Supporting Information

ABSTRACT: The metal nodes in metal-organic frameworks (MOFs) are known to act as Lewis acid catalysts, but few reports have explored their ability to mediate reactions that require electron transfer. The unique chemical environments at the nodes should facilitate unusual redox chemistry, but the difficulty in synthesizing MOFs with metal ions in reduced oxidation states has precluded such studies. Herein, we demonstrate that MZn$_3$O(O$_2$C)$_3$ (MOF-5) serve as hosts for V$^{2+}$ and Ti$^{3+}$ ions and enable the synthesis of the first MOFs containing these reduced early metal ions, which can be accessed from MOF-5 by postsynthetic ion metathesis (PSIM). Additional MOF-5 analogues featuring Cr$^{2+}$, Cr$^{3+}$, Mn$^{2+}$, and Fe$^{2+}$ at the metal nodes can be obtained by similar postsynthetic methods and are reported here for the first time. The inserted metal ions are coordinated within an unusual all-oxygen trigonal ligand and are accessible to both inner- and outer-sphere oxidants: Cr$^{2+}$-converts into Cr$^{3+}$-substituted MOF-5, while Fe$^{2+}$-MOF-5 activates NO to produce an unusual Fe-nitrosyl complex.

INTRODUCTION

The secondary building units (SBUs) in metal-organic frameworks (MOFs) can be regarded as electronically isolated molecular units that often lack structural precedent in molecular chemistry. Because of their site isolation, some SBUs feature metal cations with up to four open coordination sites, priming them for inner-sphere redox reactivity. Despite these attractive properties, reactivity and catalysis studies of SBUs in MOFs have centered on their Lewis acid properties, while studies of their redox reactivity remain an area open for exploration. The dearth of SBU redox reactivity studies is partly due to the general incompatibility of reduced metal cations such as Ti$^{3+}$, V$^{2+}$, and Cr$^{2+}$ with the typical conditions required for MOF synthesis, which often mediate the oxidation of such species. Among the thousands of reported MOFs, none are known to contain Ti$^{3+}$ or V$^{2+}$ while those made from Cr$^{2+}$ or Fe$^{2+}$ are exceedingly rare. Employing reactive conditions to access SBUs without molecular precedent would pave the way to novel coordination chemistry and potentially to unprecedented redox catalysis. Herein, we report that Ti$^{3+}$, V$^{2+}$, V$^{3+}$, Cr$^{2+}$, Cr$^{3+}$, Mn$^{2+}$, and Fe$^{2+}$ incorporate into the SBUs of MOF-5 using mild synthetic methods. As shown below, the MZn$_3$O(O$_2$C)$_3$ clusters in MOF-5 offer electronically unique and structurally flexible dianionic pseudotetrahedral or pseudotrigonal bipyramidal all-oxygen coordination environments. We demonstrate that MOF-5, conveyed as a ligand, enables reactions of the inserted metal ions with both inner- and outer-sphere oxidants, which are requisites for small molecule activation. Thus, we provide the first evidence of redox activity in MOF-5 analogues with the stoichiometric single electron oxidation of Cr$^{2+}$-MOF-5, and demonstrate that Fe-MOF-5 activates NO via electron transfer from the Fe center.

RESULTS AND DISCUSSION

The redox-active MOF-5 analogues, denoted M-MOF-5 and CIM-MOF-5 for divalent and trivalent inserted metal ions, respectively, were accessed using postsynthetic ion metathesis (PSIM) at room temperature under conditions mirroring those we reported for the isolation of Ni-MOF-5. Although Ni-MOF-5 could be obtained by direct solvothermal synthesis from Ni(NO$_3$)$_2$ and Zn(NO$_3$)$_2$, attempts to synthesize (Cl)M-MOF-5 analogues directly by reacting terephthalic acid with CrCl$_3$ and Fe(BF$_4$)$_2$·6H$_2$O for one week furnished M-MOF-5 (M = V$^{2+}$, Cr$^{3+}$, Mn$^{2+}$, or Fe$^{2+}$) salts were unsuccessful. Instead, soaking crystals of MOF-5 in concentrated DMF solutions of VCl$_2$(pyridine)$_4$, CrCl$_3$, MnCl$_2$, and Fe(BF$_4$)$_2$·6H$_2$O for one week furnished M-MOF-5 (M = V$^{2+}$, Cr$^{3+}$, Mn$^{2+}$, or Fe$^{2+}$), while identical procedures involving TiCl$_3$·3THF, VCl$_3$·3THF, or CrCl$_3$·3THF produced CIM-MOF-5 (M = Ti$^{3+}$, V$^{3+}$, or Cr$^{3+}$) (Figure 1). Powder X-ray diffraction patterns of the (Cl)M-MOF-5 materials, shown in Figure 2, confirmed that the materials retained the MOF-5 morphology. Discrepancies in peak intensities are due to preferential orientation because we avoided grinding the samples in order to preserve their structural integrity. Although additional peaks were observed for Cr-MOF-5 and CIV-MOF-5 at 2θ = 7.0° and 13.5°, potentially indicative of long-range order...
imposed by the inserted metal ions, a supercell was not
discernible by single crystal X-ray di-

We determined the degree of cation substitution and the
formula of each new MOF-5 analogue by inductively coupled
atomic emission spectroscopy (ICP-AES) and elemental
microanalysis (EA). As shown in Table 1, the degree of
exchange after 1 week under otherwise identical conditions
varied drastically. Because the rate of solvent and ligand
exchange depends on the nature of each cation, this data
suggests that the ion metathesis reactions do not reach equil-
librium after 1 week. Instead, the degree of exchange is
kinetically controlled by the stability constants of each
substituting cation.29 The agreement between ICP-AES metals
analysis and the C, H, and N analysis by EA confirms that the
cations exchanged into the Zn₄O clusters and did not simply
reside in the pores. Furthermore, we did not find evidence of
halides or other anions that would necessarily be included for
charge balance if metal addition, rather than substitution,
occurred. These results are consistent with the structural
assignment in Ni-MOF-5 and Co-MOF-5 where definitive
substitution into the SBU has been demonstrated pre-
viously.13,30,31 Energy-dispersive X-ray (EDX) spectra and
optical microscope images of these samples depict the inserted
metal ions distributed throughout the crystals, not solely at the
surface (see Figures S1–S7 in the Supporting Information),
demonstrating that homogeneous substitution occurs through-
out the entire crystal.32 Moreover, because the shape of the
crystals and the total crystalline mass did not change
throughout the PSIM procedure, these data suggest that the
substitution occurs in a crystal-to-crystal fashion rather than a
dissolution-recrystallization mechanism.

Electronic spectroscopy provided additional evidence for the
formation of site-isolated (Cl)ₓMₓ₄₋ₓO(O₂C−)₆ clusters. A
diffuse reflectance UV–vis–NIR spectrum of activated CITi-
MOF-5 showed absorption bands in the visible region at 450
and 625 nm, which our time-dependent DFT (TD-DFT)
suggest are predominately d → π*(aryl) transitions. Although
these charge transfer bands also overlap with lower intensity
spin-forbidden d → d transitions, predicted by TD-DFT in the
same region, transitions involving d electrons are consistent
with a Ti^{3+} oxidation state. The high Cr loading in Cr-MOF-5
and ClCr-MOF-5 enabled suf-
ficient absorbance in the UV–
vis–NIR region to permit well-resolved diffuse reflectance
spectra, shown in Figure 3. These differ from the absorption
profiles of the starting materials, CrCl₂ and CrCl₃·3THF in
DMF, with absorption maxima that are shifted to higher energy,
as expected for the stronger ligand field provided by MOF-5.15
The spectra of these materials would show additional
overlapping absorptions bands if other metal complexes resided
in the pores; the lack of such electronic absorption features
further supports the assertion that substitution occurs at the
metal nodes.

Figure 1. MOF-5 cluster acts as a unique tripodal chelating ligand for pseudotetrahedral V^{2+}, Cr^{3+}, Mn^{2+}, Fe^{2+}, Co^{2+}, and Ni^{2+} and pseudotrigonal bipyramidal Ti^{3+}, V^{3+}, and Cr^{3+} with terminal chloride moieties. These molecular structures depict substitution of a single Zn atom, although higher degrees of substitution are possible (see Table 1).

Figure 2. Powder X-ray diffraction patterns of MOF-5 exchanged with Ti^{3+}, V^{3+}, V^{2+}, Cr^{3+}, Cr^{2+}, Mn^{2+}, and Fe^{2+} juxtaposed with the calculated pattern of MOF-5.

Figure 3. Diffuse reflectance UV–vis–NIR spectra of ClCr-MOF-5, Cr-MOF-5, and Cr-MOF-5 after treatment with NOBF₄ to afford BF₄Cr-MOF-5.
Electron paramagnetic resonance (EPR) spectroscopy provided further confirmation of the oxidation state, coordination environment, and the associated electronic structures of the inserted metal ions. Indeed, materials with half-integer spin cations, expected to display degenerate ground \( m_I \) states (Kramers doublet ions), produced spectra that differed from the parent solutions. Thus, CITi-MOF-5 displayed a well-resolved, sharp axial signal consistent with an \( S = 1/2 \) system with \( g_{zz} = 1.93 \) and \( g_{xx} = 2.09 \) (Figure S10 in the Supporting Information), while Mn-MOF-5 and CICr-MOF-5 produced broad axial signals (see Figures S8 and S9). As expected for an \( S = 1/2 \) (\( L = 0 \)) ion, the broad signal of Mn-MOF-5 fits to \( g_{xx} = 2.00 \), while the spectrum of ClCr-MOF-5 illustrates the strong axial symmetry imparted by the terminal chloride on the \( S = 3/2 \) ion, giving \( g_{xx} = 4.27 \) and \( g_{yy} = 1.93 \). We assign the difference in resolution between the \( \text{Ti}^{3+} \) and \( \text{Cr}^{3+}/\text{Mn}^{2+}\text{-MOF-5} \) to the higher Cr and Mn content relative to Ti. Because the inserted metal ions incorporate homogeneously throughout the lattice, as discussed above, higher loadings bring the paramagnetic ions in close proximity, leading to short spin–spin relaxation times and loss of signal and hyperfine resolution in the Cr and Mn materials.\(^{33}\) The signals for these two MOFs are nevertheless consistent with \( \text{Mn}^{2+} \) and \( \text{Cr}^{3+} \) trapped in solid lattices (see Figures S8 and S9 in the Supporting Information).\(^{34,35}\) Our explanation for the resolution differences in the EPR spectra is corroborated by the spectrum collected for V-MOF-5, shown in Figure 4, where the low loading of the \( I = 7/2 \text{V} \) nucleus (see Figure S11 in the Supporting Information) confirmed that all the materials were highly porous, with apparent BET surface areas ranging from 2393 m\(^2\)/g for V-MOF-5 to 2700 m\(^2\)/g for ClCr-MOF-5. These are lower than the highest value reported for MOF-5, 3300 m\(^2\)/g,\(^{36}\) and that reported for Ni-MOF-5.\(^{33}\)

We note, however, that the exchange of \( \text{Ni}^{2+} \) is much slower than those observed with the cations we report here; the rapid exchange of these metals might partially disrupt the MOF lattice and introduce defects that lead to reduced surface areas. We are currently studying the PSIM mechanism and the degree of disorder introduced during these exchanges.

Our motivation for incorporating metal ions with reduced oxidation states in MOF-5 was to enable redox reactivity at the SBUs. To demonstrate the viability of this strategy, we monitored the response of representative examples of these to both inner- and outer-sphere oxidants. Thus, combining green crystals of \( \text{Cr}^{3+}\text{-MOF-5} \) with \( \text{NOBF}_4 \) in acetonitrile caused the rapid formation of blue (\( \text{BF}_4 \)Cr\(^{3+}\))MOF-5. The transformation from \( \text{Cr}^{2+} \) to \( \text{Cr}^{3+} \) within MOF-5 was examined by electronic spectroscopy of activated samples, shown in Figure 3. Similar to CITi-MOF-5, the \( \lambda_{\text{max}} \) at 700 nm of the \( \text{Cr}^{2+} \) material arises from a \( d \to \pi^* \) (aryl) transition, while both \( \text{Cr}^{3+} \) materials exhibit \( \lambda_{\text{max}} \) at 620 nm, assignable to \( d \to d \) transitions. The small blue-shift of the higher energy peak in (\( \text{BF}_4 \)Cr)MOF-5 versus ClCr-MOF-5 can be attributed to the different geometries of the pseudotetrahedral \( \text{Cr}^{3+} \) center in the former versus that of the \( \text{Cr}^{3+} \) ion in the latter. TD-DFT calculations of geometry-optimized truncated models of the (\( \text{Cr}^{2+}\text{-Zn}_4\text{O}(\text{O}_2\text{C}^-)\text{)}_6 \) SBUs with and without coordinated chloride anions agree well with the experimental traces for the \( \text{Cr}^{2+}\text{-substituted MOF-5 analogues and therefore substantiate a single electron oxidation of } \text{Cr}^{2+} \text{ to } \text{Cr}^{3+} \text{ (see Figures S13–S16 in the Supporting Information). PXRD and N}_2\text{ isotherms of } (\text{BF}_4)\text{Cr-MOF-5} \text{ confirm that the lattice remains crystalline and porous after the oxidation reaction (see Figures S17 and S18 in the Supporting Information). Though the overall N}_2\text{ uptake decreases to give a surface area of 1010 m}^2\text{ g}^{-1}, \text{ the initial uptake of } (\text{BF}_4)\text{Cr-MOF-5} \text{ at low pressures mirrors what is normally observed for MOF-5, while the second expected uptake does not occur at higher pressures (as shown in the inset of Figure S18). Following a report by Snurr et al.,}\(^{37}\) \text{ this initial uptake corresponds to } \text{N}_2 \text{ covering the pore exterior, while the absence of the second suggests the pore interiors may be blocked by solvated } \text{BF}_4^- \text{ ions.}

We demonstrated the ability of the inserted metal ions to undergo inner sphere oxidation with the reaction between NO and Fe-MOF-5. Iron nitrosyl complexes are widely studied due to their relevance to biology, and reactions involving nitric oxide are useful tests because the vibrational frequency of the N–O stretch offers insight into the electronic properties of the iron center. The reaction of NO gas with Fe-MOF-5 was monitored in situ by diffuse reflectance infrared Fourier transform spectroscopy (DRIFTS), as depicted in Figure 5. Upon exposure of activated Fe-MOF-5 to NO, a new resonance appears, centered at 1788 cm\(^{-1}\). This is lower than the stretch (\( \nu_{\text{N}–\text{O}} \)) of free NO (1876 cm\(^{-1}\)) and the \( \nu_{\text{N}–\text{O}} \) we observed for pristine (all-zinc) MOF-5 after exposure to NO (1815 cm\(^{-1}\)) (see Figure S19 in the Supporting Information), indicating that NO is bound and activated at the iron center. PXRD of the resulting crystals confirms that they retain the MOF-5 crystalline lattice (see Figure S19 in the Supporting Information). The value of \( \nu_{\text{N}–\text{O}} \) in Fe-MOF-5 is in fact lower than those observed in all other MOFs thus far (see Table 1) enabled the resolution of fine structure and permitted a quantitative analysis of the axial symmetry and metal–ligand interaction. Here, the curvature of the baseline is likely a broad signal resulting from \( V^2+ \) (\( S = 3/2 \)) ions that are in near proximity, making the overall signal a superposition of short and long \( T_1 \) values. A good fit to the spectrum of V-MOF-5 was obtained using \( g_{xx} = 1.97, g_y = 1.93, A_{xx} = -200.66 \text{ MHz, } A_y = -539.72 \text{ MHz, and } S = 3/2 \). The strong axial signal is consistent with the expected \( C_3v \) symmetry about \( V^{2+} \), while the large difference in the hyperfine coupling constants reveals the dissimilarity between the metal-\( \mu_4\text{-oxo bond and that with the carbonate oxygen atoms. Fe-MOF-5, Cr-MOF-5, and CIV-MOF-5, all expected to be of integer spin, were indeed EPR silent.}

To examine the porosity of the MOF-5 analogues, the materials were activated under conditions reported for pristine MOF-5.\(^{38}\) \( \text{N}_2 \) adsorption isotherms collected at 77 K (see Figure S12 in the Supporting Information) confirmed that all the materials were highly porous, with apparent BET surface areas ranging from 2393 m\(^2\)/g for V-MOF-5 to 2700 m\(^2\)/g for ClCr-MOF-5. These are lower than the highest value reported for MOF-5, 3300 m\(^2\)/g,\(^{36}\) and that reported for Ni-MOF-5.\(^{33}\)
The trigonal symmetric carboxylate arms of the Zn$_3$O(O$_2$C$^\text{-}$)$_3$ and N$_{\text{sca}}$ denoted similarly as N$_{\text{nocx}}$ in [Fe(nta)(NO)] enhances the iron-to-NO backbonding, leading to lower values of $\nu_3$ of the NO fragment. The corresponding transitions most likely result from (|± 1/2|) states, whereas the splitting of (|± 3/2|) is too large to observe under the experimental conditions. Hence, due to its heterogeneous nature, a (Fe-NO)$^7$ fragment in the solid-state lattice of MOF-5 offers a distinct reactivity landscape from the solution-phase chemistry of metal nitrosyls and is the first such species in an all-oxygen ligand field. Unlike previous examples of NO activation by MOFs, the value of $\nu_3$ in (NO)Fe-MOF-5 is consistent with electron transfer by the metal center and portends novel redox transformations between the various MOF-5 analogues and small molecules, which we are currently investigating.

Table 2 was provided to support the discussion on the reactivity of (NO)Fe-MOF-5 compared to other MOFs and nitrosyl compounds. The values of $\nu_3$ and $\lambda_{\text{max}}$ are shown for various systems, including MOF-5 analogues and small molecules, to illustrate the unique redox transformations that can be observed.

Enemark and Feltham notation, the MOF-5 ligand, abbreviated O(O)$_3$ where O is the μ-goxo and O are the trigonally symmetric carboxylate arms of the Zn$_3$O(O$_2$C$^\text{-}$)$_3$. SBU, produces an (Fe-NO)$^7$ complex that fits into a series of (Fe-NO)$^7$ compounds based on trigonal tetradentate ligands denoted similarly as N(O)$_3$, N(N)$_3$, and N(S)$_3$. The greater electron density of N(S)$_3$ in [Me$_2$N][Fe(NS$_3$)$_3$(NO)] and N(N)$_3$ in [Fe(1iPr)(NO)] enhances the iron-to-NO backbonding, leading to lower values of $\nu_3$(O) compared to (NO)Fe-MOF-5. This observation is in line with the assignment of O in MOF-5 as a strong Lewis base on the basis of EPR experiments (vide supra). Comparisons with other structurally unrelated ligand fields of biological (Fe-NO)$^7$ species offer another basis for evaluating (NO)Fe-MOF-5. For instance, although both support pentacoordinate nitrosyl species, the biomolecule HemeA activates NO to a far greater degree than MOF-5 due to the strong ligand field of the porphyrin ring. Conversely, the amino-acid ligand field of superoxide reductase generates only a slightly more activated nitrosyl species than MOF-5. The zeolite Fe-ZSM-5, which is known to catalyze the reduction of NO by ammonia and thus binds NO, provides a relevant comparison with our material, but shows only weak NO binding with $\nu_3$(O) at 1880 cm$^{-1}$. (NO)Fe-MOF-5 also displays two new bands in the visible region of its electronic absorption spectrum, shown in Figure S20. The bands at 395 and 476 nm are characteristic of ligand-to-metal NO($\pi^*$) → d charge transfer and are similar to assignments observed for the complexes in Table 2. Notably, returning the sample to vacuum reverts it to the original color, suggesting reversibility of the NO binding. EPR of (NO)Fe-MOF-5, shown in Figure S22, displays two signals at $g_1 = 4.5$ and $g_2 = 2.00$. On the basis of assignments from similar (Fe-NO)$^7$ complexes, these reflect the axial symmetry of the ligand field and an overall $S = 3/2$ arising from strong antiferromagnetic coupling between the $S = 3/2$ iron and $S = 1/2$ NO fragment. The corresponding transitions most likely result from (|± 1/2|) states, whereas the splitting of (|± 3/2|) is too large to observe under the experimental conditions.

**CONCLUSION**

We have shown that redox-active di- and trivalent first row transition metals can be substituted into MOF-5 to give materials that are inaccessible by typical synthetic pathways. In particular, we have reported the first examples of Ti$^{3+}$- and V$^{2+}$-containing MOFs, along with five other previously unknown analogues of MOF-5 itself. The inserted metal ions resemble the molecular species of coordination chemistry and catalysis, yet the solid-state lattice provides a unique platform for future reactivity studies. As a proof of this concept, we demonstrated that outer-sphere electron transfer can be achieved in Cr-MOF-5 and that Fe-MOF-5 activates NO more than any other MOF. These experiments illustrate rare examples of stoichiometric redox reactivity at MOF SBUs and emphasize the unique coordination environment and ligand field character of the metal nodes when regarded as ligands.
