDC) are comparable to those found in organic semiconductors such as polythiophenes ([Σμ = 0.003–0.1 cm² V⁻¹ s⁻¹]),14a,17 and rubrene ([Σμ = 0.05 cm² V⁻¹ s⁻¹]),18 as measured by the same technique, highlighting the potential utility of MOFs for the construction of various electronic devices that combine high surface area and high charge mobility. In fact, at 978 m²/g, Mn₂(DSBDC) has the highest surface area by almost 50% among MOFs that have demonstrated intrinsic charge delocalization to date, such as Cu[Ni(pyrazine-2,3-dithiolate)], (385 m²/g),14 Fe(1,2,3-triazolate) (450 m²/g),16
Cu and Ni catecholates (425–490 m2/g),3d and Zn2(TTF-tetrazenoate) (662 m2/g).3c Notably, the pore size of the M2(DOBDC) structure type can be extended into the mesoporous regime,19 if it is assumed that a similar isoreticular approach is applicable to Mn2(DSBDC), these results reinforce the idea that high surface area, porosity, and high charge mobility are not mutually exclusive.

In summary, a redox-matching strategy8 aimed at isomorphous substitution of O atoms by S atoms to yield infinite 1D metal–sulfur chains has led to the synthesis of a new MOF with high charge mobility. Because the isomorphous replacement strategy could be amenable to many other MOFs containing metal–oxygen chains, this study provides a potentially general mechanism for the formation of other porous crystalline materials with high charge mobility, not least of which are members of the M2(DEBDC) (E = O, S, Se) structure types with other transition metals.
