Preface to the Third Edition

The field of matrix computations continues to grow and mature. In the Third Edition we have added over 300 new references and 100 new problems. The LINPACK and EISPACK citations have been replaced with appropriate pointers to LAPACK with key codes tabulated at the beginning of appropriate chapters.

In the First Edition and Second Edition we identified a small number of global references: Wilkinson (1965), Forsythe and Moler (1967), Stewart (1973), Hanson and Lawson (1974) and Parlett (1980). These volumes are as important as ever to the research landscape, but there are some magnificent new textbooks and monographs on the scene. See The Literature section that follows.

We continue as before with the practice of giving references at the end of each section and a master bibliography at the end of the book.

The earlier editions suffered from a large number of typographical errors and we are obliged to the dozens of readers who have brought these to our attention. Many corrections and clarifications have been made.

Here are some specific highlights of the new edition. Chapter 1 (Matrix Multiplication Problems) and Chapter 6 (Parallel Matrix Computations) have been completely rewritten with less formality. We think that this facilitates the building of intuition for high performance computing and draws a better line between algorithm and implementation on the printed page.

In Chapter 2 (Matrix Analysis) we expanded the treatment of CS decomposition and included a proof. The overview of floating point arithmetic has been brought up to date. In Chapter 4 (Special Linear Systems) we embellished the Toeplitz section with connections to circulant matrices and the fast Fourier transform. A subsection on equilibrium systems has been included in our treatment of indefinite systems.

A more accurate rendition of the modified Gram-Schmidt process is offered in Chapter 5 (Orthogonalization and Least Squares). Chapter 8 (The Symmetric Eigenproblem) has been extensively rewritten and rearranged so as to minimize its dependence upon Chapter 7 (The Unsymmetric Eigenproblem). Indeed, the coupling between these two chapters is now so minimal that it is possible to read either one first.

In Chapter 9 (Lanczos Methods) we have expanded the discussion of
the unsymmetric Lanczos process and the Arnoldi iteration. The "unsymmetric component" of Chapter 10 (Iterative Methods for Linear Systems) has likewise been broadened with a whole new section devoted to various Krylov space methods designed to handle the sparse unsymmetric linear system problem.

In §12.5 (Updating Orthogonal Decompositions) we included a new subsection on ULV updating. Toeplitz matrix eigenproblems and orthogonal matrix eigenproblems are discussed in §12.6.

Both of us look forward to continuing the dialog with our readers. As we said in the Preface to the Second Edition, "It has been a pleasure to deal with such an interested and friendly readership."

Many individuals made valuable Third Edition suggestions, but Greg Ammar, Mike Heath, Nick Trefethen, and Steve Vavasis deserve special thanks.

Finally, we would like to acknowledge the support of Cindy Robinson at Cornell. A dedicated assistant makes a big difference.
Software

LAPACK

Many of the algorithms in this book are implemented in the software package LAPACK:

Pointers to some of the more important routines in this package are given at the beginning of selected chapters:

Chapter 1. Level-1, Level-2, Level-3 BLAS
Chapter 3. General Linear Systems
Chapter 4. Positive Definite and Band Systems
Chapter 5. Orthogonalization and Least Squares Problems
Chapter 7. The Unsymmetric Eigenvalue Problem
Chapter 8. The Symmetric Eigenvalue Problem

Our LAPACK references are spare in detail but rich enough to "get you started." Thus, when we say that _TRSV_ can be used to solve a triangular system $Ax = b$, we leave it to you to discover through the LAPACK manual that $A$ can be either upper or lower triangular and that the transposed system $A^T x = b$ can be handled as well. Moreover, the underscore is a placeholder whose mission is to designate type (single, double, complex, etc).

LAPACK stands on the shoulders of two other packages that are milestones in the history of software development. EISPACK was developed in the early 1970s and is dedicated to solving symmetric, unsymmetric, and generalized eigenproblems:

LINPACK was developed in the late 1970s for linear equations and least squares problems:

EISPACK and LINPACK have their roots in sequence of papers that feature Algol implementations of some of the key matrix factorizations. These papers are collected in

**NETLIB**

A wide range of software including LAPACK, EISPACK, and LINPACK is available electronically via Netlib:

Via email, send a one-line message:

```

to get started.

**MATLAB®**

Complementing LAPACK and defining a very popular matrix computation environment is MATLAB:

Many of the problems in *Matrix Computations* are best posed to students as MATLAB problems. We make extensive use of MATLAB notation in the presentation of algorithms.
Selected References

Each section in the book concludes with an annotated list of references. A master bibliography is given at the end of the text.

Useful books that collectively cover the field, are cited below. Chapter titles are included if appropriate but do not infer too much from the level of detail because one author's chapter may be another's subsection. The citations are classified as follows:

Pre-1970 Classics. Early volumes that set the stage.
Introductory (General). Suitable for the undergraduate classroom.
Advanced (General). Best for practitioners and graduate students.
Analytical. For the supporting mathematics.
Linear Equation Problems. $Ax = b$.
Linear Fitting Problems. $Ax \approx b$.
Eigenvalue Problems. $Ax = \lambda x$.
High Performance. Parallel/vector issues.
Edited Volumes. Useful, thematic collections.

Within each group the entries are specified in chronological order.

Pre-1970 Classics

Basic Material from Linear Algebra. Systems of Linear Equations. The Proper Numbers and Proper Vectors of a Matrix.

Introductory (General)

Fortran 77, The Basic Linear Algebra Subprograms, Linpack, MATLAB.

Advanced (General)

Matrix Computations
Chapter 1

Matrix Multiplication
Problems

§1.1 Basic Algorithms and Notation
§1.2 Exploiting Structure
§1.3 Block Matrices and Algorithms
§1.4 Vectorization and Re-Use Issues

The proper study of matrix computations begins with the study of the matrix-matrix multiplication problem. Although this problem is simple mathematically it is very rich from the computational point of view. We begin in §1.1 by looking at the several ways that the matrix multiplication problem can be organized. The "language" of partitioned matrices is established and used to characterize several linear algebraic "levels" of computation.

If a matrix has structure, then it is usually possible to exploit it. For example, a symmetric matrix can be stored in half the space as a general matrix. A matrix-vector product that involves a matrix with many zero entries may require much less time to execute than a full matrix times a vector. These matters are discussed in §1.2.

In §1.3 block matrix notation is established. A block matrix is a matrix with matrix entries. This concept is very important from the standpoint of both theory and practice. On the theoretical side, block matrix notation allows us to prove important matrix factorizations very succinctly. These factorizations are the cornerstone of numerical linear algebra. From the computational point of view, block algorithms are important because they
are rich in matrix multiplication, the operation of choice for many new high
performance computer architectures.

These new architectures require the algorithm designer to pay as much
attention to memory traffic as to the actual amount of arithmetic. This
aspect of scientific computation is illustrated in §1.4 where the critical is-
Sues of vector pipeline computing are discussed: stride, vector length, the
number of vector loads and stores, and the level of vector re-use.

Before You Begin

It is important to be familiar with the MATLAB language. See the
texts by Pratap(1995) and Van Loan (1996). A richer introduction to high
performance matrix computations is given in Dongarra, Duff, Sorensen, and
Duff (1991). This chapter’s LAPACK connections include

1.1 Basic Algorithms and Notation

Matrix computations are built upon a hierarchy of linear algebraic opera-
tions. Dot products involve the scalar operations of addition and multipli-
cation. Matrix-vector multiplication is made up of dot products. Matrix-
matrix multiplication amounts to a collection of matrix-vector products.
All of these operations can be described in algorithmic form or in the lan-
guage of linear algebra. Our primary objective in this section is to show
how these two styles of expression complement each another. Along the way we pick up notation and acquaint the reader with the kind of thinking that underpins the matrix computation area. The discussion revolves around the matrix multiplication problem, a computation that can be organized in several ways.

1.1.1 Matrix Notation

Let \( \mathbb{R} \) denote the set of real numbers. We denote the vector space of all \( m \times n \) real matrices by \( \mathbb{R}^{m \times n} \):

\[
A \in \mathbb{R}^{m \times n} \iff A = (a_{ij}) = \begin{bmatrix}
    a_{11} & \cdots & a_{1n} \\
    \vdots & \ddots & \vdots \\
    a_{m1} & \cdots & a_{mn}
\end{bmatrix} \quad a_{ij} \in \mathbb{R}.
\]

If a capital letter is used to denote a matrix (e.g. \( A, B, \Delta \)), then the corresponding lower case letter with subscript \( ij \) refers to the \((i, j)\) entry (e.g., \( a_{ij}, b_{ij}, \delta_{ij} \)). As appropriate, we also use the notation \([ A ]_{ij}\) and \(A(i, j)\) to designate the matrix elements.

1.1.2 Matrix Operations

Basic matrix operations include transposition \((\mathbb{R}^{m \times n} \to \mathbb{R}^{n \times m})\),

\[
C = A^T \quad \Rightarrow \quad c_{ij} = a_{ji},
\]

addition \((\mathbb{R}^{m \times n} \times \mathbb{R}^{m \times n} \to \mathbb{R}^{m \times n})\),

\[
C = A + B \quad \Rightarrow \quad c_{ij} = a_{ij} + b_{ij},
\]

scalar-matrix multiplication, \((\mathbb{R} \times \mathbb{R}^{m \times n} \to \mathbb{R}^{m \times n})\),

\[
C = \alpha A \quad \Rightarrow \quad c_{ij} = \alpha a_{ij},
\]

and matrix-matrix multiplication \((\mathbb{R}^{m \times p} \times \mathbb{R}^{p \times n} \to \mathbb{R}^{m \times n})\),

\[
C = AB \quad \Rightarrow \quad c_{ij} = \sum_{k=1}^{p} a_{ik} b_{kj}.
\]

These are the building blocks of matrix computations.
1.1.3 Vector Notation

Let $\mathbb{R}^n$ denote the vector space of real $n$-vectors:

$$
  x \in \mathbb{R}^n \iff x = \begin{bmatrix} x_1 \\ \vdots \\ x_n \end{bmatrix}, \quad x_i \in \mathbb{R}.
$$

We refer to $x_i$ as the $i$th component of $x$. Depending upon context, the alternative notations $[x]_i$ and $x(i)$ are sometimes used.

Notice that we are identifying $\mathbb{R}^n$ with $\mathbb{R}^{n \times 1}$ and so the members of $\mathbb{R}^n$ are column vectors. On the other hand, the elements of $\mathbb{R}^{1 \times n}$ are row vectors:

$$
  x \in \mathbb{R}^{1 \times n} \iff x = (x_1, \ldots, x_n).
$$

If $x$ is a column vector, then $y = x^T$ is a row vector.

1.1.4 Vector Operations

Assume $a \in \mathbb{R}$, $x \in \mathbb{R}^n$, and $y \in \mathbb{R}^n$. Basic vector operations include scalar-vector multiplication,

$$
  z = ax \implies z_i = ax_i,
$$

vector addition,

$$
  z = x + y \implies z_i = x_i + y_i,
$$

the dot product (or inner product),

$$
  c = x^T y \implies c = \sum_{i=1}^{n} x_i y_i,
$$

and vector multiply (or the Hadamard product)

$$
  z = x \ast y \implies z_i = x_i y_i.
$$

Another very important operation which we write in "update form" is the saxpy:

$$
  y = ax + y \implies y_i = ax_i + y_i
$$

Here, the symbol "\(=\)" is being used to denote assignment, not mathematical equality. The vector $y$ is being updated. The name "saxpy" is used in LAPACK, a software package that implements many of the algorithms in this book. One can think of "saxpy" as a mnemonic for "scalar $a$ $x$ plus $y".\)
1.1.5 The Computation of Dot Products and Saxyps

We have chosen to express algorithms in a stylized version of the MATLAB language. MATLAB is a powerful interactive system that is ideal for matrix computation work. We gradually introduce our stylized MATLAB notation in this chapter beginning with an algorithm for computing dot products.

Algorithm 1.1.1 (Dot Product) If \( x, y \in \mathbb{R}^n \), then this algorithm computes their dot product \( c = x^T y \).

\[
\begin{align*}
c &= 0 \\
&\text{for } i = 1:n \\
&\quad c = c + x(i)y(i) \\
&\text{end}
\end{align*}
\]

The dot product of two \( n \)-vectors involves \( n \) multiplications and \( n \) additions. It is an \( "O(n)" \) operation, meaning that the amount of work is linear in the dimension. The saxpy computation is also an \( O(n) \) operation, but it returns a vector instead of a scalar.

Algorithm 1.1.2 (Saxpy) If \( x, y \in \mathbb{R}^n \) and \( a \in \mathbb{R} \), then this algorithm overwrites \( y \) with \( ax + y \).

\[
\begin{align*}
&\text{for } i = 1:n \\
&\quad y(i) = ax(i) + y(i) \\
&\text{end}
\end{align*}
\]

It must be stressed that the algorithms in this book are encapsulations of critical computational ideas and not "production codes."

1.1.6 Matrix-Vector Multiplication and the Gaxpy

Suppose \( A \in \mathbb{R}^{m \times n} \) and that we wish to compute the update

\[
y = Ax + y
\]

where \( x \in \mathbb{R}^n \) and \( y \in \mathbb{R}^m \) are given. This generalized saxpy operation is referred to as a gaxpy. A standard way that this computation proceeds is to update the components one at a time:

\[
y_i = \sum_{j=1}^{n} a_{ij}x_j + y_i \quad i = 1:m.
\]

This gives the following algorithm.

Algorithm 1.1.3 (Gaxpy: Row Version) If \( A \in \mathbb{R}^{m \times n} \), \( x \in \mathbb{R}^n \), and \( y \in \mathbb{R}^m \), then this algorithm overwrites \( y \) with \( Ax + y \).
for $i = 1:m$
  for $j = 1:n$
    $y(i) = A(i,j)x(j) + y(i)$
  end
end

An alternative algorithm results if we regard $Ax$ as a linear combination of $A$'s columns, e.g.,

$$
\begin{bmatrix}
1 & 2 \\
3 & 4
\end{bmatrix}
\begin{bmatrix}
7 \\
8
\end{bmatrix}
= 7
\begin{bmatrix}
1 \\
3
\end{bmatrix}
+ 8
\begin{bmatrix}
2 \\
4
\end{bmatrix}
= 53
\begin{bmatrix}
23 \\
83
\end{bmatrix}.
$$

Algorithm 1.1.4 (Gaxpy: Column Version) If $A \in \mathbb{R}^{m \times n}$, $x \in \mathbb{R}^n$, and $y \in \mathbb{R}^m$, then this algorithm overwrites $y$ with $Ax + y$.

for $j = 1:n$
  for $i = 1:m$
    $y(i) = A(i,j)x(j) + y(i)$
  end
end

Note that the inner loop in either gaxpy algorithm carries out a saxpy operation. The column version was derived by rethinking what matrix-vector multiplication "means" at the vector level, but it could also have been obtained simply by interchanging the order of the loops in the row version. In matrix computations, it is important to relate loop interchanges to the underlying linear algebra.

1.1.7 Partitioning a Matrix into Rows and Columns

Algorithms 1.1.3 and 1.1.4 access the data in $A$ by row and by column respectively. To highlight these orientations more clearly we introduce the language of partitioned matrices.

From the row point of view, a matrix is a stack of row vectors:

$$A \in \mathbb{R}^{m \times n} \iff A = \begin{bmatrix}
r_1^T \\
\vdots \\
r_k^T
\end{bmatrix} \quad r_k \in \mathbb{R}^n. \quad (1.1.1)$$

This is called a row partition of $A$. Thus, if we row partition

$$\begin{bmatrix}
1 & 2 \\
3 & 4 \\
5 & 6
\end{bmatrix},$$
then we are choosing to think of $A$ as a collection of rows with
\[ r_1^T = [1 \ 2], \quad r_2^T = [3 \ 4], \quad \text{and} \quad r_3^T = [5 \ 6]. \]

With the row partitioning (1.1.1) Algorithm 1.1.3 can be expressed as follows:

\[
\text{for } i = 1:m \\
y_i = r_i^T x + y(i) \\
\text{end}
\]

Alternatively, a matrix is a collection of column vectors:
\[ A \in \mathbb{R}^{m \times n} \iff A = [c_1, \ldots, c_n], \quad c_k \in \mathbb{R}^{m}. \quad (1.1.2) \]

We refer to this as a column partition of $A$. In the 3-by-2 example above, we thus would set $c_1$ and $c_2$ to be the first and second columns of $A$ respectively:
\[ c_1 = \begin{bmatrix} 1 \\ 3 \\ 5 \end{bmatrix}, \quad c_2 = \begin{bmatrix} 2 \\ 4 \\ 6 \end{bmatrix}. \]

With (1.1.2) we see that Algorithm 1.1.4 is a saxpy procedure that accesses $A$ by columns:

\[
\text{for } j = 1:n \\
y = x_j c_j + y \\
\text{end}
\]

In this context appreciate $y$ as a running vector sum that undergoes repeated saxpy updates.

1.1.8 The Colon Notation

A handy way to specify a column or row of a matrix is with the "colon" notation. If $A \in \mathbb{R}^{m \times n}$, then $A(k,:)\text{ designates the } k\text{th row, i.e.,}$
\[ A(k,:) = [a_{k1}, \ldots, a_{kn}] . \]

The $k\text{th column is specified by}$
\[ A(:,k) = \begin{bmatrix} a_{1k} \\ \vdots \\ a_{mk} \end{bmatrix} . \]

With these conventions we can rewrite Algorithms 1.1.3 and 1.1.4 as

\[
\text{for } i = 1:m \\
y(i) = A(i,:)x + y(i) \\
\text{end}
\]
and

\[
\text{for } j = 1:n \\
\quad y = x(j)A(:, j) + y \\
\text{end}
\]

respectively. With the colon notation we are able to suppress iteration
details. This frees us to think at the vector level and focus on larger com-
putational issues.

1.1.9 The Outer Product Update

As a preliminary application of the colon notation, we use it to understand
the outer product update

\[ A = A + xy^T, \quad A \in \mathbb{R}^{m \times n}, \ x \in \mathbb{R}^m, \ y \in \mathbb{R}^n. \]

The outer product operation \( xy^T \) "looks funny" but is perfectly legal, e.g.,

\[
\begin{bmatrix}
1 \\
2 \\
3
\end{bmatrix}
\begin{bmatrix}
4 & 5 \\
8 & 10 \\
12 & 15
\end{bmatrix}.
\]

This is because \( xy^T \) is the product of two "skinny" matrices and the number
of columns in the left matrix \( x \) equals the number of rows in the right matrix
\( y^T \). The entries in the outer product update are prescribed by

\[
\text{for } i = 1:m \\
\quad \text{for } j = 1:n \\
\quad \quad a_{ij} = a_{ij} + x_i y_j \\
\quad \text{end} \\
\text{end}
\]

The mission of the \( j \) loop is to add a multiple of \( y^T \) to the \( i \)-th row of \( A \),
i.e.,

\[
\text{for } i = 1:m \\
\quad A(i, :) = A(i, :) + x(i)y^T \\
\text{end}
\]

On the other hand, if we make the \( i \)-loop the inner loop, then its task is to
add a multiple of \( x \) to the \( j \)-th column of \( A \):

\[
\text{for } j = 1:n \\
\quad A(:, j) = A(:, j) + y(j)x \\
\text{end}
\]

Note that both outer product algorithms amount to a set of saxpy updates.
1.1.10 Matrix-Matrix Multiplication

Consider the 2-by-2 matrix-matrix multiplication $AB$. In the dot product formulation each entry is computed as a dot product:

$$
\begin{bmatrix}
1 & 2 \\
3 & 4
\end{bmatrix}
\begin{bmatrix}
5 & 6 \\
7 & 8
\end{bmatrix} =
\begin{bmatrix}
1 \cdot 5 + 2 \cdot 7 & 1 \cdot 6 + 2 \cdot 8 \\
3 \cdot 5 + 4 \cdot 7 & 3 \cdot 6 + 4 \cdot 8
\end{bmatrix}.
$$

In the saxpy version each column in the product is regarded as a linear combination of columns of $A$:

$$
\begin{bmatrix}
1 & 2 \\
3 & 4
\end{bmatrix}
\begin{bmatrix}
5 & 6 \\
7 & 8
\end{bmatrix} =
\begin{bmatrix}
5 \begin{bmatrix} 1 \\ 3 \end{bmatrix} + 7 \begin{bmatrix} 2 \\ 4 \end{bmatrix}, & 6 \begin{bmatrix} 1 \\ 3 \end{bmatrix} + 8 \begin{bmatrix} 2 \\ 4 \end{bmatrix}
\end{bmatrix}.
$$

Finally, in the outer product version, the result is regarded as the sum of outer products:

$$
\begin{bmatrix}
1 & 2 \\
3 & 4
\end{bmatrix}
\begin{bmatrix}
5 & 6 \\
7 & 8
\end{bmatrix} =
\begin{bmatrix}
1 & 5 & 6 \\
3 & 7 & 8
\end{bmatrix} +
\begin{bmatrix}
2 & 5 & 6 \\
4 & 7 & 8
\end{bmatrix}.
$$

Although equivalent mathematically, it turns out that these versions of matrix multiplication can have very different levels of performance because of their memory traffic properties. This matter is pursued in §1.4. For now, it is worth detailing the above three approaches to matrix multiplication because it gives us a chance to review notation and to practice thinking at different linear algebraic levels.

1.1.11 Scalar-Level Specifications

To fix the discussion we focus on the following matrix multiplication update:

$$
C = AB + C \quad A \in \mathbb{R}^{m \times p}, \ B \in \mathbb{R}^{p \times n}, \ C \in \mathbb{R}^{m \times n}.
$$

The starting point is the familiar triply-nested loop algorithm:

Algorithm 1.1.5 (Matrix Multiplication: $ijk$ Variant) If $A \in \mathbb{R}^{m \times p}$, $B \in \mathbb{R}^{p \times n}$, and $C \in \mathbb{R}^{m \times n}$ are given, then this algorithm overwrites $C$ with $AB + C$.

for $i = 1:m$
    for $j = 1:n$
        for $k = 1:p$
            $C(i, j) = A(i, k)B(k, j) + C(i, j)$
        end
    end
end
This is the "$ijk$ variant" because we identify the rows of $C$ (and $A$) with $i$, the columns of $C$ (and $B$) with $j$, and the summation index with $k$.

We consider the update $C = AB + C$ instead of just $C = AB$ for two reasons. We do not have to bother with $C = 0$ initializations and updates of the form $C = AB + C$ arise more frequently in practice.

The three loops in the matrix multiplication update can be arbitrarily ordered giving $3! = 6$ variations. Thus,

\[
\begin{align*}
\text{for } j &= 1:n \\
\text{for } k &= 1:p \\
\text{for } i &= 1:m \\
C(i,j) &= A(i,k)B(k,j) + C(i,j)
\end{align*}
\]

end
end

is the $jki$ variant. Each of the six possibilities ($ijk$, $jik$, $ikj$, $jki$, $kij$, $kji$) features an inner loop operation (dot product or saxpy) and has its own pattern of data flow. For example, in the $ijk$ variant, the inner loop oversees a dot product that requires access to a row of $A$ and a column of $B$. The $jki$ variant involves a saxpy that requires access to a column of $C$ and a column of $A$. These attributes are summarized in Table 1.1.1 along with an interpretation of what is going on when the middle and inner loop are considered together. Each variant involves the same amount of floating point arithmetic, but accesses the $A$, $B$, and $C$ data differently.

**Table 1.1.1. Matrix Multiplication: Loop Orderings and Properties**

1.1.12 A Dot Product Formulation

The usual matrix multiplication procedure regards $AB$ as an array of dot products to be computed one at a time in left-to-right, top-to-bottom order.
This is the idea behind Algorithm 1.1.5. Using the colon notation we can highlight this dot-product formulation:

**Algorithm 1.1.6 (Matrix Multiplication: Dot Product Version)**

If $A \in \mathbb{R}^{m \times p}$, $B \in \mathbb{R}^{p \times n}$, and $C \in \mathbb{R}^{m \times n}$ are given, then this algorithm overwrites $C$ with $AB + C$.

\[
\text{for } i = 1:m \\
\quad \text{for } j = 1:n \\
\quad \quad C(i,j) = A(i,:)B(:,j) + C(i,j) \\
\quad \text{end} \\
\text{end}
\]

In the language of partitioned matrices, if

\[
A = \begin{bmatrix} a_1^T \\ \vdots \\ a_m^T \end{bmatrix} \quad a_k \in \mathbb{R}^p
\]

and

\[
B = \{b_1, \ldots, b_n\} \quad b_k \in \mathbb{R}^p
\]

then Algorithm 1.1.6 has this interpretation:

\[
\text{for } i = 1:m \\
\quad \text{for } j = 1:n \\
\quad \quad c_{ij} = a_i^T b_j + c_{ij} \\
\quad \text{end} \\
\text{end}
\]

Note that the "mission" of the $j$-loop is to compute the $i$th row of the update. To emphasize this we could write

\[
\text{for } i = 1:m \\
\quad c_i^T = a_i^T B + c_i^T \\
\text{end}
\]

where

\[
C = \begin{bmatrix} c_1^T \\ \vdots \\ c_m^T \end{bmatrix}
\]

is a row partitioning of $C$. To say the same thing with the colon notation we write

\[
\text{for } i = 1:m \\
\quad C(i,:) = A(i,:)B + C(i,:) \\
\text{end}
\]

Either way we see that the inner two loops of the $ijk$ variant define a row-oriented gaxpy operation.
1.1.13 A Saxpy Formulation

Suppose $A$ and $C$ are column-partitioned as follows

$$A = [a_1, \ldots, a_p] \quad a_j \in \mathbb{R}^m$$

$$C = [c_1, \ldots, c_n] \quad c_j \in \mathbb{R}^m.$$ 

By comparing $j$th columns in $C = AB + C$ we see that

$$c_j = \sum_{k=1}^{p} b_{kj}a_k + c_j, \quad j = 1:n.$$ 

These vector sums can be put together with a sequence of saxpy updates.

Algorithm 1.1.7 (Matrix Multiplication: Saxpy Version) If the matrices $A \in \mathbb{R}^{m \times p}$, $B \in \mathbb{R}^{p \times n}$, and $C \in \mathbb{R}^{m \times n}$ are given, then this algorithm overwrites $C$ with $AB + C$.

for $j = 1:n$
  for $k = 1:p$
    $C(:,j) = A(:,k)B(k,j) + C(:,j)$
  end
end

Note that the $k$-loop oversees a gaxpy operation:

for $j = 1:n$
  $C(:,j) = AB(:,j) + C(:,j)$
end

1.1.14 An Outer Product Formulation

Consider the $kij$ variant of Algorithm 1.1.5:

for $k = 1:p$
  for $j = 1:n$
    for $i = 1:m$
      $C(i,j) = A(i,k)B(k,j) + C(i,j)$
    end
  end
end

The inner two loops oversee the outer product update

$$C = a_kb_k^T + C$$
where

\[ A = [a_1, \ldots, a_p] \quad \text{and} \quad B = \begin{bmatrix} b_1^T \\ \vdots \\ b_p^T \end{bmatrix} \]  \hspace{1cm} (1.1.3) 

with \( a_k \in \mathbb{R}^m \) and \( b_k \in \mathbb{R}^n \). We therefore obtain

Algorithm 1.1.8 (Matrix Multiplication: Outer Product Version)  
If \( A \in \mathbb{R}^{m \times p} \), \( B \in \mathbb{R}^{p \times n} \), and \( C \in \mathbb{R}^{m \times n} \) are given, then this algorithm overwrites \( C \) with \( AB + C \).

\[
\text{for } k = 1:p \\
\quad C = A(:,k)B(k,:) + C \\
\text{end}
\]

This implementation revolves around the fact that \( AB \) is the sum of \( p \) outer products.

1.1.15 The Notion of “Level”

The dot product and saxpy operations are examples of “level-1” operations. Level-1 operations involve an amount of data and an amount of arithmetic that is linear in the dimension of the operation. An \( m \)-by-\( n \) outer product update or gaxpy operation involves a quadratic amount of data \((O(mn))\) and a quadratic amount of work \((O(mn))\). They are examples of “level-2” operations.

The matrix update \( C = AB + C \) is a “level-3” operation. Level-3 operations involve a quadratic amount of data and a cubic amount of work. If \( A \), \( B \), and \( C \) are \( n \)-by-\( n \) matrices, then \( C = AB + C \) involves \( O(n^2) \) matrix entries and \( O(n^3) \) arithmetic operations.

The design of matrix algorithms that are rich in high-level linear algebra operations is a recurring theme in the book. For example, a high performance linear equation solver may require a level-3 organization of Gaussian elimination. This requires some algorithmic rethinking because that method is usually specified in level-1 terms, e.g., “multiply row 1 by a scalar and add the result to row 2.”

1.1.16 A Note on Matrix Equations

In striving to understand matrix multiplication via outer products, we essentially established the matrix equation

\[ AB = \sum_{k=1}^{p} a_k b_k^T \]

where the \( a_k \) and \( b_k \) are defined by the partitionings in (1.1.3).
Numerous matrix equations are developed in subsequent chapters. Sometimes they are established algorithmically like the above outer product expansion and other times they are proved at the $ij$-component level. As an example of the latter, we prove an important result that characterizes transposes of products.

**Theorem 1.1.1** If $A \in \mathbb{R}^{m \times p}$ and $B \in \mathbb{R}^{p \times n}$, then $(AB)^T = B^T A^T$.

**Proof.** If $C = (AB)^T$, then

$$c_{ij} = [(AB)^T]_{ij} = [AB]_{ji} = \sum_{k=1}^{p} a_{jk} b_{ki}.$$ 

On the other hand, if $D = B^T A^T$, then

$$d_{ij} = [B^T A^T]_{ij} = \sum_{k=1}^{p} [B^T]_{ik} [A^T]_{kj} = \sum_{k=1}^{p} b_{ki} a_{jk}.$$ 

Since $c_{ij} = d_{ij}$ for all $i$ and $j$, it follows that $C = D$. □

Scalar-level proofs such as this one are usually not very insightful. However, they are sometimes the only way to proceed.

1.1.17 Complex Matrices

From time to time computations that involve complex matrices are discussed. The vector space of $m$-by-$n$ complex matrices is designated by $\mathbb{C}^{m \times n}$. The scaling, addition, and multiplication of complex matrices corresponds exactly to the real case. However, transposition becomes **conjugate transposition**:

$$C = A^H \implies c_{ij} = \overline{a_{ji}}.$$ 

The vector space of complex $n$-vectors is designated by $\mathbb{C}^n$. The dot product of complex $n$-vectors $x$ and $y$ is prescribed by

$$s = x^H y = \sum_{i=1}^{n} x_i y_i.$$ 

Finally, if $A = B + iC \in \mathbb{C}^{m \times n}$, then we designate the real and imaginary parts of $A$ by $\text{Re}(A) = B$ and $\text{Im}(A) = C$ respectively.

**Problems**

P1.1.1 Suppose $A \in \mathbb{R}^{n \times n}$ and $z \in \mathbb{R}^n$ are given. Give a succinct algorithm for computing the first column of $M = (A - z_1 I) \cdots (A - z_r I)$. 
P1.1.2 In the conventional 2-by-2 matrix multiplication $C = AB$, there are eight multiplications: $a_{11}b_{11}, a_{11}b_{12}, a_{21}b_{11}, a_{21}b_{12}, a_{12}b_{21}, a_{12}b_{22}, a_{22}b_{21}$ and $a_{22}b_{22}$. Make a table that indicates the order that these multiplications are performed for the $ijk$, $ikj$, $kij$, $tkj$, $jki$, and $kji$ matrix multiply algorithms.

P1.1.3 Give an algorithm for computing $C = (xy^T)^k$ where $x$ and $y$ are $n$-vectors.

P1.1.4 Specify an algorithm for computing $(XY^T)^k$ where $X, Y \in \mathbb{R}^{m \times 2}$.

P1.1.5 Formulate an outer product algorithm for the update $C = AB^T + C$ where $A \in \mathbb{R}^{m \times r}, B \in \mathbb{R}^{n \times r}$, and $C \in \mathbb{R}^{m \times n}$.

P1.1.6 Suppose we have real $n$-by-$n$ matrices $C$, $D$, $E$, and $F$. Show how to compute real $n$-by-$n$ matrices $A$ and $B$ with just three real $n$-by-$n$ matrix multiplications so that $(A + iB) = (C + iD)(E + iF)$. Hint: Compute $W = (C + D)(E - F)$.

Notes and References for Sec. 1.1

It must be stressed that the development of quality software from any of our "semi-formal" algorithmic presentations is a long and arduous task. Even the implementation of the level-1,2, and 3 BLAS require care:

Other BLAS references include

For an appreciation of the subtleties associated with software development we recommend

and a browse through the LAPACK manual.
1.2 Exploiting Structure

The efficiency of a given matrix algorithm depends on many things. Most obvious and what we treat in this section is the amount of required arithmetic and storage. We continue to use matrix-vector and matrix-matrix multiplication as a vehicle for introducing the key ideas. As examples of exploitable structure we have chosen the properties of bandedness and symmetry. Band matrices have many zero entries and so it is no surprise that band matrix manipulation allows for many arithmetic and storage shortcuts. Arithmetic complexity and data structures are discussed in this context.

Symmetric matrices provide another set of examples that can be used to illustrate structure exploitation. Symmetric linear systems and eigenvalue problems have a very prominent role to play in matrix computations and so it is important to be familiar with their manipulation.

1.2.1 Band Matrices and the $x$-0 Notation

We say that $A \in \mathbb{R}^{m \times n}$ has lower bandwidth $p$ if $a_{ij} = 0$ whenever $i > j + p$ and upper bandwidth $q$ if $j > i + q$ implies $a_{ij} = 0$. Here is an example of an 8-by-5 matrix that has lower bandwidth 1 and upper bandwidth 2:

$$
\begin{bmatrix}
\times & \times & \times & 0 & 0 \\
\times & \times & \times & 0 & 0 \\
0 & \times & \times & \times & 0 \\
0 & 0 & \times & \times & 0 \\
0 & 0 & 0 & \times & 0 \\
0 & 0 & 0 & 0 & 0
\end{bmatrix}.
$$

The $\times$'s designates arbitrary nonzero entries. This notation is handy to indicate the zero-nonzero structure of a matrix and we use it extensively. Band structures that occur frequently are tabulated in Table 1.2.1.

1.2.2 Diagonal Matrix Manipulation

Matrices with upper and lower bandwidth zero are diagonal. If $D \in \mathbb{R}^{m \times n}$ is diagonal, then

$$
D = \text{diag}(d_1, \ldots, d_q), \quad q = \min\{m, n\} \iff d_i = d_{ii}.
$$

If $D$ is diagonal and $A$ is a matrix, then $DA$ is a row scaling of $A$ and $AD$ is a column scaling of $A$. 
### 1.2.3 Triangular Matrix Multiplication

To introduce band matrix "thinking" we look at the matrix multiplication problem $C = AB$ when $A$ and $B$ are both $n$-by-$n$ and upper triangular. The 3-by-3 case is illuminating:

$$C = \begin{bmatrix}
a_{11}b_{11} & a_{11}b_{12} + a_{12}b_{22} & a_{11}b_{13} + a_{12}b_{23} + a_{13}b_{33} \\
0 & a_{22}b_{22} & a_{22}b_{23} + a_{23}b_{33} \\
0 & 0 & a_{33}b_{33}
\end{bmatrix}.$$ 

It suggests that the product is upper triangular and that its upper triangular entries are the result of abbreviated inner products. Indeed, since $a_{ik}b_{kj} = 0$ whenever $k < i$ or $j < k$ we see that

$$c_{ij} = \sum_{k=i}^{j} a_{ik}b_{kj}$$

and so we obtain:

**Algorithm 1.2.1 (Triangular Matrix Multiplication)** If $A, B \in \mathbb{R}^{n \times n}$ are upper triangular, then this algorithm computes $C = AB$.

```plaintext
C = 0
for i = 1:n
    for j = i:n
        for k = i:j
            C(i,j) = A(i,k)B(k,j) + C(i,j)
        end
    end
end
```
To quantify the savings in this algorithm we need some tools for measuring the amount of work.

1.2.4 Flops

Obviously, upper triangular matrix multiplication involves less arithmetic than when the matrices are full. One way to quantify this is with the notion of a flop. A flop\(^1\) is a floating point operation. A dot product or saxpy operation of length \(n\) involves \(2n\) flops because there are \(n\) multiplications and \(n\) adds in either of these vector operations.

The axpy \(y = Ax + y\) where \(A \in \mathbb{R}^{m \times n}\) involves \(2mn\) flops as does an \(m\)-by-\(n\) outer product update of the form \(A = A + xy^T\).

The matrix multiply update \(C = AB + C\) where \(A \in \mathbb{R}^{m \times p}\), \(B \in \mathbb{R}^{p \times n}\), and \(C \in \mathbb{R}^{m \times n}\) involves \(2mnp\) flops.

Flop counts are usually obtained by summing the amount of arithmetic associated with the most deeply nested statements in an algorithm. For matrix-matrix multiplication, this is the statement,

\[
C(i, j) = A(i, k)B(k, j) + C(i, j)
\]

which involves two flops and is executed \(mnp\) times as a simple loop accounting indicates. Hence the conclusion that general matrix multiplication requires \(2mnp\) flops.

Now let us investigate the amount of work involved in Algorithm 1.2.1. Note that \(c_{ij}, (i \leq j)\) requires \(2(j - i + 1)\) flops. Using the heuristics

\[
\sum_{p=1}^{q} p = \frac{q(q + 1)}{2} \approx \frac{q^2}{2}
\]

and

\[
\sum_{p=1}^{q} p^2 = \frac{q^3}{3} + \frac{q^2}{2} + \frac{q}{6} \approx \frac{q^3}{3}
\]

we find that triangular matrix multiplication requires one-sixth the number of flops as full matrix multiplication:

\[
\sum_{i=1}^{n} \sum_{j=i}^{n} 2(j - i + 1) = \sum_{i=1}^{n} \sum_{j=1}^{n-i+1} 2j \approx \sum_{i=1}^{n} \frac{2(n - i + 1)^2}{2} = \sum_{i=1}^{n} i^2 \approx \frac{n^3}{3}.
\]

We throw away the low order terms since their inclusion does not contribute to what the flop count "says." For example, an exact flop count of Algorithm 1.2.1 reveals that precisely \(n^3/3 + n^2 + 2n/3\) flops are involved. For

---

\(^1\)In the first edition of this book we defined a flop to be the amount of work associated with an operation of the form \(a_{ij} = a_{ij} + a_{kj}a_{kj}\), i.e., a floating point add, a floating point multiply, and some subscripting. Thus, an "old flop" involves two "new flops." In defining a flop to be a single floating point operation we are opting for a more precise measure of arithmetic complexity.
large \( n \) (the typical situation of interest) we see that the exact flop count offers no insight beyond the \( n^3/3 \) approximation.

Flop counting is a necessarily crude approach to the measuring of program efficiency since it ignores subscripting, memory traffic, and the countless other overheads associated with program execution. We must not infer too much from a comparison of flops counts. We cannot conclude, for example, that triangular matrix multiplication is six times faster than square matrix multiplication. Flop counting is just a "quick and dirty" accounting method that captures only one of the several dimensions of the efficiency issue.

1.2.5 The Colon Notation—Again

The dot product that the \( k \)-loop performs in Algorithm 1.2.1 can be succinctly stated if we extend the colon notation introduced in §1.1.8. Suppose \( A \in \mathbb{R}^{m \times n} \) and the integers \( p, q, \) and \( r \) satisfy \( 1 \leq p \leq q \leq n \) and \( 1 \leq r \leq m \). We then define

\[
A(r,p,q) = [a_{rp}, \ldots, a_{rq}] \in \mathbb{R}^{1 \times (q-p+1)}.
\]

Likewise, if \( 1 \leq p \leq q \leq m \) and \( 1 \leq c \leq n \), then

\[
A(p,q,c) = \begin{bmatrix} a_{pc} \\ \vdots \\ a_{qc} \end{bmatrix} \in \mathbb{R}^{q-p+1}.
\]

With this notation we can rewrite Algorithm 1.2.1 as

\[
C(1:n,1:n) = 0 \\
\text{for } i = 1:n \\
\quad \text{for } j = i:n \\
\quad \quad C(i,j) = A(i,i:j)B(i:j,j) + C(i,j) \\
\quad \text{end} \\
\text{end}
\]

We mention one additional feature of the colon notation. Negative increments are allowed. Thus, if \( x \) and \( y \) are \( n \)-vectors, then \( s = x^T y(n:-1:1) \) is the summation

\[
s = \sum_{i=1}^{n} x_i y_{n-i+1}.
\]

1.2.6 Band Storage

Suppose \( A \in \mathbb{R}^{n \times n} \) has lower bandwidth \( p \) and upper bandwidth \( q \) and assume that \( p \) and \( q \) are much smaller than \( n \). Such a matrix can be stored in a \((p + q + 1)\)-by-\( n \) array \( A.band \) with the convention that

\[
a_{ij} = A.band(i-j+p+1,j) \quad (1.2.1)
\]
for all \((i, j)\) that fall inside the band. Thus, if

\[
A = \begin{bmatrix}
  a_{11} & a_{12} & a_{13} & 0 & 0 & 0 \\
  a_{21} & a_{22} & a_{23} & a_{24} & 0 & 0 \\
  0 & a_{32} & a_{33} & a_{34} & a_{35} & 0 \\
  0 & 0 & a_{43} & a_{44} & a_{45} & a_{46} \\
  0 & 0 & 0 & a_{54} & a_{55} & a_{56} \\
  0 & 0 & 0 & 0 & a_{65} & a_{66}
\end{bmatrix},
\]

then

\[
A_{\text{band}} = \begin{bmatrix}
  0 & 0 & a_{13} & a_{24} & a_{35} & a_{46} \\
  0 & a_{12} & a_{23} & a_{34} & a_{45} & a_{56} \\
  a_{11} & a_{22} & a_{33} & a_{44} & a_{55} & a_{66} \\
  a_{21} & a_{32} & a_{43} & a_{54} & a_{65} & 0
\end{bmatrix}.
\]

Here, the "0" entries are unused. With this data structure, our column-oriented gaxpy algorithm transforms to the following:

**Algorithm 1.2.2 (Band Gaxpy)** Suppose \(A \in \mathbb{R}^{n \times n}\) has lower bandwidth \(p\) and upper bandwidth \(q\) and is stored in the \(A_{\text{band}}\) format (1.2.1). If \(x, y \in \mathbb{R}^n\), then this algorithm overwrites \(y\) with \(Ax + y\).

for \(j = 1:n\)
\[
\begin{align*}
  y_{\text{top}} &= \max(1, j - q) \\
  y_{\text{bot}} &= \min(n, j + p) \\
  a_{\text{top}} &= \max(1, q + 2 - j) \\
  a_{\text{bot}} &= a_{\text{top}} + y_{\text{bot}} - y_{\text{top}} \\
  y(y_{\text{top}}; y_{\text{bot}}) &= x(j)A_{\text{band}}(a_{\text{top}}; a_{\text{bot}}, j) + y(y_{\text{top}}; y_{\text{bot}})
\end{align*}
\]

end

Notice that by storing \(A\) by column in \(A_{\text{band}}\), we obtain a saxpy, column access procedure. Indeed, Algorithm 1.2.2 is obtained from Algorithm 1.1.4 by recognizing that each saxpy involves a vector with a small number of nonzeros. Integer arithmetic is used to identify the location of these nonzeros. As a result of this careful zero/nonzero analysis, the algorithm involves just \(2n(p + q + 1)\) flops with the assumption that \(p\) and \(q\) are much smaller than \(n\).

### 1.2.7 Symmetry

We say that \(A \in \mathbb{R}^{n \times n}\) is symmetric if \(A^T = A\). Thus,

\[
A = \begin{bmatrix}
  1 & 2 & 3 \\
  2 & 4 & 5 \\
  3 & 5 & 6
\end{bmatrix}
\]
is symmetric. Storage requirements can be halved if we just store the lower triangle of elements, e.g., $A.\text{vec} = \begin{bmatrix} 1 & 2 & 3 & 4 & 5 & 6 \end{bmatrix}$. In general, with this data structure we agree to store the $a_{ij}$ as follows:

$$a_{ij} = A.\text{vec}((j - 1)n - j(i - 1)/2 + i) \quad (i \geq j) \quad (1.2.2)$$

Let us look at the column-oriented gaxpy operation with the matrix $A$ represented in $A.\text{vec}$.

Algorithm 1.2.3 (Symmetric Storage Gaxpy) Suppose $A \in \mathbb{R}^{n \times n}$ is symmetric and stored in the $A.\text{vec}$ style (1.2.2). If $x, y \in \mathbb{R}^n$, then this algorithm overwrites $y$ with $Ax + y$.

for $j = 1:n$
    for $i = 1:j - 1$
        $y(i) = A.\text{vec}((i - 1)n - i(i - 1)/2 + j)x(j) + y(i)$
    end
    for $i = j:n$
        $y(i) = A.\text{vec}((j - 1)n - j(j - 1)/2 + i)x(j) + y(i)$
    end
end

This algorithm requires the same $2n^2$ flops that an ordinary gaxpy requires. Notice that the halving of the storage requirement is purchased with some awkward subscripting.

1.2.8 Store by Diagonal

Symmetric matrices can also be stored by diagonal. If

$$A = \begin{bmatrix} 1 & 2 & 3 \\ 2 & 4 & 5 \\ 3 & 5 & 6 \end{bmatrix},$$

then in a store-by-diagonal scheme we represent $A$ with the vector

$$A.\text{diag} = \begin{bmatrix} 1 & 4 & 6 & 2 & 5 & 3 \end{bmatrix}.$$

In general, if $i \geq j$, then

$$a_{i+k,i} = A.\text{diag}(i + nk - k(k - 1)/2) \quad (k \geq 0) \quad (1.2.3)$$

Some notation simplifies the discussion of how to use this data structure in a matrix-vector multiplication.

If $A \in \mathbb{R}^{m \times n}$, then let $D(A, k) \in \mathbb{R}^{m \times n}$ designate the $k$th diagonal of $A$ as follows:

$$[D(A, k)]_{ij} = \begin{cases} a_{ij} & j = i + k, \quad 1 \leq i \leq m, \quad 1 \leq j \leq n \\ 0 & \text{otherwise.} \end{cases}$$
Thus,

\[
A = \begin{bmatrix}
1 & 2 & 3 \\
2 & 4 & 5 \\
3 & 5 & 6
\end{bmatrix} = \begin{bmatrix}
0 & 0 & 3 \\
0 & 0 & 0 \\
0 & 0 & 0
\end{bmatrix}_D(A,2) + \begin{bmatrix}
0 & 2 & 0 \\
0 & 0 & 5 \\
0 & 0 & 0
\end{bmatrix}_D(A,1) + \begin{bmatrix}
1 & 0 & 0 \\
0 & 4 & 0 \\
0 & 0 & 6
\end{bmatrix}_D(A,0) + \begin{bmatrix}
0 & 0 & 0 \\
2 & 0 & 0 \\
0 & 5 & 0
\end{bmatrix}_D(A,-1) + \begin{bmatrix}
0 & 0 & 0 \\
0 & 0 & 0 \\
3 & 0 & 0
\end{bmatrix}_D(A,-2).
\]

Returning to our store-by-diagonal data structure, we see that the nonzero parts of \(D(A, 0), D(A, 1), \ldots, D(A, n - 1)\) are sequentially stored in the \(A.diag\) scheme (1.2.3). The gaxpy \(y = Ax + y\) can then be organized as follows:

\[
y = D(A, 0)x + \sum_{k=1}^{n-1} (D(A, k) + D(A, k^T))x + y.
\]

Working out the details we obtain the following algorithm.

**Algorithm 1.2.4 (Store-By-Diagonal Gaxpy)** Suppose \(A \in \mathbb{R}^{n \times n}\) is symmetric and stored in the \(A.diag\) style (1.2.3). If \(x, y \in \mathbb{R}^n\), then this algorithm overwrites \(y\) with \(Ax + y\).

```plaintext
for i = 1:n
    y(i) = A.diag(i)x(i) + y(i)
end
for k = 1:n - 1
    t = nk - k(k - 1)/2
    \{y = D(A, k)x + y\}
    for i = 1:n - k
        y(i) = A.diag(i + t)x(i + k) + y(i)
    end
    \{y = D(A, k)^T x + y\}
    for i = 1:n - k
        y(i + k) = A.diag(i + t)x(i) + y(i + k)
    end
end
```

Note that the inner loops oversee vector multiplications:

\[
y(1:n - k) = A.diag(t + 1:t + n - k) \ast x(k + 1:n) + y(1:n - k)
\]
\[
y(k + 1:n) = A.diag(t + 1:t + n - k) \ast x(1:n - k) + y(k + 1:n)
\]
1.2.9 A Note on Overwriting and Workspaces

An undercurrent in the above discussion has been the economical use of storage. Overwriting input data is another way to control the amount of memory that a matrix computation requires. Consider the $n$-by-$n$ matrix multiplication problem $C = AB$ with the proviso that the "input matrix" $B$ is to be overwritten by the "output matrix" $C$. We cannot simply transform

$$C(1:n, 1:n) = 0$$
for $j = 1:n$
for $k = 1:n$
$$C(:, j) = C(:, j) + A(:, k)B(k, j)$$
end
end

to

for $j = 1:n$
for $k = 1:n$
$$B(:, j) = B(:, j) + A(:, k)B(k, j)$$
end
end

because $B(:, j)$ is needed throughout the entire $k$-loop. A linear workspace is needed to hold the $j$th column of the product until it is "safe" to overwrite $B(:, j)$:

for $j = 1:n$
$$w(1:n) = 0$$
for $k = 1:n$
$$w( :) = w( :) + A(:, k)B(k, j)$$
end
$$B(:, j) = w( :)$$
end

A linear workspace overhead is usually not important in a matrix computation that has a 2-dimensional array of the same order.

Problems

P1.2.1 Give an algorithm that overwrites $A$ with $A^2$ where $A \in \mathbb{R}^{n \times n}$ is (a) upper triangular and (b) square. Strive for a minimum workspace in each case.

P1.2.2 Suppose $A \in \mathbb{R}^{n \times n}$ is upper Hessenberg and that scalars $\lambda_1, \ldots, \lambda_r$ are given. Give a saxpy algorithm for computing the first column of $M = (A - \lambda_1 I) \cdots (A - \lambda_r I)$.

P1.2.3 Give a column saxpy algorithm for the $n$-by-$n$ matrix multiplication problem
Chapter 1. Matrix Multiplication Problems

C = AB where A is upper triangular and B is lower triangular.

P1.2.4 Extend Algorithm 1.2.2 so that it can handle rectangular band matrices. Be sure to describe the underlying data structure.

P1.2.5 A ∈ R^n×n is Hermitian if A^H = A. If A = B + iC, then it is easy to show that B^T = B and C^T = -C. Suppose we represent A in an array A herm with the property that A herm(i, j) houses b_{ij} if i ≥ j and c_{ij} if j > i. Using this data structure write a matrix-vector multiply function that computes Re(z) and Im(z) from Re(z) and Im(z) so that z = Ax.

P1.2.6 Suppose X ∈ R^n×p and A ∈ R^n×n, with A symmetric and stored by diagonal. Give an algorithm that computes Y = X^TAX and stores the result by diagonal. Use separate arrays for A and Y.

P1.2.7 Suppose a ∈ R^n is given and that A ∈ R^n×n has the property that a_{ij} = a_{i-j+1}. Give an algorithm that overwrites y with Ax + y where x, y ∈ R^n are given.

P1.2.8 Suppose a ∈ R^n is given and that A ∈ R^n×n has the property that a_{ij} = a_{(i+j-1) mod n+1}. Give an algorithm that overwrites y with Ax + y where x, y ∈ R^n are given.

P1.2.9 Develop a compact store-by-diagonal scheme for unsymmetric band matrices and write the corresponding gaxpy algorithm.

P1.2.10 Suppose p and q are n-vectors and that A = (a_{ij}) is defined by a_{ij} = a_{ji} = p_{i}q_{j} for 1 ≤ i ≤ j ≤ n. How many flops are required to compute y = Ax where x ∈ R^n is given?

Notes and References for Sec. 1.2

Consult the LAPACK manual for a discussion about appropriate data structures when symmetry and/or bandedness is present. See also

1.3 Block Matrices and Algorithms

Having a facility with block matrix notation is crucial in matrix computations because it simplifies the derivation of many central algorithms. Moreover, “block algorithms” are increasingly important in high performance computing. By a block algorithm we essentially mean an algorithm that is rich in matrix-matrix multiplication. Algorithms of this type turn out to be more efficient in many computing environments than those that are organized at a lower linear algebraic level.

1.3.1 Block Matrix Notation

Column and row partitionings are special cases of matrix blocking. In general we can partition both the rows and columns of an m-by-n matrix
1.3. Block Matrices and Algorithms

$A$ to obtain

$$A = \begin{bmatrix}
A_{11} & \ldots & A_{1r} \\
\vdots & \ddots & \vdots \\
A_{q1} & \ldots & A_{qr}
\end{bmatrix}
\begin{bmatrix}
m_1 \\
\vdots \\
m_q
\end{bmatrix}
\begin{bmatrix}
n_1 \\
n_r
\end{bmatrix}$$

where $m_1 + \ldots + m_q = m$, $n_1 + \ldots + n_r = n$, and $A_{\alpha\beta}$ designates the $(\alpha, \beta)$ block or submatrix. With this notation, block $A_{\alpha\beta}$ has dimension $m_\alpha$-by-$n_\beta$ and we say that $A = (A_{\alpha\beta})$ is a $q$-by-$r$ block matrix.

1.3.2 Block Matrix Manipulation

Block matrices combine just like matrices with scalar entries as long as certain dimension requirements are met. For example, if

$$B = \begin{bmatrix}
B_{11} & \ldots & B_{1r} \\
\vdots & \ddots & \vdots \\
B_{q1} & \ldots & B_{qr}
\end{bmatrix}
\begin{bmatrix}
m_1 \\
\vdots \\
m_q
\end{bmatrix}
\begin{bmatrix}
n_1 \\
n_r
\end{bmatrix}$$

then we say that $B$ is partitioned conformably with the matrix $A$ above. The sum $C = A + B$ can also be regarded as a $q$-by-$r$ block matrix:

$$C = \begin{bmatrix}
C_{11} & \ldots & C_{1r} \\
\vdots & \ddots & \vdots \\
C_{q1} & \ldots & C_{qr}
\end{bmatrix}
\begin{bmatrix}
A_{11} + B_{11} & \ldots & A_{1r} + B_{1r} \\
\vdots & \ddots & \vdots \\
A_{q1} + B_{q1} & \ldots & A_{qr} + B_{qr}
\end{bmatrix}$$

The multiplication of block matrices is a little trickier. We start with a pair of lemmas.

**Lemma 1.3.1** If $A \in \mathbb{R}^{m \times p}$, $B \in \mathbb{R}^{p \times n}$,

$$A = \begin{bmatrix}
A_1 \\
\vdots \\
A_q
\end{bmatrix}
\begin{bmatrix}
m_1 \\
\vdots \\
m_q
\end{bmatrix}$$

$$B = \begin{bmatrix}
B_1 \\
\vdots \\
B_r
\end{bmatrix}
\begin{bmatrix}
n_1 \\
n_r
\end{bmatrix}$$

then

$$AB = C = \begin{bmatrix}
C_{11} & \ldots & C_{1r} \\
\vdots & \ddots & \vdots \\
C_{q1} & \ldots & C_{qr}
\end{bmatrix}
\begin{bmatrix}
m_1 \\
\vdots \\
m_q
\end{bmatrix}$$

where $C_{\alpha\beta} = A_{\alpha}B_{\beta}$ for $\alpha = 1:q$ and $\beta = 1:r$. 
Proof. First we relate scalar entries in block $C_{\alpha \beta}$ to scalar entries in $C$. For $1 \leq \alpha \leq q$, $1 \leq \beta \leq r$, $1 \leq i \leq m_\alpha$, and $1 \leq j \leq n_\beta$ we have

$$[C_{\alpha \beta}]_{ij} = c_{\lambda+i, \mu+j}$$

where

$$\lambda = m_1 + \cdots + m_{\alpha-1}$$
$$\mu = n_1 + \cdots + n_{\beta-1}.$$ 

But

$$c_{\lambda+i, \mu+j} = \sum_{k=1}^{p} a_{\lambda+i,k} b_{k,\mu+j} = \sum_{k=1}^{p} [A_\alpha]_{ik} [B_\beta]_{kj} = [A_\alpha B_\beta]_{ij}.$$ 

Thus, $C_{\alpha \beta} = A_\alpha B_\beta$. □

Lemma 1.3.2 If $A \in \mathbb{R}^{m \times p}$, $B \in \mathbb{R}^{p \times n}$,

$$A = \begin{bmatrix} A_1 & \cdots & A_s \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} B_1 \\ \vdots \\ B_s \end{bmatrix} \quad \text{then} \quad AB = C = \sum_{\gamma=1}^{s} A_\gamma B_\gamma.$$ 

Proof. We set $s = 2$ and leave the general $s$ case to the reader. (See P1.3.6.) For $1 \leq i \leq m$ and $1 \leq j \leq n$ we have

$$c_{ij} = \sum_{k=1}^{p} a_{i,k} b_{k,j} = \sum_{k=1}^{p_1} a_{i,k} b_{k,j} + \sum_{k=p_1+1}^{p_1+p_2} a_{i,k} b_{k,j}$$

$$= [A_1 B_1]_{ij} + [A_2 B_2]_{ij} = [A_1 B_1 + A_2 B_2]_{ij}.$$ 

Thus, $C = A_1 B_1 + A_2 B_2$. □

For general block matrix multiplication we have the following result:

Theorem 1.3.3 If

$$A = \begin{bmatrix} A_{11} & \cdots & A_{1s} \\ \vdots & \ddots & \vdots \\ A_{q1} & \cdots & A_{qs} \end{bmatrix} \quad m_1 \quad \text{and} \quad B = \begin{bmatrix} B_{11} & \cdots & B_{1r} \\ \vdots & \ddots & \vdots \\ B_{s1} & \cdots & B_{sr} \end{bmatrix} \quad \text{then} \quad$$

$$AB = C = \begin{bmatrix} \text{Product of blocks} \end{bmatrix}.$$
1.3. BLOCK MATRICES AND ALGORITHMS

and we partition the product \( C = AB \) as follows,

\[
C = \begin{bmatrix}
    C_{11} & \ldots & C_{1r} \\
    \vdots & & \vdots \\
    C_{q1} & \ldots & C_{qr} \\
\end{bmatrix}
\begin{bmatrix}
m_1 \\
\vdots \\
m_q \\
\end{bmatrix},
\]

then

\[
C_{\alpha \beta} = \sum_{\gamma=1}^{s} A_{\alpha \gamma} B_{\gamma \beta} \quad \alpha = 1:q, \quad \beta = 1:r.
\]

Proof. See P1.3.7. \( \square \)

A very important special case arises if we set \( s = 2 \), \( r = 1 \), and \( n_1 = 1 \):

\[
\begin{bmatrix}
    A_{11} & A_{12} \\
    A_{21} & A_{22}
\end{bmatrix}
\begin{bmatrix}
x_1 \\
x_2
\end{bmatrix} =
\begin{bmatrix}
    A_{11}x_1 + A_{12}x_2 \\
    A_{21}x_1 + A_{22}x_2
\end{bmatrix}.
\]

This partitioned matrix-vector product is used over and over again in subsequent chapters.

1.3.3 Submatrix Designation

As with "ordinary" matrix multiplication, block matrix multiplication can be organized in several ways. To specify the computations precisely, we need some notation.

Suppose \( A \in \mathbb{R}^{m \times n} \) and that \( i = (i_1, \ldots, i_r) \) and \( j = (j_1, \ldots, j_c) \) are integer vectors with the property that

\[
i_1, \ldots, i_r \in \{1,2,\ldots,m\}
\]
\[
j_1, \ldots, j_c \in \{1,2,\ldots,n\}.
\]

We let \( A(i,j) \) denote the \( r \)-by-\( c \) submatrix

\[
A(i,j) = \begin{bmatrix}
    A(i_1,j_1) & \ldots & A(i_1,j_c) \\
    \vdots & & \vdots \\
    A(i_r,j_1) & \ldots & A(i_r,j_c)
\end{bmatrix}.
\]

If the entries in the subscript vectors \( i \) and \( j \) are contiguous, then the "colon" notation can be used to define \( A(i,j) \) in terms of the scalar entries in \( A \). In particular, if \( 1 \leq i_1 \leq i_2 \leq m \) and \( 1 \leq j_1 \leq j_2 \leq n \), then \( A(i_1:i_2,j_1:j_2) \) is the submatrix obtained by extracting rows \( i_1 \) through \( i_2 \) and columns \( j_1 \) through \( j_2 \), e.g.

\[
A(3:5,1:2) = \begin{bmatrix}
a_{31} & a_{32} \\
a_{41} & a_{42} \\
a_{51} & a_{52}
\end{bmatrix}.
\]
While on the subject of submatrices, recall from §1.1.8 that if \( i \) and \( j \) are scalars, then \( A(i,:) \) designates the \( i \)th row of \( A \) and \( A(:,j) \) designates the \( j \)th column of \( A \).

### 1.3.4 Block Matrix Times Vector

An important situation covered by Theorem 1.3.3 is the case of a block matrix times vector. Let us consider the details of the gaxpy \( y = Ax + y \) where \( A \in \mathbb{R}^{m \times n} \), \( x \in \mathbb{R}^n \), \( y \in \mathbb{R}^m \), and

\[
A = \begin{bmatrix} A_1 & \cdots & A_q \end{bmatrix} \quad \text{and} \quad y = \begin{bmatrix} y_1 \\ \vdots \\ y_q \end{bmatrix}.
\]

We refer to \( A_i \) as the \( i \)th block row. If \( m.\text{vec} = (m_1, \ldots, m_q) \) is the vector of block row "heights", then from

\[
\begin{bmatrix} y_1 \\ \vdots \\ y_q \end{bmatrix} = \begin{bmatrix} A_1 \\ \vdots \\ A_q \end{bmatrix} x + \begin{bmatrix} y_1 \\ \vdots \\ y_q \end{bmatrix}
\]

we obtain

\[
\text{last} = 0 \quad \quad \text{for } i = 1:q \\
\quad \quad \text{first} = \text{last} + 1 \\
\quad \quad \text{last} = \text{first} + m.\text{vec}(i) - 1 \\
\quad \quad y(\text{first}:\text{last}) = A(\text{first}:\text{last},:)x + y(\text{first}:\text{last})
\]

(1.3.1)

Each time through the loop an "ordinary" gaxpy is performed so Algorithms 1.1.3 and 1.1.4 apply.

Another way to block the gaxpy computation is to partition \( A \) and \( x \) as follows:

\[
A = \begin{bmatrix} A_1 & \cdots & A_r \end{bmatrix} \quad x = \begin{bmatrix} x_1 \\ \vdots \\ x_r \end{bmatrix}.
\]

In this case we refer to \( A_j \) as the \( j \)th block column of \( A \). If \( n.\text{vec} = (n_1, \ldots, n_r) \) is the vector of block column widths, then from

\[
y = [A_1, \ldots, A_r] \begin{bmatrix} x_1 \\ \vdots \\ x_r \end{bmatrix} + y = \sum_{j=1}^{r} A_j x_j + y
\]

we obtain
\[ \text{last} = 0 \]
\[
\text{for } j = 1:r \\
\quad \text{first} = \text{last} + 1 \\
\quad \text{last} = \text{first} + n \cdot \text{vec}(j) - 1 \\
\quad y = A(:, \text{first}:\text{last})x(\text{first}:\text{last}) + y
\]
end

Again, the gaxpy's performed each time through the loop can be carried out with Algorithm 1.1.3 or 1.1.4.

### 1.3.5 Block Matrix Multiplication

Just as ordinary, scalar-level matrix multiplication can be arranged in several possible ways, so can the multiplication of block matrices. Different blockings for \( A, B, \) and \( C \) can set the stage for block versions of the dot product, saxpy, and outer product algorithms of §1.1. To illustrate this with a minimum of subscript clutter, we assume that these three matrices are all \( n \)-by-\( n \) and that \( n = N \ell \) where \( N \) and \( \ell \) are positive integers.

If \( A = (A_{\alpha\beta}), B = (B_{\alpha\beta}), \) and \( C = (C_{\alpha\beta}) \) are \( N \)-by-\( N \) block matrices with \( \ell \)-by-\( \ell \) blocks, then from Theorem 1.3.3

\[
C_{\alpha\beta} = \sum_{\gamma=1}^{N} A_{\alpha\gamma}B_{\gamma\beta} + C_{\alpha\beta} \quad \alpha = 1:N, \quad \beta = 1:N.
\]

If we organize a matrix multiplication procedure around this summation, then we obtain a block analog of Algorithm 1.1.5:

\[
\text{for } \alpha = 1:N \\
\quad i = (\alpha - 1)\ell + 1:\alpha\ell \\
\text{for } \beta = 1:N \\
\quad j = (\beta - 1)\ell + 1:\beta\ell \\
\text{for } \gamma = 1:N \\
\quad k = (\gamma - 1)\ell + 1:\gamma\ell \\
\quad C(i, j) = A(i, k)B(k, j) + C(i, j)
\]
end
end

Note that if \( \ell = 1 \), then \( \alpha \equiv i, \beta \equiv j, \) and \( \gamma \equiv k \) and we revert to Algorithm 1.1.5.

To obtain a block saxpy matrix multiply, we write \( C = AB + C \) as

\[
\begin{bmatrix}
C_1, \ldots, C_N
\end{bmatrix} = \begin{bmatrix}
A_1, \ldots, A_N
\end{bmatrix} \begin{bmatrix}
B_{11} & \cdots & B_{1N} \\
: & \ddots & : \\
B_{N1} & \cdots & B_{NN}
\end{bmatrix} + \begin{bmatrix}
C_1, \ldots, C_N
\end{bmatrix}
\]

where \( A_\alpha, C_\alpha \in \mathbb{R}^{n \times \ell} \), and \( B_{\alpha\beta} \in \mathbb{R}^{\ell \times \ell} \). From this we obtain
for $\beta = 1:N$
\[ j = (\beta - 1)\ell + 1: \beta\ell \]
for $\alpha = 1:N$
\[ i = (\alpha - 1)\ell + 1: \alpha\ell \]
\[ C(:, j) = A(:, i)B(i, j) + C(:, j) \]
end
end

This is the block version of Algorithm 1.1.7.

A block outer product scheme results if we work with the blockings

\[
A = [A_1, \ldots, A_N] \quad B = \begin{bmatrix} \phantom{B_1^T} \\ \vdots \\ B_N^T \end{bmatrix}
\]

where $A_\gamma, B_\gamma \in \mathbb{R}^{n \times \ell}$. From Lemma 1.3.2 we have

\[
C = \sum_{\gamma=1}^{N} A_\gamma B_\gamma^T + C
\]

and so

for $\gamma = 1:N$
\[ k = (\gamma - 1)\ell + 1: \gamma\ell \]
\[ C = A(:, k)B(k, :) + C \]  

end

This is the block version of Algorithm 1.1.8.

1.3.6 Complex Matrix Multiplication

Consider the complex matrix multiplication update

\[
C_1 + iC_2 = (A_1 + iA_2)(B_1 + iB_2) + (C_1 + iC_2)
\]

where all the matrices are real and $i^2 = -1$. Comparing the real and imaginary parts we find

\[
C_1 = A_1B_1 - A_2B_2 + C_1
\]
\[
C_2 = A_1B_2 + A_2B_1 + C_2
\]

and this can be expressed as follows:

\[
\begin{bmatrix} C_1 \\ C_2 \end{bmatrix} = \begin{bmatrix} A_1 & -A_2 \\ A_2 & A_1 \end{bmatrix} \begin{bmatrix} B_1 \\ B_2 \end{bmatrix} + \begin{bmatrix} C_1 \\ C_2 \end{bmatrix}.
\]
This suggests how real matrix software might be applied to solve complex matrix problems. The only snag is that the explicit formation of

$$\begin{bmatrix}
  A_1 & -A_2 \\
  A_2 & A_1
\end{bmatrix}$$

requires the “double storage” of the matrices $A_1$ and $A_2$.

1.3.7 A Divide and Conquer Matrix Multiplication

We conclude this section with a completely different approach to the matrix-matrix multiplication problem. The starting point in the discussion is the 2-by-2 block matrix multiplication

$$\begin{bmatrix}
  C_{11} & C_{12} \\
  C_{21} & C_{22}
\end{bmatrix} = \begin{bmatrix}
  A_{11} & A_{12} \\
  A_{21} & A_{22}
\end{bmatrix} \begin{bmatrix}
  B_{11} & B_{12} \\
  B_{21} & B_{22}
\end{bmatrix}$$

where each block is square. In the ordinary algorithm, $C_{ij} = A_{i1}B_{1j} + A_{i2}B_{2j}$. There are 8 multiplies and 4 adds. Strassen (1969) has shown how to compute $C$ with just 7 multiplies and 18 adds:

$$P_1 = (A_{11} + A_{22})(B_{11} + B_{22})$$
$$P_2 = (A_{21} + A_{22})B_{11}$$
$$P_3 = A_{11}(B_{12} - B_{22})$$
$$P_4 = A_{22}(B_{21} - B_{11})$$
$$P_5 = (A_{11} + A_{12})B_{22}$$
$$P_6 = (A_{21} - A_{11})(B_{11} + B_{12})$$
$$P_7 = (A_{12} - A_{22})(B_{21} + B_{22})$$
$$C_{11} = P_1 + P_4 - P_5 + P_7$$
$$C_{12} = P_3 + P_5$$
$$C_{21} = P_2 + P_4$$
$$C_{22} = P_1 + P_3 - P_2 + P_6$$

These equations are easily confirmed by substitution. Suppose $n = 2m$ so that the blocks are $m$-by-$m$. Counting adds and multiplies in the computation $C = AB$ we find that conventional matrix multiplication involves $(2m)^3$ multiplies and $(2m)^3 - (2m)^2$ adds. In contrast, if Strassen’s algorithm is applied with conventional multiplication at the block level, then $7m^3$ multiplies and $7m^3 + 11m^2$ adds are required. If $m \gg 1$, then the Strassen method involves about 7/8ths the arithmetic of the fully conventional algorithm.

Now recognize that we can recur on the Strassen idea. In particular, we can apply the Strassen algorithm to each of the half-sized block multiplications associated with the $P_i$. Thus, if the original $A$ and $B$ are $n$-by-$n$ and $n = 2^a$, then we can repeatedly apply the Strassen multiplication algorithm. At the bottom “level,” the blocks are 1-by-1. Of course, there is no need to
recur down to the $n = 1$ level. When the block size gets sufficiently small, $(n \leq n_{\text{min}})$, it may be sensible to use conventional matrix multiplication when finding the $P_i$. Here is the overall procedure:

**Algorithm 1.3.1 (Strassen Multiplication)** Suppose $n = 2^q$ and that $A \in \mathbb{R}^{n \times n}$ and $B \in \mathbb{R}^{n \times n}$. If $n_{\text{min}} = 2^d$ with $d \leq q$, then this algorithm computes $C = AB$ by applying Strassen procedure recursively $q - d$ times.

```plaintext
function: $C = \text{strass}(A, B, n, n_{\text{min}})$
if $n \leq n_{\text{min}}$
    $C = AB$
else
    $m = n/2; u = 1:m; v = m + 1:n$;
    $P_1 = \text{strass}(A(u, u) + A(v, v), B(u, u) + B(v, v), m, n_{\text{min}})$
    $P_2 = \text{strass}(A(v, u) + A(v, v), B(u, u), m, n_{\text{min}})$
    $P_3 = \text{strass}(A(u, u), B(v, u) - B(v, v), m, n_{\text{min}})$
    $P_4 = \text{strass}(A(v, v), B(v, u) - B(u, u), m, n_{\text{min}})$
    $P_5 = \text{strass}(A(u, u) + A(u, v), B(v, v), m, n_{\text{min}})$
    $P_6 = \text{strass}(A(v, u) - A(u, u), B(u, u) + B(u, v), m, n_{\text{min}})$
    $P_7 = \text{strass}(A(u, v) - A(v, v), B(v, u) + B(v, v), m, n_{\text{min}})$
    $C(u, u) = P_1 + P_4 - P_5 + P_7$
    $C(u, v) = P_3 + P_5$
    $C(v, u) = P_2 + P_4$
    $C(v, v) = P_1 + P_3 - P_2 + P_6$
end
```

Unlike any of our previous algorithms strass is recursive, meaning that it calls itself. Divide and conquer algorithms are often best described in this manner. We have presented this algorithm in the style of a MATLAB function so that the recursive calls can be stated with precision.

The amount of arithmetic associated with strass is a complicated function of $n$ and $n_{\text{min}}$. If $n_{\text{min}} \gg 1$, then it suffices to count multiplications as the number of additions is roughly the same. If we just count the multiplications, then it suffices to examine the deepest level of the recursion as that is where all the multiplications occur. In strass there are $q - d$ subdivisions and thus, $7^{q-d}$ conventional matrix-matrix multiplications to perform. These multiplications have size $n_{\text{min}}$ and thus strass involves about $s = (2^d)^3 7^{q-d}$ multiplications compared to $c = (2^q)^3$, the number of multiplications in the conventional approach. Notice that

$$\frac{s}{c} = \left(\frac{2^d}{2^q}\right)^3 7^{q-d} = \left(\frac{7}{8}\right)^{q-d}.$$
If \( d = 0 \), i.e., we recur on down to the 1-by-1 level, then

\[
s = \left( \frac{7}{8} \right)^q c = 7^q = n^{\log_2 7} \approx n^{2.807}.
\]

Thus, asymptotically, the number of multiplications in the Strassen procedure is \( O(n^{2.807}) \). However, the number of additions (relative to the number of multiplications) becomes significant as \( n_{\text{min}} \) gets small.

**Example 1.3.1** If \( n = 1024 \) and \( n_{\text{min}} = 64 \), then \( \text{strass} \) involves \( (7/8)^{10-6} \approx .6 \) the arithmetic of the conventional algorithm.

**Problems**

P1.3.1 Generalize (1.3.3) so that it can handle the variable block-size problem covered by Theorem 1.3.3.

P1.3.2 Generalize (1.3.4) and (1.3.5) so that they can handle the variable block-size case.

P1.3.3 Adapt \( \text{strass} \) so that it can handle square matrix multiplication of any order. Hint: If the “current” \( A \) has odd dimension, append a zero row and column.

P1.3.4 Prove that if

\[
A = \begin{bmatrix}
A_{11} & \cdots & A_{1r} \\
\vdots & \ddots & \vdots \\
A_{q1} & \cdots & A_{qr}
\end{bmatrix}
\]

is a blocking of the matrix \( A \), then

\[
A^T = \begin{bmatrix}
A_{11}^T & \cdots & A_{q1}^T \\
\vdots & \ddots & \vdots \\
A_{1r}^T & \cdots & A_{qr}^T
\end{bmatrix}.
\]

P1.3.5 Suppose \( n \) is even and define the following function from \( \mathbb{R}^n \) to \( \mathbb{R} \):

\[
f(x) = x(1:2:n)^T x(2:n) = \sum_{i=1}^{n/2} x_{2i-1} x_{2i}
\]

(a) Show that if \( x, y \in \mathbb{R}^n \) then

\[
x^T y = \sum_{i=1}^{n/2} (x_{2i-1} + y_{2i})(x_{2i} + y_{2i-1}) - f(x) - f(y)
\]

(b) Now consider the \( n \)-by-\( n \) matrix multiplication \( C = AB \). Give an algorithm for computing this product that requires \( n^3/2 \) multiplies once \( f \) is applied to the rows of \( A \) and the columns of \( B \). See Winograd (1968) for details.

P1.3.6 Prove Lemma 1.3.2 for general \( s \). Hint. Set

\[
\rho_\gamma = \rho_1 + \cdots + \rho_{\gamma-1}, \quad \gamma = 1:s + 1
\]

and show that

\[
c_{ij} = \sum_{\gamma=1}^{s} \sum_{k=\rho_\gamma + 1}^{\rho_{\gamma+1}} a_{ik} b_{kj}.
\]
P1.3.7 Use Lemmas 1.3.1 and 1.3.2 to prove Theorem 1.3.3. In particular, set

\[
A_\gamma = \begin{bmatrix} A_{1\gamma} \\ \vdots \\ A_{r\gamma} \end{bmatrix} \quad \text{and} \quad B_\gamma = \begin{bmatrix} B_{\gamma 1} & \cdots & B_{\gamma r} \end{bmatrix}
\]

and note from Lemma 1.3.2 that

\[
C = \sum_{\gamma=1}^{s} A_\gamma B_\gamma.
\]

Now analyze each \(A_\gamma B_\gamma\) with the help of Lemma 1.3.1.

Notes and References for Sec. 1.3

For quite some time fast methods for matrix multiplication have attracted a lot of attention within computer science. See

Many of these methods have dubious practical value. However, with the publication of

it is clear that the blanket dismissal of these fast procedures is unwise. The "stability" of the Strassen algorithm is discussed in §2.4.10. See also

1.4 Vectorization and Re-Use Issues

The matrix manipulations discussed in this book are mostly built upon dot products and saxpy operations. *Vector pipeline computers* are able to perform vector operations such as these very fast because of special hardware that is able to exploit the fact that a vector operation is a very regular sequence of scalar operations. Whether or not high performance is extracted from such a computer depends upon the length of the vector operands and a number of other factors that pertain to the movement of data such as vector stride, the number of vector loads and stores, and the level of data re-use. Our goal is to build a useful awareness of these issues. We are not trying to build a comprehensive model of vector pipeline
computing that might be used to predict performance. We simply want to identify the kind of thinking that goes into the design of an effective vector pipeline code. We do not mention any particular machine. The literature is filled with case studies.

1.4.1 Pipelining Arithmetic Operations

The primary reason why vector computers are fast has to do with pipelining. The concept of pipelining is best understood by making an analogy to assembly line production. Suppose the assembly of an individual automobile requires one minute at each of sixty workstations along an assembly line. If the line is well staffed and able to initiate the assembly of a new car every minute, then 1000 cars can be produced from scratch in about 1000 + 60 = 1060 minutes. For a work order of this size the line has an effective "vector speed" of 1000/1060 automobiles per minute. On the other hand, if the assembly line is understaffed and a new assembly can be initiated just once an hour, then 1000 hours are required to produce 1000 cars. In this case the line has an effective "scalar speed" of 1/60th automobile per minute.

So it is with a pipelined vector operation such as the vector add $z = x+y$. The scalar operations $z_i = x_i + y_i$ are the cars. The number of elements is the size of the work order. If the start-to-finish time required for each $z_i$ is $\tau$, then a pipelined, length $n$ vector add could be completed in time much less than $n\tau$. This gives vector speed. Without the pipelining, the vector computation would proceed at a scalar rate and would approximately require time $n\tau$ for completion.

Let us see how a sequence of floating point operations can be pipelined. Floating point operations usually require several cycles to complete. For example, a 3-cycle addition of two scalars $x$ and $y$ may proceed as in Fig.1.4.1. To visualize the operation, continue with the above metaphor

![Fig. 1.4.1 A 3-Cycle Adder](image)

and think of the addition unit as an assembly line with three "work stations". The input scalars $x$ and $y$ proceed along the assembly line spending one cycle at each of three stations. The sum $z$ emerges after three cycles.
Note that when a single, "free standing" addition is performed, only one of the three stations is active during the computation.

Now consider a vector addition $z = x + y$. With pipelining, the $x$ and $y$ vectors are streamed through the addition unit. Once the pipeline is filled and steady state reached, a $z_i$ is produced every cycle. In Fig. 1.4.2 we depict what the pipeline might look like once this steady state is achieved. In this case, vector speed is about three times scalar speed because the time for an individual add is three cycles.

1.4.2 Vector Operations

A vector pipeline computer comes with a repertoire of vector instructions, such as vector add, vector multiply, vector scale, dot product, and saxpy. We assume for clarity that these operations take place in vector registers. Vectors travel between the registers and memory by means of vector load and vector store instructions.

An important attribute of a vector processor is the length of its vector registers which we designate by $v_L$. A length-$n$ vector operation must be broken down into subvector operations of length $v_L$ or less. Here is how such a partitioning might be managed in the case of a vector addition $z = x + y$ where $x$ and $y$ are $n$-vectors:

\[
\begin{align*}
\text{first} & = 1 \\
\text{while} & \quad \text{first} \leq n \\
\text{last} & = \min\{n, \text{first} + v_L - 1\} \\
\text{Vector load} & \quad x(\text{first}:\text{last}). \\
\text{Vector load} & \quad y(\text{first}:\text{last}). \\
\text{Vector add:} & \quad z(\text{first}:\text{last}) = x(\text{first}:\text{last}) + y(\text{first}:\text{last}). \\
\text{Vector store} & \quad z(\text{first}:\text{last}). \\
\text{first} & = \text{last} + 1 \\
\end{align*}
\]

A reasonable compiler for a vector computer would automatically generate these vector instructions from a programmer specified $z = x + y$ command.
1.4.3 The Vector Length Issue

Suppose the pipeline for the vector operation $\text{op}$ takes $\tau_{\text{op}}$ cycles to "set up." Assume that one component of the result is obtained per cycle once the pipeline is filled. The time required to perform an $n$-dimensional $\text{op}$ is then given by

$$T_{\text{op}}(n) = (\tau_{\text{op}} + n)\mu \quad n \leq v_L$$

where $\mu$ is the cycle time and $v_L$ is the length of the vector hardware.

If the vectors to be combined are longer than the vector hardware length, then as we have seen the overall vector operation must be broken down into hardware-manageable chunks. Thus, if

$$n = n_1 v_L + n_0 \quad 0 \leq n_0 < v_L,$$

then we assume that

$$T_{\text{op}}(n) = \begin{cases} 
   n_1 (\tau_{\text{op}} + v_L) \mu & n_0 = 0 \\
   (n_1 (\tau_{\text{op}} + v_L) + \tau_{\text{op}} + n_0) \mu & n_0 \neq 0
\end{cases}$$

specifies the overall time required to perform a length-$n$ $\text{op}$. This simplifies to

$$T_{\text{op}}(n) = (n + \tau_{\text{op}} \text{ceil}(n/v_L)) \mu$$

where ceil($\alpha$) is the smallest integer such that $\alpha \leq \text{ceil}(\alpha)$. If $\rho$ flops per component are involved, then the effective rate of computation for general $n$ is given by

$$R_{\text{op}}(n) = \frac{\rho n}{T_{\text{op}}(n)} = \frac{\rho}{\mu} \frac{1}{1 + \frac{\tau_{\text{op}}}{\mu} \text{ceil}\left(\frac{n}{v_L}\right)} .$$

(If $\mu$ is in seconds, then $R_{\text{op}}$ is in flops per second.) The asymptotic rate of performance is given by

$$\lim_{n \to \infty} R_{\text{op}}(n) = \frac{1}{1 + \frac{\tau_{\text{op}}}{\mu}} \frac{\rho}{\mu} .$$

As a way of assessing how serious the start-up overhead is for a vector operation, Hockney and Jesshope (1988) define the quantity $n_{1/2}$ to be the smallest $n$ for which half of peak performance is achieved, i.e.,

$$\frac{\rho n_{1/2}}{T_{\text{op}}(n_{1/2})} = \frac{1}{2} \frac{\rho}{\mu} .$$

Machines that have big $n_{1/2}$ factors do not perform well on short vector operations.

Let us see what the above performance model says about the design of the matrix multiply update $C = AB + C$ where $A \in \mathbb{R}^{m \times p}$, $B \in \mathbb{R}^{p \times n}$, and $C \in \mathbb{R}^{m \times n}$. Recall from §1.1.11 that there are six possible versions of the conventional algorithm and they correspond to the six possible loop orderings of
for $i = 1:m$
    for $j = 1:n$
        for $k = 1:p$
            $C(i,j) = A(i,k)B(k,j) + C(i,j)$
        end
    end
end

This is the $ijk$ variant and its innermost loop oversees a length-$p$ dot product. Thus, our performance model predicts that

$$T_{ijk} = mnp + mn \cdot \text{ceil}(p/v_L) \tau_{dot}$$

cycles are required. A similar analysis for each of the other variants leads to the following table:

<table>
<thead>
<tr>
<th>Variant</th>
<th>Cycles</th>
</tr>
</thead>
<tbody>
<tr>
<td>$ijk$</td>
<td>$mnp + mn \cdot \tau_{dot}(p/v_L)$</td>
</tr>
<tr>
<td>$jik$</td>
<td>$mnp + mn \cdot \tau_{dot}(p/v_L)$</td>
</tr>
<tr>
<td>$ikj$</td>
<td>$mnp + mp \cdot \tau_{sax}(n/v_L)$</td>
</tr>
<tr>
<td>$jki$</td>
<td>$mnp + np \cdot \tau_{sax}(m/v_L)$</td>
</tr>
<tr>
<td>$kij$</td>
<td>$mnp + mp \cdot \tau_{sax}(n/v_L)$</td>
</tr>
<tr>
<td>$kji$</td>
<td>$mnp + np \cdot \tau_{sax}(m/v_L)$</td>
</tr>
</tbody>
</table>

We make a few observations based upon some elementary integer arithmetic manipulation. Assume that $\tau_{sax}$ and $\tau_{dot}$ are roughly equal. If $m$, $n$, and $p$ are all less than $v_L$, then the most efficient variants will have the longest inner loops. If $m$, $n$, and $p$ are much bigger than $v_L$, then the distinction between the six options is small.

1.4.4 The Stride Issue

The "layout" of a vector operand in memory often has a bearing on execution speed. The key factor is stride. The stride of a stored floating point vector is the distance (in logical memory locations) between the vector's components. Accessing a row in a two-dimensional Fortran array is not a unit stride operation because arrays are stored by column. In C, it is just the opposite as matrices are stored by row. Nonunit stride vector operations may interfere with the pipelining capability of a computer degrading performance.

To clarify the stride issue we consider how the six variants of matrix multiplication "pull up" data from the $A$, $B$, and $C$ matrices in the inner loop. This is where the vector calculation occurs (dot product or saxpy) and there are three possibilities:
1.4. **Vectorization and Re-Use Issues**

\[ jki \text{ or } kji: \]
\[ \text{for } i = 1:n \]
\[ C(i, j) = C(i, j) + A(i, k)B(k, j) \]
\[ \text{end} \]

\[ ikj \text{ or } kij: \]
\[ \text{for } j = 1:n \]
\[ C(i, j) = C(i, j) + A(i, k)B(k, j) \]
\[ \text{end} \]

\[ ijk \text{ or } jik: \]
\[ \text{for } k = 1:p \]
\[ C(i, j) = C(i, j) + A(i, k)B(k, j) \]
\[ \text{end} \]

Here is a table that specifies the \( A, B, \) and \( C \) strides associated with each of these possibilities:

<table>
<thead>
<tr>
<th>Variant</th>
<th>( A ) Stride</th>
<th>( B ) Stride</th>
<th>( C ) Stride</th>
</tr>
</thead>
<tbody>
<tr>
<td>( jki \text{ or } kji )</td>
<td>Unit</td>
<td>0</td>
<td>Unit</td>
</tr>
<tr>
<td>( ikj \text{ or } kij )</td>
<td>0</td>
<td>Non-Unit</td>
<td>Non-Unit</td>
</tr>
<tr>
<td>( ijk \text{ or } jik )</td>
<td>Non-Unit</td>
<td>Unit</td>
<td>0</td>
</tr>
</tbody>
</table>

Storage in column-major order is assumed. A stride of zero means that only a single array element is accessed in the inner loop. From the stride point of view, it is clear that we should favor the \( jki \) and \( kji \) variants. This may not coincide with a preference that is based on vector length considerations. Dilemmas of this type are typical in high performance computing. One goal (maximize vector length) can conflict with another (impose unit stride).

Sometimes a vector stride/vector length conflict can be resolved through the intelligent choice of data structures. Consider the gaxpy \( y = Ax + y \) where \( A \in \mathbb{R}^{n \times n} \) is symmetric. Assume that \( n \leq v_L \) for simplicity. If \( A \) is stored conventionally and Algorithm 1.1.4 is used, then the central computation entails \( n \), unit stride saxpy’s each having length \( n \):

\[ \text{for } j = 1:n \]
\[ y = A(:, j)x(j) + y \]
\[ \text{end} \]

Our simple execution model tells us that

\[ T_1 = n(v_{ax} + n) \]

cycles are required.

In §1.2.7 we introduced the lower triangular storage scheme for symmetric matrices and obtained this version of the gaxpy:
for $j = 1:n$
  for $i = 1:j - 1$
    $y(i) = A.vec((i - 1)n - i(i - 1)/2 + j)x(j) + y(i)$
  end
  for $i = j:n$
    $y(i) = A.vec((j - 1)n - j(j - 1)/2 + i)x(j) + y(i)$
  end
end

Notice that the first $i$-loop does not define a unit stride saxpy. If we assume that a length $n$, nonunit stride saxpy is equivalent to $n$ unit-length saxpys (a worst case scenario), then this implementation involves

$$T_2 = n \left( \frac{n}{2} \tau_{sax} + n \right)$$

cycles.

In §1.2.8 we developed the store-by-diagonal version:

for $i = 1:n$
  $y(i) = A.diag(i)x(i) + y(i)$
end

for $k = 1:n - 1$
  $t = nk - k(k - 1)/2$
  $\{y = D(A, k)x + y\}$
  for $i = 1:n - k$
    $y(i) = A.diag(i + t)x(i + k) + y(i)$
  end
  $\{y = D(A, k)^T x + y\}$
  for $i = 1:n - k$
    $y(i + k) = A.diag(i + t)x(i) + y(i + k)$
  end
end

In this case both inner loops define a unit stride vector multiply ($vm$) and our model of execution predicts

$$T_3 = n \left( 2\tau_{vm} + n \right)$$

cycles.

The example shows how the choice of data structure can effect the stride attributes of an algorithm. Store by diagonal seems attractive because it represents the matrix compactly and has unit stride. However, a careful which-is-best analysis would depend upon the values of $\tau_{sax}$ and $\tau_{vm}$ and the precise penalties for nonunit stride computation and excess storage. The complexity of the situation would call for careful benchmarking.
1.4.5 Thinking About Data Motion

Another important attribute of a matrix algorithm concerns the actual volume of data that has to be moved around during execution. Matrices sit in memory but the computations that involve their entries take place in functional units. The control of memory traffic is crucial to performance in many computers. To continue with the factory metaphor used at the beginning of this section: Can we keep the superfast arithmetic units busy with enough deliveries of matrix data and can we ship the results back to memory fast enough to avoid backlog? Fig. 1.4.3 depicts the typical situation in an advanced uniprocessor environment. Details vary from machine to machine, but two "axioms" prevail:

- Each level in the hierarchy has a limited capacity and for economic reasons this capacity is usually smaller as we ascend the hierarchy.

- There is a cost, sometimes relatively great, associated with the moving of data between two levels in the hierarchy.

The design of an efficient matrix algorithm requires careful thinking about the flow of data in between the various levels of storage. The vector touch and data re-use issues are important in this regard.

1.4.6 The Vector Touch Issue

In many advanced computers, data is moved around in chunks, e.g., vectors. The time required to read or write a vector to memory is comparable to the time required to engage the vector in a dot product or saxpy. Thus, the number of vector touches associated with a matrix code is a very important statistic. By a "vector touch" we mean either a vector load or store.
Let's count the number of vector touches associated with an \( m \times n \) outer product. Assume that \( m = m_1 v_L \) and \( n = n_1 v_L \) where \( v_L \) is the vector hardware length. (See §1.4.3.) In this environment, the outer product update \( A = A + xy^T \) would be arranged as follows:

\[
\text{for } \alpha = 1:m_1
\]
\[
i = (\alpha - 1)v_L + 1:\alpha v_L
\]
\[
\text{for } \beta = 1:n_1
\]
\[
j = (\beta - 1)v_L + 1:\beta v_L
\]
\[
A(i, j) = A(i, j) + x(i)y(j)^T
\]
\[
\text{end}
\]
\[
\text{end}
\]

Each column of the submatrix \( A(i, j) \) must be loaded, updated, and then stored. Not forgetting to account for the vector touches associated with \( x \) and \( y \) we see that approximately

\[
\sum_{\alpha=1}^{m_1} \left( 1 + \sum_{\beta=1}^{n_1} (1 + 2v_L) \right) \approx 2m_1 n
\]

vector touches are required. (Low order terms do not contribute to the analysis.)

Now consider the gaxpy update \( y = Ax + y \) where \( y \in \mathbb{R}^n \), \( x \in \mathbb{R}^n \) and \( A \in \mathbb{R}^{m \times n} \). Breaking this computation down into segments of length \( v_L \) gives

\[
\text{for } \alpha = 1:m_1
\]
\[
i = (\alpha - 1)v_L + 1:\alpha v_L
\]
\[
\text{for } \beta = 1:n_1
\]
\[
j = (\beta - 1)v_L + 1:\beta v_L
\]
\[
y(i) = y(i) + A(i, j)x(j)
\]
\[
\text{end}
\]
\[
\text{end}
\]

Again, each column of submatrix \( A(i, j) \) must be read but the only writing to memory involves subvectors of \( y \). Thus, the number of vector touches for an \( m \times n \) gaxpy is

\[
\sum_{\alpha=1}^{m_1} \left( 2 + \sum_{\beta=1}^{n_1} (1 + v_L) \right) \approx m_1 n .
\]

This is half the number required by an identically-sized the outer product. Thus, if a computation can be arranged in terms of either outer products or gaxyps, then the former is preferable from the vector touch standpoint.
1.4.7 Blocking and Re-Use

A cache is a small high-speed memory situated in between the functional units and main memory. See Fig. 1.4.3. Cache utilization colors performance because it has a direct bearing upon how data flows in between the functional units and the lower levels of memory.

To illustrate this we consider the computation of the matrix multiply update \( C = AB + C \) where \( A, B, C \in \mathbb{R}^{n \times n} \) reside in main memory\(^2\). All data must pass through the cache on its way to the functional units where the floating point computations are carried out. If the cache is small and \( n \) is big, then the update must be broken down into smaller parts so that the cache can "gracefully" process the flow of data.

One strategy is to block the \( B \) and \( C \) matrices,

\[
B = \begin{bmatrix} B_1 & \cdots & B_N \end{bmatrix} \quad C = \begin{bmatrix} C_1 & \cdots & C_N \end{bmatrix}
\]

where we assume that \( n = \ell N \). From the expansion

\[
C_\alpha = AB_\alpha + C_\alpha = \sum_{k=1}^{n} A(:, k)B_\alpha(k,:) + C_\alpha
\]

we obtain the following computational framework:

for \( \alpha = 1:N \)

Load \( B_\alpha \) and \( C_\alpha \) into cache.

for \( k = 1:n \)

Load \( A(:, k) \) into cache and update \( C_\alpha \):

\[
C_\alpha = A(:, k)B_\alpha(k,:) + C_\alpha
\]

end

Store \( C_\alpha \) in main memory.
end

Note that if \( M \) is the cache size measured in floating point words, then we must have

\[
2n\ell + n \leq M.
\] (1.4.1)

Let \( \Gamma_1 \) be the number of floating point numbers that flow (in either direction) between cache and main memory. Note that every entry in \( B \) is loaded into cache once, every entry in \( C \) is loaded into cache once and stored back in main memory once, and every entry in \( A \) is loaded into cache \( N = n/\ell \) times. It follows that

\[
\Gamma_1 = 3n^2 + \frac{n^2}{\ell}.
\]

\(^2\)The discussion which follows would also apply if the matrices were on a disk and needed to be brought into main memory.
In the interest of keeping data motion to a minimum, we choose $\ell$ to be as large as possible subject to the constraint (1.4.1). We therefore set

$$\ell \approx \frac{1}{2} \left( \frac{M}{n} - 1 \right)$$

obtaining

$$\Gamma_1 \approx 3n^2 + \frac{2n^4}{M-n}.$$  

(We use "$\approx$" to emphasize the approximate nature of our analysis.) If cache is large enough to house the entire $B$ and $C$ matrices with room left over for a column of $A$, then $\ell = n$ and $\Gamma_1 = 4n^2$. At the other extreme, if we can just fit three columns in cache, then $\ell = 1$ and $\Gamma_1 \approx n^3$.

Now let us regard $A = (A_{\alpha\beta})$, $B = (B_{\alpha\beta})$, and $C = (C_{\alpha\beta})$ as $N$-by-$N$ block matrices with uniform block size $\ell = n/N$. With this blocking the computation of

$$C_{\alpha\beta} = \sum_{\gamma=1}^{N} A_{\alpha\gamma} B_{\gamma\beta} \quad \alpha = 1:N, \beta = 1:N$$

can be arranged as follows:

for $\alpha = 1:N$

for $\beta = 1:N$

Load $C_{\alpha\beta}$ into cache.

for $\gamma = 1:N$

Load $A_{\alpha\gamma}$ and $B_{\gamma\beta}$ into cache.

$$C_{\alpha\beta} = C_{\alpha\beta} + A_{\alpha\gamma} B_{\gamma\beta}$$

end

Store $C_{\alpha\beta}$ in main memory.

end

end

In this case the main memory/cache traffic sums to

$$\Gamma_2 = 2n^2 + \frac{2n^3}{\ell}$$

because each entry in $A$ and $B$ is loaded $N = n/\ell$ times and each entry in $C$ is loaded once and stored once. We can minimize this by choosing $\ell$ to be as large as possible subject to the constraint that three blocks fit in cache, i.e.,

$$3\ell^2 \leq M$$

Setting $\ell \approx \sqrt{M/3}$ gives

$$\Gamma_2 \approx 2n^2 + 2n^3 \sqrt{\frac{3}{M}}.$$
A manipulation shows that

\[ \frac{\Gamma_1}{\Gamma_2} \approx \frac{3n^2 + \frac{2n^4}{M} - n}{2n^2 + 2n^3 \sqrt{\frac{3}{M}}} \geq \frac{3 + 2\frac{n^2}{M}}{2 + 2\sqrt{3} \sqrt{\frac{n^2}{M}}} . \]

The key quantity here is \( n^2/M \), the ratio of matrix size (in floating point words) to cache size. As this ratio grows the we find that

\[ \frac{\Gamma_1}{\Gamma_2} \approx \frac{n}{\sqrt{3M}} \]

showing that the second blocking strategy is superior from the standpoint of data motion to and from the cache. The fundamental conclusion to be reached from all of this is that blocking effects data motion.

1.4.8 Block Matrix Data Structures

We conclude this section with a discussion about block data structures. A programming language that supports two-dimensional arrays must have a convention for storing such a structure in memory. For example, Fortran stores two-dimensional arrays in column major order. This means that the entries within a column are contiguous in memory. Thus, if 24 storage locations are allocated for \( A \in \mathbb{R}^{4 \times 6} \), then in traditional store-by-column format the matrix entries are "lined up" in memory as depicted in Fig. 1.4.4. In other words, if \( A \in \mathbb{R}^{m \times n} \) is stored in \( v(1:mn) \), then we identify

![Diagram of matrix storage](image)

**Fig. 1.4.4 Store by Column (4-by-6 case)**

\( A(i,j) \) with \( v((j - 1)m + i) \). For algorithms that access matrix data by column this is a good arrangement since the column entries are contiguous in memory.
In certain block matrix algorithms it is sometimes useful to store matrices by blocks rather than by column. Suppose, for example, that the matrix $A$ above is a 2-by-3 block matrix with 2-by-2 blocks. In a store-by-column block scheme with store-by-column within each block, the 24 entries are arranged in memory as shown in Fig. 1.4.5. This data structure can be attractive for block algorithms because the entries within a given block are contiguous in memory.

Problems

P1.4.1 Consider the matrix product $D = ABC$ where $A \in \mathbb{R}^{m \times r}$, $B \in \mathbb{R}^{r \times n}$ and $C \in \mathbb{R}^{n \times q}$. Assume that all the matrices are stored by column and that the time required to execute a unit-stride saxpy operation of length $k$ is of the form $t(k) = (L + k)\mu$ where $L$ is a constant and $\mu$ is the cycle time. Based on this model, when is it more economical to compute $D$ as $D = (AB)C$ instead of as $D = A(BC)$? Assume that all matrix multiplies are done using the jki, (gaxpy) algorithm.

P1.4.2 What is the total time spent in jki variant on the saxpy operations assuming that all the matrices are stored by column and that the time required to execute a unit-stride saxpy operation of length $k$ is of the form $t(k) = (L + k)\mu$ where $L$ is a constant and $\mu$ is the cycle time? Specialize the algorithm so that it efficiently handles the case when $A$ and $B$ are $n$-by-$n$ and upper triangular. Does it follow that the triangular implementation is six times faster as the flop count suggests?

P1.4.3 Give an algorithm for computing $C = A^TBA$ where $A$ and $B$ are $n$-by-$n$ and $B$ is symmetric. Arrays should be accessed in unit stride fashion within all innermost loops.

P1.4.4 Suppose $A \in \mathbb{R}^{m \times n}$ is stored by column in $A.col(1:mn)$. Assume that $m = \ell_1 M$
and $n = \ell_2 N$ and that we regard $A$ as an $M$-by-$N$ block matrix with $\ell_1$-by-$\ell_2$ blocks. Given $i, j, \alpha,$ and $\beta$ that satisfy $1 \leq i \leq \ell_1$, $1 \leq j \leq \ell_2$, $1 \leq \alpha \leq M$, and $1 \leq \beta \leq N$ determine $k$ so that $A_{i,j}\alpha\beta$ houses the $(i,j)$ entry of $A_{\alpha\beta}$. Give an algorithm that overwrites $A_{i,j}\alpha\beta$ with $A$ stored by block as in Figure 1.4.5. How big of a work array is required?

Matrix Analysis

§2.1 Basic Ideas from Linear Algebra
§2.2 Vector Norms
§2.3 Matrix Norms
§2.4 Finite Precision Matrix Computations
§2.5 Orthogonality and the SVD
§2.6 Projections and the CS Decomposition
§2.7 The Sensitivity of Square Linear Systems

The analysis and derivation of algorithms in the matrix computation area requires a facility with certain aspects of linear algebra. Some of the basics are reviewed in §2.1. Norms and their manipulation are covered in §2.2 and §2.3. In §2.4 we develop a model of finite precision arithmetic and then use it in a typical roundoff analysis.

The next two sections deal with orthogonality, which has a prominent role to play in matrix computations. The singular value decomposition and the CS decomposition are a pair of orthogonal reductions that provide critical insight into the important notions of rank and distance between subspaces. In §2.7 we examine how the solution of a linear system $Ax = b$ changes if $A$ and $b$ are perturbed. The important concept of matrix condition is introduced.

Before You Begin

References that complement this chapter include Forsythe and Moler (1967), Stewart (1973), Stewart and Sun (1990), and Higham (1996).

2.1 Basic Ideas from Linear Algebra

This section is a quick review of linear algebra. Readers who wish a more detailed coverage should consult the references at the end of the section.
2.1.1 Independence, Subspace, Basis, and Dimension

A set of vectors \( \{a_1, \ldots, a_n\} \) in \( \mathbb{R}^m \) is linearly independent if \( \sum_{j=1}^{n} \alpha_j a_j = 0 \) implies \( \alpha(1:n) = 0 \). Otherwise, a nontrivial combination of the \( a_i \) is zero and \( \{a_1, \ldots, a_n\} \) is said to be linearly dependent.

A subspace of \( \mathbb{R}^m \) is a subset that is also a vector space. Given a collection of vectors \( a_1, \ldots, a_n \in \mathbb{R}^m \), the set of all linear combinations of these vectors is a subspace referred to as the span of \( \{a_1, \ldots, a_n\} \):

\[
\text{span}\{a_1, \ldots, a_n\} = \left\{ \sum_{j=1}^{n} \beta_j a_j : \beta_j \in \mathbb{R} \right\}.
\]

If \( \{a_1, \ldots, a_n\} \) is independent and \( b \in \text{span}\{a_1, \ldots, a_n\} \), then \( b \) is a unique linear combination of the \( a_j \).

If \( S_1, \ldots, S_k \) are subspaces of \( \mathbb{R}^m \), then their sum is the subspace defined by \( S = \{a_1 + a_2 + \cdots + a_k : a_i \in S_i, i = 1:k\} \). \( S \) is said to be a direct sum if each \( v \in S \) has a unique representation \( v = a_1 + \cdots + a_k \) with \( a_i \in S_i \). In this case we write \( S = S_1 \oplus \cdots \oplus S_k \). The intersection of the \( S_i \) is also a subspace, \( S = S_1 \cap S_2 \cap \cdots \cap S_k \).

The subset \( \{a_{i_1}, \ldots, a_{i_k}\} \) is a maximal linearly independent subset of \( \{a_1, \ldots, a_n\} \) if it is linearly independent and is not properly contained in any linearly independent subset of \( \{a_1, \ldots, a_n\} \). If \( \{a_{i_1}, \ldots, a_{i_k}\} \) is maximal, then \( \text{span}\{a_1, \ldots, a_n\} = \text{span}\{a_{i_1}, \ldots, a_{i_k}\} \) and \( \{a_{i_1}, \ldots, a_{i_k}\} \) is a basis for \( \text{span}\{a_1, \ldots, a_n\} \). If \( S \subseteq \mathbb{R}^m \) is a subspace, then it is possible to find independent basic vectors \( a_1, \ldots, a_k \in S \) such that \( S = \text{span}\{a_1, \ldots, a_k\} \).

All bases for a subspace \( S \) have the same number of elements. This number is the dimension and is denoted by \( \text{dim}(S) \).

2.1.2 Range, Null Space, and Rank

There are two important subspaces associated with an \( m \times n \) matrix \( A \). The range of \( A \) is defined by

\[
\text{ran}(A) = \{y \in \mathbb{R}^m : y = Ax \text{ for some } x \in \mathbb{R}^n\},
\]

and the null space of \( A \) is defined by

\[
\text{null}(A) = \{x \in \mathbb{R}^n : Ax = 0\}.
\]

If \( A = [a_1, \ldots, a_n] \) is a column partitioning, then

\[
\text{ran}(A) = \text{span}\{a_1, \ldots, a_n\}.
\]

The rank of a matrix \( A \) is defined by

\[
\text{rank}(A) = \text{dim}(\text{ran}(A)).
\]

It can be shown that \( \text{rank}(A) = \text{rank}(A^T) \). We say that \( A \in \mathbb{R}^{m \times n} \) is rank deficient if \( \text{rank}(A) < \min\{m, n\} \). If \( A \in \mathbb{R}^{m \times n} \), then

\[
\text{dim}(\text{null}(A)) + \text{rank}(A) = n.
\]
2.1.3 Matrix Inverse

The \( n \)-by-\( n \) identity matrix \( I_n \) is defined by the column partitioning

\[
I_n = [e_1, \ldots, e_n]
\]

where \( e_k \) is the \( k \)th "canonical" vector:

\[
e_k = (0, \ldots, 0, 1, 0, \ldots, 0)^T.
\]

The canonical vectors arise frequently in matrix analysis and if their dimension is ever ambiguous, we use superscripts, i.e., \( e_k^{(n)} \in \mathbb{R}^n \).

If \( A \) and \( X \) are in \( \mathbb{R}^{n \times n} \) and satisfy \( AX = I \), then \( X \) is the inverse of \( A \) and is denoted by \( A^{-1} \). If \( A^{-1} \) exists, then \( A \) is said to be nonsingular. Otherwise, we say \( A \) is singular.

Several matrix inverse properties have an important role to play in matrix computations. The inverse of a product is the reverse product of the inverses:

\[
(AB)^{-1} = B^{-1}A^{-1}.
\] (2.1.1)

The transpose of the inverse is the inverse of the transpose:

\[
(A^{-1})^T = (A^T)^{-1} \equiv A^{-T}.
\] (2.1.2)

The identity

\[
B^{-1} = A^{-1} - B^{-1}(B - A)A^{-1}
\] (2.1.3)

shows how the inverse changes if the matrix changes.

The Sherman-Morrison-Woodbury formula gives a convenient expression for the inverse of \((A + UV^T)\) where \( A \in \mathbb{R}^{n \times n} \) and \( U \) and \( V \) are \( n \)-by-\( k \):

\[
(A + UV^T)^{-1} = A^{-1} - A^{-1}U(I + V^TA^{-1}U)^{-1}V^TA^{-1}.
\] (2.1.4)

A rank \( k \) correction to a matrix results in a rank \( k \) correction of the inverse. In (2.1.4) we assume that both \( A \) and \( (I + V^TA^{-1}U) \) are nonsingular.

Any of these facts can be verified by just showing that the "proposed" inverse does the job. For example, here is how to confirm (2.1.3):

\[
B \left(A^{-1} - B^{-1}(B - A)A^{-1}\right) = BA^{-1} - (B - A)A^{-1} = I.
\]

2.1.4 The Determinant

If \( A = (a) \in \mathbb{R}^{1 \times 1} \), then its determinant is given by \( \det(A) = a \). The determinant of \( A \in \mathbb{R}^{n \times n} \) is defined in terms of order \( n - 1 \) determinants:

\[
\det(A) = \sum_{j=1}^{n} (-1)^{j+1} a_{1j} \det(A_{1j}).
\]
Here, $A_{ij}$ is an $(n-1)$-by-$(n-1)$ matrix obtained by deleting the first row and $j$th column of $A$. Useful properties of the determinant include

$$
\begin{align*}
\det(AB) &= \det(A)\det(B), & A, B \in \mathbb{R}^{n \times n} \\
\det(A^T) &= \det(A), & A \in \mathbb{R}^{n \times n} \\
\det(cA) &= c^n\det(A), & c \in \mathbb{R}, A \in \mathbb{R}^{n \times n} \\
\det(A) \neq 0 \iff A \text{ is nonsingular} & A \in \mathbb{R}^{n \times n}
\end{align*}
$$

### 2.1.5 Differentiation

Suppose $\alpha$ is a scalar and that $A(\alpha)$ is an $m$-by-$n$ matrix with entries $a_{ij}(\alpha)$. If $a_{ij}(\alpha)$ is a differentiable function of $\alpha$ for all $i$ and $j$, then by $\dot{A}(\alpha)$ we mean the matrix

$$
\dot{A}(\alpha) = \frac{d}{d\alpha} A(\alpha) = \left( \frac{d}{d\alpha} a_{ij}(\alpha) \right) = (\dot{a}_{ij}(\alpha)).
$$

The differentiation of a parameterized matrix turns out to be a handy way to examine the sensitivity of various matrix problems.

### Problems

**P2.1.1** Show that if $A \in \mathbb{R}^{m \times n}$ has rank $p$, then there exists an $X \in \mathbb{R}^{m \times p}$ and a $Y \in \mathbb{R}^{n \times p}$ such that $A = XY^T$, where rank$(X) = \text{rank}(Y) = p$.

**P2.1.2** Suppose $A(\alpha) \in \mathbb{R}^{m \times n}$ and $B(\alpha) \in \mathbb{R}^{n \times n}$ are matrices whose entries are differentiable functions of the scalar $\alpha$. Show

$$
\frac{d}{d\alpha} [A(\alpha)B(\alpha)] = \left[ \frac{d}{d\alpha} A(\alpha) \right] B(\alpha) + A(\alpha) \left[ \frac{d}{d\alpha} B(\alpha) \right].
$$

**P2.1.3** Suppose $A(\alpha) \in \mathbb{R}^{n \times n}$ has entries that are differentiable functions of the scalar $\alpha$. Assuming $A(\alpha)$ is always nonsingular, show

$$
\frac{d}{d\alpha} [A(\alpha)^{-1}] = -A(\alpha)^{-1} \left[ \frac{d}{d\alpha} A(\alpha) \right] A(\alpha)^{-1}.
$$

**P2.1.4** Suppose $A \in \mathbb{R}^{n \times n}$, $b \in \mathbb{R}^n$ and that $\phi(x) = \frac{1}{2}x^T A x - x^T b$. Show that the gradient of $\phi$ is given by $\nabla \phi(x) = \frac{1}{2}(A^T + A)x - b$.

**P2.1.5** Assume that both $A$ and $A+uv^T$ are nonsingular where $A \in \mathbb{R}^{n \times n}$ and $u, v \in \mathbb{R}$. Show that if $x$ solves $(A+uv^T)x = b$, then it also solves a perturbed right hand side problem of the form $Ax = b+c\alpha u$. Give an expression for $\alpha$ in terms of $A$, $u$, and $v$.

### Notes and References for Sec. 2.1

There are many introductory linear algebra texts. Among them, the following are particularly useful:

2.2 Vector Norms

Norms serve the same purpose on vector spaces that absolute value does on the real line: they furnish a measure of distance. More precisely, \( \mathbb{R}^n \) together with a norm on \( \mathbb{R}^n \) defines a metric space. Therefore, we have the familiar notions of neighborhood, open sets, convergence, and continuity when working with vectors and vector-valued functions.

2.2.1 Definitions

A vector norm on \( \mathbb{R}^n \) is a function \( f: \mathbb{R}^n \rightarrow \mathbb{R} \) that satisfies the following properties:

\[
\begin{align*}
    f(x) & \geq 0 \quad x \in \mathbb{R}^n, \quad (f(x) = 0 \text{ iff } x = 0) \\
    f(x + y) & \leq f(x) + f(y) \quad x, y \in \mathbb{R}^n \\
    f(\alpha x) & = |\alpha| f(x) \quad \alpha \in \mathbb{R}, x \in \mathbb{R}^n
\end{align*}
\]

We denote such a function with a double bar notation: \( f(x) = \| x \| \). Subscripts on the double bar are used to distinguish between various norms.

A useful class of vector norms are the \( p \)-norms defined by

\[
\| x \|_p = (|x_1|^p + \cdots + |x_n|^p) ^{\frac{1}{p}} \quad p \geq 1.
\]

(2.2.1)

Of these the 1, 2, and \( \infty \) norms are the most important:

\[
\begin{align*}
    \| x \|_1 & = |x_1| + \cdots + |x_n| \\
    \| x \|_2 & = (|x_1|^2 + \cdots + |x_n|^2)^{\frac{1}{2}} = (x^T x)^{\frac{1}{2}} \\
    \| x \|_\infty & = \max_{1 \leq i \leq n} |x_i|
\end{align*}
\]
A unit vector with respect to the norm $\| \cdot \|$ is a vector $x$ that satisfies $\| x \| = 1$.

### 2.2.2 Some Vector Norm Properties

A classic result concerning $p$-norms is the **Holder inequality**:

$$|x^T y| \leq \| x \|_p \| y \|_q \quad \frac{1}{p} + \frac{1}{q} = 1. \quad (2.2.2)$$

A very important special case of this is the **Cauchy-Schwartz inequality**:

$$|x^T y| \leq \| x \|_2 \| y \|_2. \quad (2.2.3)$$

All norms on $\mathbb{R}^n$ are equivalent, i.e., if $\| \cdot \|_\alpha$ and $\| \cdot \|_\beta$ are norms on $\mathbb{R}^n$, then there exist positive constants, $c_1$ and $c_2$ such that

$$c_1 \| x \|_\alpha \leq \| x \|_\beta \leq c_2 \| x \|_\alpha \quad (2.2.4)$$

for all $x \in \mathbb{R}^n$. For example, if $x \in \mathbb{R}^n$, then

$$\| x \|_2 \leq \| x \|_1 \leq \sqrt{n} \| x \|_2 \quad (2.2.5)$$

$$\| x \|_\infty \leq \| x \|_2 \leq \sqrt{n} \| x \|_\infty \quad (2.2.6)$$

$$\| x \|_\infty \leq \| x \|_1 \leq n \| x \|_\infty. \quad (2.2.7)$$

### 2.2.3 Absolute and Relative Error

Suppose $\hat{x} \in \mathbb{R}^n$ is an approximation to $x \in \mathbb{R}^n$. For a given vector norm $\| \cdot \|$ we say that

$$\epsilon_{abs} = \| \hat{x} - x \|$$

is the **absolute error** in $\hat{x}$. If $x \neq 0$, then

$$\epsilon_{rel} = \frac{\| \hat{x} - x \|}{\| x \|}$$

prescribes the **relative error** in $\hat{x}$. Relative error in the $\infty$-norm can be translated into a statement about the number of correct significant digits in $\hat{x}$. In particular, if

$$\frac{\| \hat{x} - x \|_\infty}{\| x \|_\infty} \approx 10^{-p},$$

then the largest component of $\hat{x}$ has approximately $p$ correct significant digits.

**Example 2.2.1** If $x = (1.234, 0.05674)^T$ and $\hat{x} = (1.235, 0.05128)^T$, then $\| \hat{x} - x \|_\infty / \| x \|_\infty \approx 0.0043 \approx 10^{-3}$. Note that $\hat{x}_1$ has about three significant digits that are correct while only one significant digit in $\hat{x}_2$ is correct.
2.2.4 Convergence

We say that a sequence \( \{ x^{(k)} \} \) of \( n \)-vectors converges to \( x \) if

\[
\lim_{k \to \infty} \| x^{(k)} - x \| = 0.
\]

Note that because of (2.2.4), convergence in the \( \alpha \)-norm implies convergence in the \( \beta \)-norm and vice versa.

Problems

P2.2.1 Show that if \( x \in \mathbb{R}^n \), then \( \lim_{p \to \infty} \| x \|_p = \| x \|_\infty \).

P2.2.2 Prove the Cauchy-Schwartz inequality (2.2.3) by considering the inequality

\[
0 \leq (ax + by)^T (ax + by) \text{ for suitable scalars } a \text{ and } b.
\]

P2.2.3 Verify that \( \| \cdot \|_1, \| \cdot \|_2, \text{ and } \| \cdot \|_\infty \) are vector norms.

P2.2.4 Verify (2.2.5)-(2.2.7). When is equality achieved in each result?

P2.2.5 Show that in \( \mathbb{R}^n \), \( x^{(i)} \to x \) if and only if \( x_h^{(i)} \to x_h \) for \( k = 1:n \).

P2.2.6 Show that any vector norm on \( \mathbb{R}^n \) is uniformly continuous by verifying the inequality

\[
\| x \| - \| y \| \leq \| x - y \|.
\]

P2.2.7 Let \( \| \cdot \| \) be a vector norm on \( \mathbb{R}^n \) and assume \( A \in \mathbb{R}^{m \times n} \). Show that if \( \operatorname{rank}(A) = n \), then \( \| x \|_A = \| Ax \| \) is a vector norm on \( \mathbb{R}^n \).

P2.2.8 Let \( x \) and \( y \) be in \( \mathbb{R}^n \) and define \( \psi: \mathbb{R} \to \mathbb{R} \) by \( \psi(\alpha) = \| x - \alpha y \|_2 \). Show that \( \psi \) is minimized when \( \alpha = x^Ty/y^Ty \).

P2.2.9 (a) Verify that \( \| x \|_p = (|x_1|^p + \cdots + |x_n|^p)^{1/p} \) is a vector norm on \( \mathbb{C}^n \). (b) Show that if \( x \in \mathbb{C}^n \) then \( \| x \|_p \leq c \left( \| \operatorname{Re}(x) \|_p + \| \operatorname{Im}(x) \|_p \right) \). (c) Find a constant \( c_n \) such that \( c_n (\| \operatorname{Re}(x) \|_2 + \| \operatorname{Im}(x) \|_2) \leq \| x \|_2 \) for all \( x \in \mathbb{C}^n \).

P2.2.10 Prove or disprove:

\[
u \in \mathbb{R}^n \Rightarrow \| v \|_1 \| v \|_\infty \leq \frac{1 + \sqrt{n}}{2} \| v \|_2.
\]

Notes and References for Sec. 2.2

Although a vector norm is "just" a generalization of the absolute value concept, there are some noteworthy subtleties:

2.3 Matrix Norms

The analysis of matrix algorithms frequently requires use of matrix norms. For example, the quality of a linear system solver may be poor if the matrix of coefficients is "nearly singular." To quantify the notion of near-singularity we need a measure of distance on the space of matrices. Matrix norms provide that measure.
2.3.1 Definitions

Since $\mathbb{R}^{m \times n}$ is isomorphic to $\mathbb{R}^{mn}$, the definition of a matrix norm should be equivalent to the definition of a vector norm. In particular, $f: \mathbb{R}^{m \times n} \to \mathbb{R}$ is a matrix norm if the following three properties hold:

\[
\begin{align*}
f(A) & \geq 0 & A & \in \mathbb{R}^{m \times n}, & (f(A) = 0 \text{ iff } A = 0) \\
f(A + B) & \leq f(A) + f(B) & A, B & \in \mathbb{R}^{m \times n}, \\
f(\alpha A) & = |\alpha| f(A) & \alpha & \in \mathbb{R}, A & \in \mathbb{R}^{m \times n}.
\end{align*}
\]

As with vector norms, we use a double bar notation with subscripts to designate matrix norms, i.e., $\| A \| = f(A)$.

The most frequently used matrix norms in numerical linear algebra are the Frobenius norm,

\[
\| A \|_F = \sqrt{\sum_{i=1}^{m} \sum_{j=1}^{n} |a_{ij}|^2} \quad (2.3.1)
\]

and the $p$-norms

\[
\| A \|_p = \sup_{x \neq 0} \frac{\| Ax \|_p}{\| x \|_p}. \quad (2.3.2)
\]

Note that the matrix $p$-norms are defined in terms of the vector $p$-norms that we discussed in the previous section. The verification that (2.3.1) and (2.3.2) are matrix norms is left as an exercise. It is clear that $\| A \|_p$ is the $p$-norm of the largest vector obtained by applying $A$ to a unit $p$-norm vector:

\[
\| A \|_p = \sup_{x \neq 0} \left\| A \left( \frac{x}{\| x \|_p} \right) \right\|_p = \max_{\| x \|_p = 1} \| Ax \|_p.
\]

It is important to understand that (2.3.1) and (2.3.2) define families of norms—the 2-norm on $\mathbb{R}^{3 \times 2}$ is a different function from the 2-norm on $\mathbb{R}^{5 \times 6}$. Thus, the easily verified inequality

\[
\| AB \|_p \leq \| A \|_p \| B \|_p \quad A \in \mathbb{R}^{m \times n}, B \in \mathbb{R}^{n \times q} \quad (2.3.3)
\]

is really an observation about the relationship between three different norms. Formally, we say that norms $f_1$, $f_2$, and $f_3$ on $\mathbb{R}^{m \times q}$, $\mathbb{R}^{m \times n}$, and $\mathbb{R}^{n \times q}$ are mutually consistent if for all $A \in \mathbb{R}^{m \times n}$ and $B \in \mathbb{R}^{n \times q}$ we have $f_1(AB) \leq f_2(A)f_3(B)$.

Not all matrix norms satisfy the submultiplicative property

\[
\| AB \| \leq \| A \| \| B \|. \quad (2.3.4)
\]
For example, if \( \| A \|_\Delta = \max |a_{ij}| \) and

\[
A = B = \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix},
\]

then \( \| AB \|_\Delta > \| A \|_\Delta \| B \|_\Delta \). For the most part we work with norms that satisfy (2.3.4).

The \( p \)-norms have the important property that for every \( A \in \mathbb{R}^{m \times n} \) and \( x \in \mathbb{R}^{n} \) we have \( \| Ax \|_p \leq \| A \|_p \| x \|_p \). More generally, for any vector norm \( \| \cdot \|_\alpha \) on \( \mathbb{R}^{n} \) and \( \| \cdot \|_\beta \) on \( \mathbb{R}^{m} \) we have \( \| Ax \|_\beta \leq \| A \|_{\alpha, \beta} \| x \|_\alpha \) where \( \| A \|_{\alpha, \beta} \) is a matrix norm defined by

\[
\| A \|_{\alpha, \beta} = \sup_{x \neq 0} \frac{\| Ax \|_\beta}{\| x \|_\alpha}. \tag{2.3.5}
\]

We say that \( \| \cdot \|_{\alpha, \beta} \) is subordinate to the vector norms \( \| \cdot \|_\alpha \) and \( \| \cdot \|_\beta \).

Since the set \( \{ x \in \mathbb{R}^{n} : \| x \|_\alpha = 1 \} \) is compact and \( \| \cdot \|_\beta \) is continuous, it follows that

\[
\| A \|_{\alpha, \beta} = \max_{\| x \|_\alpha = 1} \| Ax \|_\beta = \| Ax^* \|_\beta \tag{2.3.6}
\]

for some \( x^* \in \mathbb{R}^{n} \) having unit \( \alpha \)-norm.

### 2.3.2 Some Matrix Norm Properties

The Frobenius and \( p \)-norms (especially \( p = 1, 2, \infty \)) satisfy certain inequalities that are frequently used in the analysis of matrix computations. For \( A \in \mathbb{R}^{m \times n} \) we have

\[
\| A \|_2 \leq \| A \|_F \leq \sqrt{n} \| A \|_2 \tag{2.3.7}
\]

\[
\max_{i,j} |a_{ij}| \leq \| A \|_2 \leq \sqrt{mn} \max_{i,j} |a_{ij}| \tag{2.3.8}
\]

\[
\| A \|_1 = \max_{1 \leq i \leq n} \sum_{j=1}^{m} |a_{ij}| \tag{2.3.9}
\]

\[
\| A \|_\infty = \max_{1 \leq i \leq m} \sum_{j=1}^{n} |a_{ij}| \tag{2.3.10}
\]

\[
\frac{1}{\sqrt{n}} \| A \|_\infty \leq \| A \|_2 \leq \sqrt{m} \| A \|_\infty \tag{2.3.11}
\]

\[
\frac{1}{\sqrt{m}} \| A \|_1 \leq \| A \|_2 \leq \sqrt{n} \| A \|_1 \tag{2.3.12}
\]
If $A \in \mathbb{R}^{m \times n}$, $1 \leq i_1 \leq i_2 \leq m$, and $1 \leq j_1 \leq j_2 \leq n$, then
\[
\| A(i_1:i_2,j_1:j_2) \|_p \leq \| A \|_p
\] (2.3.13)

The proofs of these relations are not hard and are left as exercises.

A sequence $\{A^{(k)}\} \in \mathbb{R}^{m \times n}$ converges if $\lim_{k \to \infty} \| A^{(k)} - A \| = 0$. Choice of norm is irrelevant since all norms on $\mathbb{R}^{m \times n}$ are equivalent.

### 2.3.3 The Matrix 2-Norm

A nice feature of the matrix 1-norm and the matrix $\infty$-norm is that they are easily computed from (2.3.9) and (2.3.10). A characterization of the 2-norm is considerably more complicated.

**Theorem 2.3.1** If $A \in \mathbb{R}^{m \times n}$, then there exists a unit 2-norm $n$-vector $z$ such that $A^T A z = \mu^2 z$ where $\mu = \| A \|_2$.

**Proof.** Suppose $z \in \mathbb{R}^n$ is a unit vector such that $\| A z \|_2 = \| A \|_2$. Since $z$ maximizes the function
\[
g(x) = \frac{1}{2} \frac{\| A x \|_2^2}{\| x \|_2^2} = \frac{1}{2} \frac{x^T A^T A x}{x^T x}
\]
it follows that it satisfies $\nabla g(z) = 0$ where $\nabla g$ is the gradient of $g$. But a tedious differentiation shows that for $i = 1:n$
\[
\frac{\partial g(z)}{\partial z_i} = \left[ (z^T z) \sum_{j=1}^n (A^T A)_{ij} z_j - (z^T A^T A z)_i \right] / (z^T z)^2.
\]
In vector notation this says $A^T A z = (z^T A^T A z) z$. The theorem follows by setting $\mu = \| A z \|_2$. $\square$

The theorem implies that $\| A \|_2^2$ is a zero of the polynomial $p(\lambda) = \det(A^T A - \lambda I)$. In particular, the 2-norm of $A$ is the square root of the largest eigenvalue of $A^T A$. We have much more to say about eigenvalues in Chapters 7 and 8. For now, we merely observe that 2-norm computation is iterative and decidedly more complicated than the computation of the matrix 1-norm or $\infty$-norm. Fortunately, if the object is to obtain an order-of-magnitude estimate of $\| A \|_2$, then (2.3.7), (2.3.11), or (2.3.12) can be used.

As another example of "norm analysis," here is a handy result for 2-norm estimation.

**Corollary 2.3.2** If $A \in \mathbb{R}^{m \times n}$, then $\| A \|_2 \leq \sqrt{\| A \|_1 \| A \|_\infty}$.

**Proof.** If $z \neq 0$ is such that $A^T A z = \mu^2 z$ with $\mu = \| A \|_2$, then $\mu^2 \| z \|_1 = \| A^T A z \|_1 \leq \| A^T \|_1 \| A \|_1 \| z \|_1 = \| A \|_\infty \| A \|_1 \| z \|_1$. $\square$
2.3.4 Perturbations and the Inverse

We frequently use norms to quantify the effect of perturbations or to prove that a sequence of matrices converges to a specified limit. As an illustration of these norm applications, let us quantify the change in $A^{-1}$ as a function of change in $A$.

**Lemma 2.3.3** If $F \in \mathbb{R}^{n \times n}$ and $\| F \|_p < 1$, then $I - F$ is nonsingular and

$$(I - F)^{-1} = \sum_{k=0}^{\infty} F^k$$

with

$$\| (I - F)^{-1} \|_p \leq \frac{1}{1 - \| F \|_p}.$$  

**Proof.** Suppose $I - F$ is singular. It follows that $(I - F)x = 0$ for some nonzero $x$. But then $\| x \|_p = \| Fx \|_p$ implies $\| F \|_p \geq 1$, a contradiction. Thus, $I - F$ is nonsingular. To obtain an expression for its inverse consider the identity

$$(\sum_{k=0}^{N} F^k)(I - F) = I - F^{N+1}.$$  

Since $\| F \|_p < 1$ it follows that $\lim_{k \to \infty} F^k = 0$ because $\| F^k \|_p \leq \| F \|_p^k$. Thus,

$$(\lim_{N \to \infty} \sum_{k=0}^{N} F^k)(I - F) = I.$$  

It follows that $(I - F)^{-1} = \lim_{N \to \infty} \sum_{k=0}^{N} F^k$. From this it is easy to show that

$$\| (I - F)^{-1} \|_p \leq \sum_{k=0}^{\infty} \| F \|_p^k = \frac{1}{1 - \| F \|_p}. \quad \Box$$

Note that $\| (I - F)^{-1} - I \|_p \leq \| F \|_p/(1 - \| F \|_p)$ as a consequence of the lemma. Thus, if $\varepsilon \ll 1$, then $O(\varepsilon)$ perturbations in $I$ induce $O(\varepsilon)$ perturbations in the inverse. We next extend this result to general matrices.

**Theorem 2.3.4** If $A$ is nonsingular and $r = \| A^{-1} E \|_p < 1$, then $A + E$ is nonsingular and $\| (A + E)^{-1} - A^{-1} \|_p \leq \| E \|_p \| A^{-1} \|_p^2/(1 - r)$.

**Proof.** Since $A$ is nonsingular $A + E = A(I - F)$ where $F = -A^{-1} E$. Since $\| F \|_p = r < 1$ it follows from Lemma 2.3.3 that $I - F$ is nonsingular and $\| (I - F)^{-1} \|_p < 1/(1 - r)$. Now $(A + E)^{-1} = (I - F)^{-1} A^{-1}$ and so

$$\| (A + E)^{-1} \|_p \leq \frac{\| A^{-1} \|_p}{1 - r}.$$
Equation (2.1.3) says that \((A + E)^{-1} - A^{-1} = -A^{-1}E(A + E)^{-1}\) and so by taking norms we find

\[
\| (A + E)^{-1} - A^{-1} \|_p \leq \| A^{-1} \|_p \| E \|_p \| (A + E)^{-1} \|_p \\
\leq \frac{\| A^{-1} \|_p^2 \| E \|_p}{1 - r}.
\]

Problems

P2.3.1 Show \(\| AB \|_p \leq \| A \|_p \| B \|_p\) where \(1 \leq p \leq \infty\).

P2.3.2 Let \(B\) be any submatrix of \(A\). Show that \(\| B \|_p \leq \| A \|_p\).

P2.3.3 Show that if \(D = \text{diag}(\mu_1, \ldots, \mu_k) \in \mathbb{R}^{m \times n}\) with \(k = \min\{m, n\}\), then \(\| D \|_p = \max |\mu_i|\).

P2.3.4 Verify (2.3.7) and (2.3.8).

P2.3.5 Verify (2.3.9) and (2.3.10).

P2.3.6 Verify (2.3.11) and (2.3.12).

P2.3.7 Verify (2.3.13).

P2.3.8 Show that if \(0 \neq s \in \mathbb{R}^n\) and \(E \in \mathbb{R}^{n \times n}\), then

\[
\left\| E \left( I - \frac{ss^T}{s^Ts} \right) \right\|_F^2 = \| E \|_F^2 - \frac{\| Es \|_2^2}{s^Ts}.
\]

P2.3.9 Suppose \(u \in \mathbb{R}^m\) and \(v \in \mathbb{R}^n\). Show that if \(E = uv^T\) then \(\| E \|_F = \| E \|_2 = \| u \|_2 \| v \|_2\) and that \(\| E \|_\infty \leq \| u \|_\infty \| v \|_1\).

P2.3.10 Suppose \(A \in \mathbb{R}^{m \times n}\), \(y \in \mathbb{R}^m\), and \(0 \neq s \in \mathbb{R}^n\). Show that \(E = (y - As)s^T/s^Ts\) has the smallest 2-norm of all \(m\)-by-\(n\) matrices \(E\) that satisfy \((A + E)s = y\).

Notes and References for Sec. 2.3

For deeper issues concerning matrix/vector norms, see

2.4 Finite Precision Matrix Computations

In part, rounding errors are what makes the matrix computation area so nontrivial and interesting. In this section we set up a model of floating point arithmetic and then use it to develop error bounds for floating point dot products, saxpy's, matrix-vector products and matrix-matrix products. For
a more comprehensive treatment than what we offer, see Higham (1996) or Wilkinson (1965). The coverage in Forsythe and Moler (1967) and Stewart (1973) is also excellent.

2.4.1 The Floating Point Numbers

When calculations are performed on a computer, each arithmetic operation is generally affected by roundoff error. This error arises because the machine hardware can only represent a subset of the real numbers. We denote this subset by F and refer to its elements as floating point numbers. Following conventions set forth in Forsythe, Malcolm, and Moler (1977, pp. 10-29), the floating point number system on a particular computer is characterized by four integers: the base $\beta$, the precision $t$, and the exponent range $[L, U]$. In particular, $F$ consists of all numbers $f$ of the form

$$f = \pm.d_1d_2\ldots d_t \times \beta^e \quad 0 \leq d_i < \beta, \quad d_1 \neq 0, \quad L \leq e \leq U$$

together with zero. Notice that for a nonzero $f \in F$ we have $m \leq |f| \leq M$ where

$$m = \beta^{L-1} \quad \text{and} \quad M = \beta^U (1 - \beta^{-t}). \quad (2.4.1)$$

As an example, if $\beta = 2$, $t = 3$, $L = 0$, and $U = 2$, then the non-negative elements of $F$ are represented by hash marks on the axis displayed in Fig. 2.4.1. Notice that the floating point numbers are not equally spaced. A

![Sample Floating Point Number System](image)

**Figure 2.4.1 Sample Floating Point Number System**

typical value for $(\beta, t, L, U)$ might be $(2, 56, -64, 64)$.

2.4.2 A Model of Floating Point Arithmetic

To make general pronouncements about the effect of rounding errors on a given algorithm, it is necessary to have a model of computer arithmetic on $F$. To this end define the set $G$ by

$$G = \{ x \in \mathbb{R} : m \leq |x| \leq M \} \cup \{0\} \quad (2.4.2)$$
and the operator $fl: G \rightarrow F$ by

$$fl(x) = \begin{cases} \text{nearest } c \in F \text{ to } x \text{ with ties handled} \\ \text{by rounding away from zero.} \end{cases}$$

The $fl$ operator can be shown to satisfy

$$fl(x) = x(1 + \epsilon) \quad |\epsilon| \leq u$$

where $u$ is the unit roundoff defined by

$$u = \frac{1}{2} \beta^{1-t}.$$ (2.4.4)

Let $a$ and $b$ be any two floating point numbers and let "op" denote any of the four arithmetic operations $+, -, \times, \div$. If $a \text{ op } b \in G$, then in our model of floating point arithmetic we assume that the computed version of $(a \text{ op } b)$ is given by $fl(a \text{ op } b)$. It follows that $fl(a \text{ op } b) = (a \text{ op } b)(1 + \epsilon)$ with $|\epsilon| \leq u$. Thus,

$$\frac{|fl(a \text{ op } b) - (a \text{ op } b)|}{|a \text{ op } b|} \leq u \quad a \text{ op } b \neq 0$$

(2.4.5)

showing that there is small relative error associated with individual arithmetic operations\(^1\). It is important to realize, however, that this is not necessarily the case when a sequence of operations is involved.

Example 2.4.1 If $\beta = 10$, $t = 3$ floating point arithmetic is used, then it can be shown that $fl(fl(10^{-4} + 1) - 1) = 0$ implying a relative error of 1. On the other hand the exact answer is given by $fl(fl(10^{-4} + fl(1 - 1)) = 10^{-4}$. Floating point arithmetic is not always associative.

If $a \text{ op } b \notin G$, then an arithmetic exception occurs. Overflow and underflow results whenever $|a \text{ op } b| > M$ or $0 < |a \text{ op } b| < m$ respectively. The handling of these and other exceptions is hardware/system dependent.

2.4.3 Cancellation

Another important aspect of finite precision arithmetic is the phenomenon of catastrophic cancellation. Roughly speaking, this term refers to the extreme loss of correct significant digits when small numbers are additively computed from large numbers. A well-known example taken from Forsythe, Malcolm and Moler (1977, pp. 14-16) is the computation of $e^{-a}$ via Taylor series with $a > 0$. The roundoff error associated with this method is

\(^1\)There are important examples of machines whose additive floating point operations satisfy $fl(a \pm b) = (1 + \epsilon_1)a \pm (1 + \epsilon_2)b$ where $|\epsilon_1|, |\epsilon_2| \leq u$. In such an environment, the inequality $|fl(a \pm b) - (a \pm b)| \leq u|a \pm b|$ need not hold.
approximately $u$ times the largest partial sum. For large $a$, this error can actually be larger than the exact exponential and there will be no correct digits in the answer no matter how many terms in the series are summed. On the other hand, if enough terms in the Taylor series for $e^a$ are added and the result reciprocated, then an estimate of $e^{-a}$ to full precision is attained.

### 2.4.4 The Absolute Value Notation

Before we proceed with the roundoff analysis of some basic matrix calculations, we acquire some useful notation. Suppose $A \in \mathbb{R}^{m \times n}$ and that we wish to quantify the errors associated with its floating point representation. Denoting the stored version of $A$ by $fl(A)$, we see that

$$[fl(A)]_{ij} = fl(a_{ij}) = a_{ij}(1 + \epsilon_{ij}) \quad |\epsilon_{ij}| \leq u$$  \hspace{1cm} (2.4.6)

for all $i$ and $j$. A better way to say the same thing results if we adopt two conventions. If $A$ and $B$ are in $\mathbb{R}^{m \times n}$, then

$$B = |A| \Rightarrow b_{ij} = |a_{ij}|, \quad i = 1:m, \quad j = 1:n$$

$$B \leq A \Rightarrow b_{ij} \leq a_{ij}, \quad i = 1:m, \quad j = 1:n.$$  

With this notation we see that (2.4.6) has the form

$$|fl(A) - A| \leq u|A|.$$  

A relation such as this can be easily turned into a norm inequality, e.g.,

$$\|fl(A) - A\|_1 \leq u\|A\|_1.$$  

However, when quantifying the rounding errors in a matrix manipulation, the absolute value notation can be a lot more informative because it provides a comment on each $(i,j)$ entry.

### 2.4.5 Roundoff in Dot Products

We begin our study of finite precision matrix computations by considering the rounding errors that result in the standard dot product algorithm:

$$s = 0$$

for $k = 1:n$

$$s = s + x_k y_k$$  \hspace{1cm} (2.4.7)

end

Here, $x$ and $y$ are $n$-by-1 floating point vectors.

In trying to quantify the rounding errors in this algorithm, we are immediately confronted with a notational problem: the distinction between computed and exact quantities. When the underlying computations are clear, we shall use the $fl(\cdot)$ operator to signify computed quantities.
Thus, \( fl(x^T y) \) denotes the computed output of (2.4.7). Let us bound 
\[ |fl(x^T y) - x^T y| \]. If
\[
s_p = fl\left( \sum_{k=1}^{p} x_k y_k \right),
\]
then \( s_1 = x_1 y_1 (1 + \delta_1) \) with \( |\delta_1| \leq u \) and for \( p = 2:n \)
\[
s_p = fl(s_{p-1} + fl(x_p y_p))
\]
\[
= (s_{p-1} + x_p y_p (1 + \delta_p)) (1 + \epsilon_p) \quad |\delta_p|, |\epsilon_p| \leq u. \quad (2.4.8)
\]
A little algebra shows that
\[
fl(x^T y) = s_n = \sum_{k=1}^{n} x_k y_k (1 + \gamma_k)
\]
where
\[
(1 + \gamma_k) = (1 + \delta_k) \prod_{j=k}^{n} (1 + \epsilon_j)
\]
with the convention that \( \epsilon_1 = 0 \). Thus,
\[
|fl(x^T y) - x^T y| \leq \sum_{k=1}^{n} |x_k y_k||\gamma_k|.
\quad (2.4.9)
\]
To proceed further, we must bound the quantities \( |\gamma_k| \) in terms of \( u \). The following result is useful for this purpose.

**Lemma 2.4.1** If \( (1 + \alpha) = \prod_{k=1}^{n} (1 + \alpha_k) \) where \( |\alpha_k| \leq u \) and \( nu \leq .01 \), then \( |\alpha| \leq 1.01nu \).

**Proof.** See Higham (1996, p. 75). \( \square \)

Applying this result to (2.4.9) under the "reasonable" assumption \( nu \leq .01 \) gives
\[
|fl(x^T y) - x^T y| \leq 1.01nu|x^T y|.
\quad (2.4.10)
\]
Notice that if \( |x^T y| \ll |x^T |y| \), then the relative error in \( fl(x^T y) \) may not be small.

### 2.4.6 Alternative Ways to Quantify Roundoff Error

An easier but less rigorous way of bounding \( \alpha \) in Lemma 2.4.1 is to say
\( |\alpha| \leq nu + O(u^2) \). With this convention we have
\[
|fl(x^T y) - x^T y| \leq nu|x^T |y| + O(u^2).
\quad (2.4.11)
\]
Other ways of expressing the same result include

\[ |f(x^T y) - x^T y| \leq \phi(n)u|x|^T|y| \]  \hspace{1cm} (2.4.12)

and

\[ |f(x^T y) - x^T y| \leq cnu|x|^T|y|, \]  \hspace{1cm} (2.4.13)

where in (2.4.12) \( \phi(n) \) is a "modest" function of \( n \) and in (2.4.13) \( c \) is a constant of order unity.

We shall not express a preference for any of the error bounding styles shown in (2.4.10)-(2.4.13). This spares us the necessity of translating the roundoff results that appear in the literature into a fixed format. Moreover, paying overly close attention to the details of an error bound is inconsistent with the "philosophy" of roundoff analysis. As Wilkinson (1971, p. 567) says,

There is still a tendency to attach too much importance to the precise error bounds obtained by an à priori error analysis. In my opinion, the bound itself is usually the least important part of it. The main object of such an analysis is to expose the potential instabilities, if any, of an algorithm so that hopefully from the insight thus obtained one might be led to improved algorithms. Usually the bound itself is weaker than it might have been because of the necessity of restricting the mass of detail to a reasonable level and because of the limitations imposed by expressing the errors in terms of matrix norms. À priori bounds are not, in general, quantities that should be used in practice. Practical error bounds should usually be determined by some form of à posteriori error analysis, since this takes full advantage of the statistical distribution of rounding errors and of any special features, such as sparseness, in the matrix.

It is important to keep these perspectives in mind.

### 2.4.7 Dot Product Accumulation

Some computers have provision for accumulating dot products in double precision. This means that if \( x \) and \( y \) are floating point vectors with length \( t \) mantissas, then the running sum \( s \) in (2.4.7) is built up in a register with a \( 2t \) digit mantissa. Since the multiplication of two \( t \)-digit floating point numbers can be stored exactly in a double precision variable, it is only when \( s \) is written to single precision memory that any roundoff occurs. In this situation one can usually assert that a computed dot product has good relative error, i.e., \( f(x^T y) = x^T y(1 + \delta) \) where \( |\delta| \approx u \). Thus, the ability to accumulate dot products is very appealing.
2.4.8 Roundoff in Other Basic Matrix Computations

It is easy to show that if $A$ and $B$ are floating point matrices and $\alpha$ is a floating point number, then

$$fl(\alpha A) = \alpha A + E \quad |E| \leq u|\alpha A|$$

(2.4.14)

and

$$fl(A + B) = (A + B) + E \quad |E| \leq u|A + B|.$$  (2.4.15)

As a consequence of these two results, it is easy to verify that computed saxpy's and outer product updates satisfy

$$fl(\alpha x + y) = \alpha x + y + z \quad |z| \leq u(2|\alpha x| + |y|) + O(u^2)$$  (2.4.16)

$$fl(C + uv^T) = C + uv^T + E \quad |E| \leq u(|C| + 2|uv^T|) + O(u^2).$$  (2.4.17)

Using (2.4.10) it is easy to show that a dot product based multiplication of two floating point matrices $A$ and $B$ satisfies

$$fl(AB) = AB + E \quad |E| \leq nu|A||B| + O(u^2).$$  (2.4.18)

The same result applies if a gaxpy or outer product based procedure is used. Notice that matrix multiplication does not necessarily give small relative error since $|AB|$ may be much smaller than $|A||B|$, e.g.,

$$
\begin{bmatrix}
1 & 1 \\
0 & 0
\end{bmatrix}
\begin{bmatrix}
1 & 0 \\
-.99 & 0
\end{bmatrix}
= 
\begin{bmatrix}
.01 & 0 \\
0 & 0
\end{bmatrix}.
$$

It is easy to obtain norm bounds from the roundoff results developed thus far. If we look at the 1-norm error in floating point matrix multiplication, then it is easy to show from (2.4.18) that

$$\|fl(AB) - AB\|_1 \leq nu\|A\|_1\|B\|_1 + O(u^2).$$  (2.4.19)

2.4.9 Forward and Backward Error Analyses

Each roundoff bound given above is the consequence of a forward error analysis. An alternative style of characterizing the roundoff errors in an algorithm is accomplished through a technique known as backward error analysis. Here, the rounding errors are related to the data of the problem rather than to its solution. By way of illustration, consider the $n = 2$ version of triangular matrix multiplication. It can be shown that:

$$fl(AB) = 
\begin{bmatrix}
a_{11}b_{11}(1 + \varepsilon_1) & (a_{11}b_{12}(1 + \varepsilon_2) + a_{12}b_{22}(1 + \varepsilon_3))(1 + \varepsilon_4) \\
0 & a_{22}b_{22}(1 + \varepsilon_5)
\end{bmatrix}$$
where $|\epsilon_i| \leq u$, for $i = 1:5$. However, if we define

$$
\hat{A} = \begin{bmatrix}
a_{11} & a_{12}(1 + \epsilon_3)(1 + \epsilon_4) \\
0 & a_{22}(1 + \epsilon_5)
\end{bmatrix}
$$

and

$$
\hat{B} = \begin{bmatrix}
b_{11}(1 + \epsilon_1) & b_{12}(1 + \epsilon_2)(1 + \epsilon_4) \\
0 & b_{22}
\end{bmatrix},
$$

then it is easily verified that $fl(AB) = \hat{A}\hat{B}$. Moreover,

$$
\hat{A} = A + E \quad |E| \leq 2u|A| + O(u^2)
$$

$$
\hat{B} = B + F \quad |F| \leq 2u|B| + O(u^2).
$$

In other words, the computed product is the exact product of slightly perturbed $A$ and $B$.

### 2.4.10 Error in Strassen Multiplication

In §1.3.8 we outlined an unconventional matrix multiplication procedure due to Strassen (1969). It is instructive to compare the effect of roundoff in this method with the effect of roundoff in any of the conventional matrix multiplication methods of §1.1.

It can be shown that the Strassen approach (Algorithm 1.3.1) produces a $\hat{C} = fl(AB)$ that satisfies an inequality of the form (2.4.19). This is perfectly satisfactory in many applications. However, the $\hat{C}$ that Strassen's method produces does not always satisfy an inequality of the form (2.4.18). To see this, suppose

$$
A = B = \begin{bmatrix}
.99 & .0010 \\
.0010 & .99
\end{bmatrix}
$$

and that we execute Algorithm 1.3.1 using 2-digit floating point arithmetic. Among other things, the following quantities are computed:

$$
\hat{P}_3 = fl(.99(.001 - .99)) = -.98
$$

$$
\hat{P}_5 = fl((.99 + .001).99) = .98
$$

$$
\hat{c}_{12} = fl(\hat{P}_3 + \hat{P}_5) = 0.0
$$

Now in exact arithmetic $c_{12} = 2(.001)(.99) = .00198$ and thus Algorithm 1.3.1 produces a $\hat{c}_{12}$ with no correct significant digits. The Strassen approach gets into trouble in this example because small off-diagonal entries are combined with large diagonal entries. Note that in conventional matrix multiplication neither $b_{12}$ and $b_{22}$ nor $a_{11}$ and $a_{12}$ are summed. Thus the contribution of
the small off-diagonal elements is not lost. Indeed, for the above $A$ and $B$ a conventional matrix multiply gives $\tilde{c}_{12} = .0020$.

Failure to produce a componentwise accurate $\tilde{C}$ can be a serious shortcoming in some applications. For example, in Markov processes the $a_{ij}$, $b_{ij}$, and $c_{ij}$ are transition probabilities and are therefore nonnegative. It may be critical to compute $c_{ij}$ accurately if it reflects a particularly important probability in the modeled phenomena. Note that if $A \geq 0$ and $B \geq 0$, then conventional matrix multiplication produces a product $\tilde{C}$ that has small componentwise relative error:

$$|\tilde{C} - C| \leq nu|A||B| + O(u^2) = nu|C| + O(u^2).$$

This follows from (2.4.18). Because we cannot say the same for the Strassen approach, we conclude that Algorithm 1.3.1 is not attractive for certain nonnegative matrix multiplication problems if relatively accurate $\tilde{c}_{ij}$ are required.

Extrapolating from this discussion we reach two fairly obvious but important conclusions:

- Different methods for computing the same quantity can produce substantially different results.
- Whether or not an algorithm produces satisfactory results depends upon the type of problem solved and the goals of the user.

These observations are clarified in subsequent chapters and are intimately related to the concepts of algorithm stability and problem condition.

Problems

P2.4.1 Show that if (2.4.7) is applied with $y = x$, then $fl(x^T x) = x^T x(1 + \alpha)$ where $|\alpha| \leq nu + O(u^2)$.

P2.4.2 Prove (2.4.3).

P2.4.3 Show that if $E \in \mathbb{R}^{m \times n}$ with $m \geq n$, then $\|E\|_2 \leq \sqrt{n}\|E\|_2$. This result is useful when deriving norm bounds from absolute value bounds.

P2.4.4 Assume the existence of a square root function satisfying $fl(\sqrt{x}) = \sqrt{x}(1 + \epsilon)$ with $|\epsilon| \leq u$. Give an algorithm for computing $\|x\|_2$ and bound the rounding errors.

P2.4.5 Suppose $A$ and $B$ are $n$-by-$n$ upper triangular floating point matrices. If $\tilde{C} = fl(AB)$ is computed using one of the conventional §1.1 algorithms, does it follow that $\tilde{C} = \tilde{A}\tilde{B}$ where $\tilde{A}$ and $\tilde{B}$ are close to $A$ and $B$?

P2.4.6 Suppose $A$ and $B$ are $n$-by-$n$ floating point matrices and that $A$ is nonsingular with $\|A^{-1}\|_2 A \|_2 = r$. Show that if $\tilde{C} = fl(AB)$ is obtained using any of the algorithms in §1.1, then there exists a $\tilde{B}$ so $\tilde{C} = A\tilde{B}$ and $\|\tilde{B} - B\|_\infty \leq nu \tau \|B\|_\infty + O(u^2)$.

P2.4.7 Prove (2.4.18).
Notes and References for Sec. 2.4

For a general introduction to the effects of roundoff error, we recommend

More recent developments in error analysis involve interval analysis, the building of statistical models of roundoff error, and the automating of the analysis itself:

Anyone engaged in serious software development needs a thorough understanding of floating point arithmetic. A good way to begin acquiring knowledge in this direction is to read about the IEEE floating point standard in

The subtleties associated with the development of high-quality software, even for "simple" problems, are immense. A good example is the design of a subroutine to compute 2-norms

For an analysis of the Strassen algorithm and other "fast" linear algebra procedures see
2.5 Orthogonality and the SVD

Orthogonality has a very prominent role to play in matrix computations. After establishing a few definitions we prove the extremely useful singular value decomposition (SVD). Among other things, the SVD enables us to intelligently handle the matrix rank problem. The concept of rank, though perfectly clear in the exact arithmetic context, is tricky in the presence of roundoff error and fuzzy data. With the SVD we can introduce the practical notion of numerical rank.

2.5.1 Orthogonality

A set of vectors \( \{x_1, \ldots, x_p\} \) in \( \mathbb{R}^m \) is orthogonal if \( x_i^T x_j = 0 \) whenever \( i \neq j \) and orthonormal if \( x_i^T x_j = \delta_{ij} \). Intuitively, orthogonal vectors are maximally independent for they point in totally different directions.

A collection of subspaces \( S_1, \ldots, S_p \) in \( \mathbb{R}^m \) is mutually orthogonal if \( x^T y = 0 \) whenever \( x \in S_i \) and \( y \in S_j \) for \( i \neq j \). The orthogonal complement of a subspace \( S \subseteq \mathbb{R}^m \) is defined by

\[
S^\perp = \{ y \in \mathbb{R}^m : y^T x = 0 \text{ for all } x \in S \}
\]

and it is not hard to show that \( \text{ran}(A)^\perp = \text{null}(A^T) \). The vectors \( v_1, \ldots, v_k \) form an orthonormal basis for a subspace \( S \subseteq \mathbb{R}^m \) if they are orthonormal and span \( S \).

A matrix \( Q \in \mathbb{R}^{m \times m} \) is said to be orthogonal if \( Q^T Q = I \). If \( Q = [q_1, \ldots, q_m] \) is orthogonal, then the \( q_i \) form an orthonormal basis for \( \mathbb{R}^m \).

It is always possible to extend such a basis to a full orthonormal basis \( \{v_1, \ldots, v_m\} \) for \( \mathbb{R}^m \):

**Theorem 2.5.1** If \( V_1 \in \mathbb{R}^{n \times r} \) has orthonormal columns, then there exists \( V_2 \in \mathbb{R}^{n \times (n-r)} \) such that

\[
V = [V_1 \ V_2]
\]

is orthogonal. Note that \( \text{ran}(V_1)^\perp = \text{ran}(V_2) \).

**Proof.** This is a standard result from introductory linear algebra. It is also a corollary of the QR factorization that we present in §5.2. □
2.5.2 Norms and Orthogonal Transformations

The 2-norm is invariant under orthogonal transformation, for if $Q^TQ = I$, then $\|Qx\|_2^2 = x^TQ^TQx = x^Tx = \|x\|_2^2$. The matrix 2-norm and the Frobenius norm are also invariant with respect to orthogonal transformations. In particular, it is easy to show that for all orthogonal $Q$ and $Z$ of appropriate dimensions we have

$$\|QAZ\|_F = \|A\|_F$$ \hspace{1cm} (2.5.1)

and

$$\|QAZ\|_2 = \|A\|_2.$$ \hspace{1cm} (2.5.2)

2.5.3 The Singular Value Decomposition

The theory of norms developed in the previous two sections can be used to prove the extremely useful singular value decomposition.

Theorem 2.5.2 (Singular Value Decomposition (SVD)) If $A$ is a real $m$-by-$n$ matrix, then there exist orthogonal matrices

$$U = [u_1, \ldots, u_m] \in \mathbb{R}^{m \times m} \quad \text{and} \quad V = [v_1, \ldots, v_n] \in \mathbb{R}^{n \times n}$$

such that

$${U^T}AV = \text{diag}(\sigma_1, \ldots, \sigma_p) \in \mathbb{R}^{m \times n} \quad p = \min\{m, n\}$$

where $\sigma_1 \geq \sigma_2 \geq \ldots \geq \sigma_p \geq 0$.

Proof. Let $x \in \mathbb{R}^m$ and $y \in \mathbb{R}^n$ be unit 2-norm vectors that satisfy $Ax = \sigma y$ with $\sigma = \|A\|_2$. From Theorem 2.5.1 there exist $V_2 \in \mathbb{R}^{n \times (n-1)}$ and $U_2 \in \mathbb{R}^{m \times (m-1)}$ so $V = [x \ V_2] \in \mathbb{R}^{m \times n}$ and $U = [y \ U_2] \in \mathbb{R}^{m \times m}$ are orthogonal. It is not hard to show that $U^TAV$ has the following structure:

$${U^T}AV = \begin{bmatrix} \sigma & w^T \\ 0 & B \end{bmatrix} \equiv A_1.$$ 

Since

$$\left\|A_1 \left( \begin{bmatrix} \sigma \\ w \end{bmatrix} \right) \right\|_2^2 \geq (\sigma^2 + w^Tw)^2$$

we have $\|A_1\|_2^2 \geq (\sigma^2 + w^Tw)$. But $\sigma^2 = \|A\|_2^2 = \|A_1\|_2^2$, and so we must have $w = 0$. An obvious induction argument completes the proof of the theorem. □

The $\sigma_i$ are the singular values of $A$ and the vectors $u_i$ and $v_i$ are the $i$th left singular vector and the $i$th right singular vector respectively. It
is easy to verify by comparing columns in the equations \( AV = U\Sigma \) and \( A^T U = V\Sigma^T \) that

\[
\begin{align*}
A v_i &= \sigma_i u_i \\
A^T u_i &= \sigma_i v_i
\end{align*}
\]

\( i = 1: \min\{m, n\} \)

It is convenient to have the following notation for designating singular values:

\[
\begin{align*}
\sigma_i(A) &= \text{the } i\text{th largest singular value of } A, \\
\sigma_{\max}(A) &= \text{the largest singular value of } A, \\
\sigma_{\min}(A) &= \text{the smallest singular value of } A.
\end{align*}
\]

The singular values of a matrix \( A \) are precisely the lengths of the semi-axes of the hyperellipsoid \( E \) defined by \( E = \{ Ax : \| x \|_2 = 1 \} \).

**Example 2.5.1**

\[
A = \begin{bmatrix}
0.96 & 1.72 \\
2.28 & 0.96
\end{bmatrix} = U\Sigma V^T = \begin{bmatrix}
0.6 & -0.8 \\
0.8 & 0.6
\end{bmatrix} \begin{bmatrix}
3 & 0 \\
0 & 1
\end{bmatrix} \begin{bmatrix}
0.6 & -0.8
\end{bmatrix}.
\]

The SVD reveals a great deal about the structure of a matrix. If the SVD of \( A \) is given by Theorem 2.5.2, and we define \( r \) by

\[
\sigma_1 \geq \cdots \geq \sigma_r > \sigma_{r+1} = \cdots = \sigma_p = 0,
\]

then

\[
\begin{align*}
\text{rank}(A) &= r \\
\text{null}(A) &= \text{span}\{v_{r+1}, \ldots, v_n\} \\
\text{ran}(A) &= \text{span}\{u_1, \ldots, u_r\},
\end{align*}
\]

and we have the SVD expansion

\[
A = \sum_{i=1}^{r} \sigma_i u_i v_i^T.
\]

Various 2-norm and Frobenius norm properties have connections to the SVD. If \( A \in \mathbb{R}^{m \times n} \), then

\[
\begin{align*}
\| A \|_F^2 &= \sigma_1^2 + \cdots + \sigma_p^2 \\
\| A \|_2 &= \sigma_1 \\
\min_{x \neq 0} \frac{\| Ax \|_2}{\| x \|_2} &= \sigma_n
\end{align*}
\]

\( p = \min\{m, n\} \)

\( m \geq n \).
2.5.4 The Thin SVD

If \( A = U \Sigma V^T \in \mathbb{R}^{m \times n} \) is the SVD of \( A \) and \( m \geq n \), then

\[
A = U_1 \Sigma_1 V^T
\]

where

\[
U_1 = U(:, 1:n) = [u_1, \ldots, u_n] \in \mathbb{R}^{m \times n}
\]

and

\[
\Sigma_1 = \Sigma(1:n, 1:n) = \text{diag}(\sigma_1, \ldots, \sigma_n) \in \mathbb{R}^{n \times n}.
\]

We refer to this much-used, trimmed down version of the SVD as the thin SVD.

2.5.5 Rank Deficiency and the SVD

One of the most valuable aspects of the SVD is that it enables us to deal sensibly with the concept of matrix rank. Numerous theorems in linear algebra have the form “if such-and-such a matrix has full rank, then such-and-such a property holds.” While neat and aesthetic, results of this flavor do not help us address the numerical difficulties frequently encountered in situations where near rank deficiency prevails. Rounding errors and fuzzy data make rank determination a nontrivial exercise. Indeed, for some small \( \epsilon \) we may be interested in the \( \epsilon \)-rank of a matrix which we define by

\[
\text{rank}(A, \epsilon) = \min_{\| A - B \|_2 \leq \epsilon} \text{rank}(B).
\]

Thus, if \( A \) is obtained in a laboratory with each \( a_{ij} \) correct to within \( \pm 0.001 \), then it might make sense to look at rank(\( A, .001 \)). Along the same lines, if \( A \) is an \( m \)-by-\( n \) floating point matrix then it is reasonable to regard \( A \) as numerically rank deficient if rank(\( A, \epsilon \)) < \( \min \{m, n\} \) with \( \epsilon = u \| A \|_2 \).

Numerical rank deficiency and \( \epsilon \)-rank are nicely characterized in terms of the SVD because the singular values indicate how near a given matrix is to a matrix of lower rank.

Theorem 2.5.3 Let the SVD of \( A \in \mathbb{R}^{m \times n} \) be given by Theorem 2.5.2. If \( k < r = \text{rank}(A) \) and

\[
A_k = \sum_{i=1}^{k} \sigma_i u_i v_i^T,
\]

then

\[
\min_{\text{rank}(B)=k} \| A - B \|_2 = \| A - A_k \|_2 = \sigma_{k+1}.
\]
Proof. Since \( U^T A_k V = \text{diag}(\sigma_1, \ldots, \sigma_k, 0, \ldots, 0) \) it follows that \( \text{rank}(A_k) = k \) and that \( U^T (A - A_k) V = \text{diag}(0, \ldots, 0, \sigma_{k+1}, \ldots, \sigma_p) \) and so \( \| A - A_k \|_2 = \sigma_{k+1} \).

Now suppose \( \text{rank}(B) = k \) for some \( B \in \mathbb{R}^{m \times n} \). It follows that we can find orthonormal vectors \( x_1, \ldots, x_{n-k} \) so \( \text{null}(B) = \text{span}\{x_1, \ldots, x_{n-k}\} \). A dimension argument shows that

\[
\text{span}\{x_1, \ldots, x_{n-k}\} \cap \text{span}\{v_1, \ldots, v_{k+1}\} \neq \{0\}.
\]

Let \( z \) be a unit 2-norm vector in this intersection. Since \( Bz = 0 \) and

\[
Ax = \sum_{i=1}^{k+1} \sigma_i(v_i^T z)u_i
\]

we have

\[
\| A - B \|_2^2 \geq \|(A - B)z\|_2^2 = \|Ax\|_2^2 = \sum_{i=1}^{k+1} \sigma_i^2(v_i^T z)^2 \geq \sigma_{k+1}^2
\]

completing the proof of the theorem. \( \square \)

Theorem 2.5.3 says that the smallest singular value of \( A \) is the 2-norm distance of \( A \) to the set of all rank-deficient matrices. It also follows that the set of full rank matrices in \( \mathbb{R}^{m \times n} \) is both open and dense.

Finally, if \( r_\varepsilon = \text{rank}(A, \varepsilon) \), then

\[
\sigma_1 \geq \cdots \geq \sigma_{r_\varepsilon} > \varepsilon \geq \sigma_{r_\varepsilon+1} \geq \cdots \geq \sigma_p \quad p = \min\{m, n\}.
\]

We have more to say about the numerical rank issue in §5.5 and §12.2.

2.5.6 Unitary Matrices

Over the complex field the unitary matrices correspond to the orthogonal matrices. In particular, \( Q \in \mathbb{C}^{m \times n} \) is unitary if \( Q^HQ = QQ^H = I_n \). Unitary matrices preserve 2-norm. The SVD of a complex matrix involves unitary matrices. If \( A \in \mathbb{C}^{m \times n} \), then there exist unitary matrices \( U \in \mathbb{C}^{m \times m} \) and \( V \in \mathbb{C}^{n \times n} \) such that

\[
U^H A V = \text{diag}(\sigma_1, \ldots, \sigma_p) \in \mathbb{R}^{m \times n} \quad p = \min\{m, n\}
\]

where \( \sigma_1 \geq \sigma_2 \geq \cdots \geq \sigma_p \geq 0. \)

Problems

P2.5.1 Show that if \( S \) is real and \( S^T = -S \), then \( I - S \) is nonsingular and the matrix \( (I - S)^{-1}(I + S) \) is orthogonal. This is known as the Cayley transform of \( S \).
P2.5.2 Show that a triangular orthogonal matrix is diagonal.

P2.5.3 Show that if \( Q = Q_1 + iQ_2 \) is unitary with \( Q_1, Q_2 \in \mathbb{R}^{n \times n} \), then the 2n-by-2n real matrix
\[
Z = \begin{bmatrix} Q_1 & -Q_2 \\ Q_2 & Q_1 \end{bmatrix}
\]
is orthogonal.

P2.5.4 Establish properties (2.5.3)-(2.5.9).

P2.5.5 Prove that
\[
\sigma_{\text{max}}(A) = \max_{y \in \mathbb{R}^n, x \in R^n} \frac{y^T A x}{\| x \|_2 \| y \|_2}
\]

P2.5.6 For the 2-by-2 matrix \( A = \begin{bmatrix} w & x \\ y & z \end{bmatrix} \), derive expressions for \( \sigma_{\text{max}}(A) \) and \( \sigma_{\text{min}}(A) \) that are functions of \( w, x, y, \) and \( z \).

P2.5.7 Show that any matrix in \( \mathbb{R}^{n \times n} \) is the limit of a sequence of full rank matrices.

P2.5.8 Show that if \( A \in \mathbb{R}^{m \times n} \) has rank \( n \), then \( \| A(A^T A)^{-1} A^T \|_2 = 1 \).

P2.5.9 What is the nearest rank-one matrix to \( A = \begin{bmatrix} 1 & M \\ 0 & 1 \end{bmatrix} \) in the Frobenius norm?

P2.5.10 Show that if \( A \in \mathbb{R}^{m \times n} \) then \( \| A \|_F \leq \sqrt{\text{rank}(A)} \| A \|_2 \), thereby sharpening (2.3.7).

Notes and References for Sec. 2.5

Forsythe and Moler (1967) offer a good account of the SVD’s role in the analysis of the \( Ax = b \) problem. Their proof of the decomposition is more traditional than ours in that it makes use of the eigenvalue theory for symmetric matrices. Historical SVD references include

One of the most significant developments in scientific computation has been the increased use of the SVD in application areas that require the intelligent handling of matrix rank. The range of applications is impressive. One of the most interesting is

For generalizations of the SVD to infinite dimensional Hilbert space, see

Reducing the rank of a matrix as in Theorem 2.5.3 when the perturbing matrix is constrained is discussed in

2.6 Projections and the CS Decomposition

If the object of a computation is to compute a matrix or a vector, then norms are useful for assessing the accuracy of the answer or for measuring progress during an iteration. If the object of a computation is to compute a subspace, then to make similar comments we need to be able to quantify the distance between two subspaces. Orthogonal projections are critical in this regard. After the elementary concepts are established we discuss the CS decomposition. This is an SVD-like decomposition that is handy when having to compare a pair of subspaces. We begin with the notion of an orthogonal projection.

2.6.1 Orthogonal Projections

Let $S \subseteq \mathbb{R}^n$ be a subspace. $P \in \mathbb{R}^{n \times n}$ is the orthogonal projection onto $S$ if $\text{ran}(P) = S$, $P^2 = P$, and $P^T = P$. From this definition it is easy to show that if $x \in \mathbb{R}^n$, then $Px \in S$ and $(I - P)x \in S^\perp$.

If $P_1$ and $P_2$ are each orthogonal projections, then for any $z \in \mathbb{R}^n$ we have

$$\| (P_1 - P_2)z \|^2 = (P_1 z)^T (I - P_2) z + (P_2 z)^T (I - P_1) z.$$  

If $\text{ran}(P_1) = \text{ran}(P_2) = S$, then the right-hand side of this expression is zero showing that the orthogonal projection for a subspace is unique. If the columns of $V = [v_1, \ldots, v_k]$ are an orthonormal basis for a subspace $S$, then it is easy to show that $P = VV^T$ is the unique orthogonal projection onto $S$. Note that if $v \in \mathbb{R}^n$, then $P = vv^T/vv^Tv$ is the orthogonal projection onto $S = \text{span}\{v\}$.

2.6.2 SVD-Related Projections

There are several important orthogonal projections associated with the singular value decomposition. Suppose $A = U\Sigma V^T \in \mathbb{R}^{m \times n}$ is the SVD of $A$ and that $r = \text{rank}(A)$. If we have the $U$ and $V$ partitionings

$$U = \begin{bmatrix} U_r & \bar{U}_r \end{bmatrix} \quad V = \begin{bmatrix} V_r & \bar{V}_r \end{bmatrix}$$

then

$$V_rV_r^T = \text{projection on to } \text{null}(A)^\perp = \text{ran}(A^T)$$

$$V_r\bar{V}_r^T = \text{projection on to } \text{null}(A)$$

$$U_rU_r^T = \text{projection on to } \text{ran}(A)$$

$$\bar{U}_r\bar{U}_r^T = \text{projection on to } \text{ran}(A)^\perp = \text{null}(A^T)$$

---

2.6.3 Distance Between Subspaces

The one-to-one correspondence between subspaces and orthogonal projections enables us to devise a notion of distance between subspaces. Suppose \( S_1 \) and \( S_2 \) are subspaces of \( \mathbb{R}^n \) and that \( \dim(S_1) = \dim(S_2) \). We define the distance between these two spaces by

\[
\text{dist}(S_1, S_2) = \| P_1 - P_2 \|_2 \quad (2.6.1)
\]

where \( P_i \) is the orthogonal projection onto \( S_i \). The distance between a pair of subspaces can be characterized in terms of the blocks of a certain orthogonal matrix.

Theorem 2.6.1 Suppose

\[
W = \begin{bmatrix} W_1 & W_2 \\ k & n-k \end{bmatrix} \quad Z = \begin{bmatrix} Z_1 & Z_2 \\ k & n-k \end{bmatrix}
\]

are \( n \)-by-\( n \) orthogonal matrices. If \( S_1 = \text{ran}(W_1) \) and \( S_2 = \text{ran}(Z_1) \), then

\[
\text{dist}(S_1, S_2) = \| W_1^T Z_2 \|_2 = \| Z_1^T W_2 \|_2.
\]

Proof.

\[
\text{dist}(S_1, S_2) = \| W_1 W_1^T - Z_1 Z_1^T \|_2 = \| W^T (W_1 W_1^T - Z_1 Z_1^T) Z \|_2
\]

\[
= \left\| \begin{bmatrix} 0 & W_1^T Z_2 \\ -W_2^T Z_1 & 0 \end{bmatrix} \right\|_2.
\]

Note that the matrices \( W_2^T Z_1 \) and \( W_1^T Z_2 \) are submatrices of the orthogonal matrix

\[
Q = \begin{bmatrix} Q_{11} & Q_{12} \\ Q_{21} & Q_{22} \end{bmatrix} = \begin{bmatrix} W_1^T Z_1 & W_1^T Z_2 \\ W_2^T Z_1 & W_2^T Z_2 \end{bmatrix} = W^T Z.
\]

Our goal is to show that \( \| Q_{21} \|_2 = \| Q_{12} \|_2 \). Since \( Q \) is orthogonal it follows from

\[
Q \begin{bmatrix} x \\ 0 \end{bmatrix} = \begin{bmatrix} Q_{11} x \\ Q_{21} x \end{bmatrix}
\]

that

\[
1 = \| Q_{11} x \|_2^2 + \| Q_{21} x \|_2^2
\]

for all unit 2-norm \( x \in \mathbb{R}^k \). Thus,

\[
\| Q_{21} \|_2^2 = \max_{\| x \|_2=1} \| Q_{21} x \|_2 = 1 - \min_{\| x \|_2=1} \| Q_{11} x \|_2^2
\]

\[
= 1 - \sigma_{\min}(Q_{11})^2.
\]
Analogously, by working with $Q^T$ (which is also orthogonal) it is possible to show that
\[\|Q_{12}^T\|_2^2 = 1 - \sigma_{\text{min}}(Q_{11})^2.\]
and therefore
\[\|Q_{12}\|_2^2 = 1 - \sigma_{\text{min}}(Q_{11})^2.\]
Thus, $\|Q_{21}\|_2 = \|Q_{12}\|_2$. $\square$

Note that if $S_1$ and $S_2$ are subspaces in $\mathbb{R}^n$ with the same dimension, then
\[0 \leq \text{dist}(S_1, S_2) \leq 1.
\]
The distance is zero if $S_1 = S_2$ and one if $S_1 \cap S_2^\perp \neq \{0\}$.

A more refined analysis of the blocks of the $Q$ matrix above sheds more light on the difference between a pair of subspaces. This requires a special SVD-like decomposition for orthogonal matrices.

### 2.6.4 The CS Decomposition

The blocks of an orthogonal matrix partitioned into 2-by-2 form have highly related SVDs. This is the gist of the \textit{CS decomposition}. We prove a very useful special case first.

**Theorem 2.6.2 (The CS Decomposition (Thin Version))** Consider the matrix
\[Q = \begin{bmatrix} Q_1 \\ Q_2 \end{bmatrix}, \quad Q_1 \in \mathbb{R}^{m_1 \times n}, Q_2 \in \mathbb{R}^{m_2 \times n}\]
where $m_1 \geq n$ and $m_2 \geq n$. If the columns of $Q$ are orthonormal, then there exist orthogonal matrices $U_1 \in \mathbb{R}^{m_1 \times m_1}$, $U_2 \in \mathbb{R}^{m_2 \times m_2}$, and $V_1 \in \mathbb{R}^{n \times n}$ such that
\[\begin{bmatrix} U_1 & 0 \\ 0 & U_2 \end{bmatrix}^T \begin{bmatrix} Q_1 \\ Q_2 \end{bmatrix} V_1 = \begin{bmatrix} C \\ S \end{bmatrix}\]
where
\[C = \text{diag}(\cos(\theta_1), \ldots, \cos(\theta_n)), \quad S = \text{diag}(\sin(\theta_1), \ldots, \sin(\theta_n)),\]
and
\[0 \leq \theta_1 \leq \theta_2 \leq \cdots \leq \theta_n \leq \frac{\pi}{2}.\]

**Proof.** Since $\|Q_{11}\|_2 \leq \|Q\|_2 = 1$, the singular values of $Q_{11}$ are all in the interval $[0, 1]$. Let
\[U_1^T Q_1 V_1 = C = \text{diag}(c_1, \ldots, c_n) = \begin{bmatrix} I_t & 0 \\ 0 & \Sigma \end{bmatrix} \begin{bmatrix} t \\ n-t \end{bmatrix} \quad \text{and} \quad m_1 - t\]
be the SVD of $Q_1$ where we assume
\[ 1 = c_1 = \cdots = c_t > c_{t+1} \geq \cdots \geq c_n \geq 0. \]
To complete the proof of the theorem we must construct the orthogonal matrix $U_2$. If
\[ Q_2 V_1 = \begin{bmatrix} W_1 & W_2 \end{bmatrix}_t \begin{bmatrix} \Sigma \end{bmatrix}_{n-t}, \]
then
\[ \begin{bmatrix} U_1 & 0 \\ 0 & I_{m_2} \end{bmatrix}^T \begin{bmatrix} Q_1 \\ Q_2 \end{bmatrix} V_1 = \begin{bmatrix} I_t & 0 \\ 0 & \Sigma \\ W_1 & W_2 \end{bmatrix}. \]
Since the columns of this matrix have unit 2-norm, $W_1 = 0$. The columns of $W_2$ are nonzero and mutually orthogonal because
\[ W_2^T W_2 = I_{n-t} - \Sigma^T \Sigma \equiv \text{diag}(1-c_{t+1}^2, \ldots, 1-c_n^2) \]
is nonsingular. If $s_k = \sqrt{1-c_k^2}$ for $k = 1:n$, then the columns of
\[ Z = W_2 \text{diag}(1/s_{t+1}, \ldots, 1/s_n) \]
are orthonormal. By Theorem 2.5.1 there exists an orthogonal matrix $U_2 \in \mathbb{R}^{m_2 \times m_2}$ with $U_2(:,t+1:n) = Z$. It is easy to verify that
\[ U_2^T Q_2 V_1 = \text{diag}(s_1, \ldots, s_n) \equiv S. \]
Since $c_k^2 + s_k^2 = 1$ for $k = 1:n$, it follows that these quantities are the required cosines and sines. □
Using the same sort of techniques it is possible to prove the following more general version of the decomposition:

Theorem 2.6.3 (CS Decomposition (General Version)) If
\[ Q = \begin{bmatrix} Q_{11} & Q_{12} \\ Q_{21} & Q_{22} \end{bmatrix} \]
is a 2-by-2 (arbitrary) partitioning of an $n$-by-$n$ orthogonal matrix, then there exist orthogonal
\[ U = \begin{bmatrix} U_1 & 0 \\ 0 & U_2 \end{bmatrix} \quad \text{and} \quad V = \begin{bmatrix} V_1 & 0 \\ 0 & V_2 \end{bmatrix} \]
such that
\[ U^T Q V = \begin{bmatrix} I & 0 & 0 & 0 & 0 & 0 \\ 0 & C & 0 & 0 & S & 0 \\ 0 & 0 & 0 & 0 & 0 & I \\ 0 & 0 & 0 & I & 0 & 0 \\ 0 & S & 0 & 0 & -C & 0 \\ 0 & 0 & I & 0 & 0 & 0 \end{bmatrix} \]
where \( C = \text{diag}(c_1, \ldots, c_p) \) and \( S = \text{diag}(s_1, \ldots, s_p) \) are square diagonal matrices with \( 0 < c_i, s_i < 1 \).

Proof. See Paige and Saunders (1981) for details. We have suppressed the dimensions of the zero submatrices, some of which may be empty. \( \square \)

The essential message of the decomposition is that the SVDs of the \( Q_{ij} \) are highly related.

Example 2.6.1 The matrix

\[
Q = \begin{bmatrix}
-0.7576 & 0.3697 & 0.3838 & 0.2126 & -0.3112 \\
-0.4077 & -0.1552 & -0.1129 & 0.2676 & 0.8517 \\
-0.0488 & 0.7240 & -0.6730 & -0.1301 & 0.0602 \\
-0.2287 & 0.0088 & 0.2235 & -0.9235 & 0.2120 \\
0.4530 & 0.5612 & 0.5806 & 0.1162 & 0.3595
\end{bmatrix}
\]

is orthogonal and with the indicated partitioning can be reduced to

\[
U^T Q V = \begin{bmatrix}
0.9837 & 0.0000 & 0.1800 & 0.0000 & 0.0000 \\
0.0000 & 0.6781 & 0.0000 & 0.7349 & 0.0000 \\
0.0000 & 0.0000 & 0.0000 & 0.0000 & 1.0000 \\
0.1800 & 0.0000 & -0.9837 & 0.0000 & 0.0000 \\
0.0000 & 0.7349 & 0.0000 & -0.6781 & 0.0000
\end{bmatrix}
\]

The angles associated with the cosines and sines turn out to be very important in a number of applications. See \S 12.4.

Problems

P2.6.1 Show that if \( P \) is an orthogonal projection, then \( Q = I - 2P \) is orthogonal.

P2.6.2 What are the singular values of an orthogonal projection?

P2.6.3 Suppose \( S_1 = \text{span}\{x\} \) and \( S_2 = \text{span}\{y\} \), where \( x \) and \( y \) are unit 2-norm vectors in \( \mathbb{R}^2 \). Working only with the definition of dist(\( \cdot \), \( \cdot \)), show that dist(\( S_1, S_2 \)) = \( \sqrt{1 - (x^T y)^2} \) verifying that the distance between \( S_1 \) and \( S_2 \) equals the sine of the angle between \( x \) and \( y \).

Notes and References for Sec. 2.6

The following papers discuss various aspects of the CS decomposition:

See §8.7 for some computational details.
For a deeper geometrical understanding of the CS decomposition and the notion of distance between subspaces, see

2.7 The Sensitivity of Square Systems

We now use some of the tools developed in previous sections to analyze the linear system problem $Ax = b$ where $A \in \mathbb{R}^{n \times n}$ is nonsingular and $b \in \mathbb{R}^n$. Our aim is to examine how perturbations in $A$ and $b$ affect the solution $x$. A much more detailed treatment may be found in Higham (1996).

2.7.1 An SVD Analysis

If

$$A = \sum_{i=1}^{n} \sigma_i u_i v_i^T = U \Sigma V^T$$

is the SVD of $A$, then

$$x = A^{-1}b = (U \Sigma V^T)^{-1}b = \sum_{i=1}^{n} \frac{u_i^T b}{\sigma_i} v_i.$$

(2.7.1)

This expansion shows that small changes in $A$ or $b$ can induce relatively large changes in $x$ if $\sigma_n$ is small.

It should come as no surprise that the magnitude of $\sigma_n$ should have a bearing on the sensitivity of the $Ax = b$ problem when we recall from Theorem 2.5.3 that $\sigma_n$ is the distance from $A$ to the set of singular matrices. As the matrix of coefficients approaches this set, it is intuitively clear that the solution $x$ should be increasingly sensitive to perturbations.

2.7.2 Condition

A precise measure of linear system sensitivity can be obtained by considering the parameterized system

$$(A + \epsilon F)x(\epsilon) = b + \epsilon f \quad x(0) = x$$

where $F \in \mathbb{R}^{n \times n}$ and $f \in \mathbb{R}^n$. If $A$ is nonsingular, then it is clear that $x(\epsilon)$ is differentiable in a neighborhood of zero. Moreover, $\dot{x}(0) = A^{-1}(f - Fx)$ and thus, the Taylor series expansion for $x(\epsilon)$ has the form

$$x(\epsilon) = x + \epsilon \dot{x}(0) + O(\epsilon^2).$$
Using any vector norm and consistent matrix norm we obtain
\[
\frac{\| x(\epsilon) - x \|}{\| x \|} \leq |\epsilon| \| A^{-1} \| \left( \frac{\| f \|}{\| x \|} + \| F \| \right) + O(\epsilon^2). \tag{2.7.2}
\]
For square matrices \( A \) define the condition number \( \kappa(A) \) by
\[
\kappa(A) = \| A \| \| A^{-1} \| \tag{2.7.3}
\]
with the convention that \( \kappa(A) = \infty \) for singular \( A \). Using the inequality \( \| b \| \leq \| A \| \| x \| \) it follows from (2.7.2) that
\[
\frac{\| x(\epsilon) - x \|}{\| x \|} \leq \kappa(A)(\rho_A + \rho_b) + O(\epsilon^2) \tag{2.7.4}
\]
where
\[
\rho_A = |\epsilon| \frac{\| F \|}{\| A \|} \quad \text{and} \quad \rho_b = |\epsilon| \frac{\| f \|}{\| b \|}
\]
represent the relative errors in \( A \) and \( b \), respectively. Thus, the relative error in \( x \) can be \( \kappa(A) \) times the relative error in \( A \) and \( b \). In this sense, the condition number \( \kappa(A) \) quantifies the sensitivity of the \( Ax = b \) problem.

Note that \( \kappa(\cdot) \) depends on the underlying norm and subscripts are used accordingly, e.g.,
\[
\kappa_2(A) = \| A \|_2 \| A^{-1} \|_2 = \frac{\sigma_1(A)}{\sigma_n(A)} \tag{2.7.5}
\]
Thus, the 2-norm condition of a matrix \( A \) measures the elongation of the hyperellipsoid \( \{ Ax : \| x \|_2 = 1 \} \).

We mention two other characterizations of the condition number. For \( p \)-norm condition numbers, we have
\[
\frac{1}{\kappa_p(A)} = \min_{A + \Delta A \text{ singular}} \frac{\| \Delta A \|_p}{\| A \|_p}. \tag{2.7.6}
\]
This result may be found in Kahan (1966) and shows that \( \kappa_p(A) \) measures the relative \( p \)-norm distance from \( A \) to the set of singular matrices.

For any norm, we also have
\[
\kappa(A) = \lim_{\epsilon \to 0} \sup_{\| \Delta A \| \leq \epsilon \| A \|} \frac{\| (A + \Delta A)^{-1} - A^{-1} \|}{\epsilon} \frac{1}{\| A^{-1} \|}. \tag{2.7.7}
\]
This imposing result merely says that the condition number is a normalized Frechet derivative of the map \( A \to A^{-1} \). Further details may be found in Rice (1966b). Recall that we were initially led to \( \kappa(A) \) through differentiation.
If \( \kappa(A) \) is large, then \( A \) is said to be an *ill-conditioned* matrix. Note that this is a norm-dependent property\(^2\). However, any two condition numbers \( \kappa_{\alpha}(\cdot) \) and \( \kappa_{\beta}(\cdot) \) on \( \mathbb{R}^{n \times n} \) are equivalent in that constants \( c_1 \) and \( c_2 \) can be found for which

\[
c_1 \kappa_{\alpha}(A) \leq \kappa_{\beta}(A) \leq c_2 \kappa_{\alpha}(A) \quad A \in \mathbb{R}^{n \times n}.
\]

For example, on \( \mathbb{R}^{n \times n} \) we have

\[
\frac{1}{n} \kappa_2(A) \leq \kappa_1(A) \leq n \kappa_2(A)
\]

\[
\frac{1}{n} \kappa_{\infty}(A) \leq \kappa_2(A) \leq n \kappa_{\infty}(A)
\]

\[ (2.7.8) \]

\[
\frac{1}{n^2} \kappa_1(A) \leq \kappa_{\infty}(A) \leq n^2 \kappa_1(A).
\]

Thus, if a matrix is ill-conditioned in the \( \alpha \)-norm, it is ill-conditioned in the \( \beta \)-norm modulo the constants \( c_1 \) and \( c_2 \) above.

For any of the \( p \)-norms, we have \( \kappa_p(A) \geq 1 \). Matrices with small condition numbers are said to be *well-conditioned*. In the 2-norm, orthogonal matrices are perfectly conditioned in that \( \kappa_2(Q) = 1 \) if \( Q \) is orthogonal.

### 2.7.3 Determinants and Nearness to Singularity

It is natural to consider how well determinant size measures ill-conditioning. If \( \det(A) = 0 \) is equivalent to singularity, is \( \det(A) \approx 0 \) equivalent to near singularity? Unfortunately, there is little correlation between \( \det(A) \) and the condition of \( Ax = b \). For example, the matrix \( B_n \) defined by

\[
B_n = \begin{bmatrix}
1 & -1 & \cdots & -1 \\
0 & 1 & \cdots & -1 \\
\vdots & \vdots & \ddots & \vdots \\
0 & 0 & \cdots & 1
\end{bmatrix} \in \mathbb{R}^{n \times n} \tag{2.7.9}
\]

has determinant 1, but \( \kappa_{\infty}(B_n) = n2^{n-1} \). On the other hand, a very well conditioned matrix can have a very small determinant. For example,

\[
D_n = \mathrm{diag}(10^{-1}, \ldots, 10^{-1}) \in \mathbb{R}^{n \times n}
\]

satisfies \( \kappa_p(D_n) = 1 \) although \( \det(D_n) = 10^{-n} \).

### 2.7.4 A Rigorous Norm Bound

Recall that the derivation of (2.7.4) was valuable because it highlighted the connection between \( \kappa(A) \) and the rate of change of \( x(\epsilon) \) at \( \epsilon = 0 \). However,

\[ \text{It also depends upon the definition of "large." The matter is pursued in §3.5} \]
it is a little unsatisfying because it is contingent on ε being "small enough" and because it sheds no light on the size of the O(ε²) term. In this and the next subsection we develop some additional Ax = b perturbation theorems that are completely rigorous.

We first establish a useful lemma that indicates in terms of κ(A) when we can expect a perturbed system to be nonsingular.

Lemma 2.7.1 Suppose

\[ Ax = b \quad A \in \mathbb{R}^{n \times n}, \quad 0 \neq b \in \mathbb{R}^n \]

\[ (A + \Delta A)y = b + \Delta b \quad \Delta A \in \mathbb{R}^{n \times n}, \quad \Delta b \in \mathbb{R}^n \]

with \( \| \Delta A \| \leq \varepsilon \| A \| \) and \( \| \Delta b \| \leq \varepsilon \| b \| \). If \( \varepsilon \kappa(A) = r < 1 \), then \( A + \Delta A \) is nonsingular and

\[ \frac{\| y \|}{\| x \|} \leq \frac{1 + r}{1 - r}. \]

Proof. Since \( \| A^{-1} \Delta A \| \leq \varepsilon \| A^{-1} \| \| A \| = r < 1 \) it follows from Theorem 2.3.4 that \( (A + \Delta A) \) is nonsingular. Using Lemma 2.3.3 and the equality \( (I + A^{-1} \Delta A)y = x + A^{-1} \Delta b \) we find

\[ \| y \| \leq (I + A^{-1} \Delta A)^{-1} \| (x \| + \varepsilon \| A^{-1} \| \| b \|) \]

\[ \leq \frac{1}{1 - r} (\| x \| + \varepsilon \| A^{-1} \| \| b \|) = \frac{1}{1 - r} \left( \| x \| + r \frac{\| b \|}{\| A \|} \right). \]

Since \( \| b \| = \| Ax \| \leq \| A \| \| x \| \) it follows that

\[ \| y \| \leq \frac{1}{1 - r} \left( \| x \| + r \| x \| \right). \Box \]

We are now set to establish a rigorous Ax = b perturbation bound.

Theorem 2.7.2 If the conditions of Lemma 2.7.1 hold, then

\[ \frac{\| y - x \|}{\| x \|} \leq \frac{2\varepsilon}{1 - r} \kappa(A) \tag{2.7.10} \]

Proof. Since

\[ y - x = A^{-1} \Delta b - A^{-1} \Delta Ay \tag{2.7.11} \]

we have \( \| y - x \| \leq \varepsilon \| A^{-1} \| \| b \| + \varepsilon \| A^{-1} \| \| A \| \| y \| \) and so

\[ \frac{\| y - x \|}{\| x \|} \leq \varepsilon \kappa(A) \frac{\| b \|}{\| A \| \| x \|} + \varepsilon \kappa(A) \frac{\| y \|}{\| x \|} \]

\[ \leq \varepsilon \kappa(A) \left( 1 + \frac{1 + r}{1 - r} \right) = \frac{2\varepsilon}{1 - r} \kappa(A). \Box \]
Example 2.7.1 The $Ax = b$ problem

$$
\begin{bmatrix}
1 & 0 \\
0 & 10^{-6}
\end{bmatrix}
\begin{bmatrix}
z_1 \\
z_2
\end{bmatrix}
= 
\begin{bmatrix}
1 \\
10^{-6}
\end{bmatrix}
$$

has solution $z = (1, 1)^T$ and condition $\kappa_\infty(A) = 10^6$. If $\Delta b = (10^{-6}, 0)^T$, $\Delta A = 0$, and $(A + \Delta A)y = b + \Delta b$, then $y = (1 + 10^{-6}, 1)^T$ and the inequality (2.7.10) says

$$
10^{-6} \leq \frac{\| x - y \|_\infty}{\| x \|_\infty} \leq \frac{\| \Delta b \|_\infty}{\| b \|_\infty} \kappa_\infty(A) = 10^{-6}10^6 = 1.
$$

Thus, the upper bound in (2.7.10) can be a gross overestimate of the error induced by the perturbation. On the other hand, if $\Delta b = (0, 10^{-6})^T$, $\Delta A = 0$, and $(A + \Delta A)y = b + \Delta b$, then this inequality says

$$
\frac{10^0}{10^6} \leq 2 \times 10^{-6}10^6.
$$

Thus, there are perturbations for which the bound in (2.7.10) is essentially attained.

2.7.5 Some Rigorous Componentwise Bounds

We conclude this section by showing that a more refined perturbation theory is possible if componentwise perturbation bounds are in effect and if we make use of the absolute value notation.

Theorem 2.7.3 Suppose

$$
Ax = b \quad A \in \mathbb{R}^{n \times n}, \ 0 \neq b \in \mathbb{R}^n
$$

$$(A + \Delta A)y = b + \Delta b \quad \Delta A \in \mathbb{R}^{n \times n}, \ \Delta b \in \mathbb{R}^n$$

and that $|\Delta A| \leq \epsilon|A|$ and $|\Delta b| \leq \epsilon|b|$. If $\delta \kappa_\infty(A) = r < 1$, then $(A + \Delta A)$ is nonsingular and

$$
\frac{\| y - x \|_\infty}{\| x \|_\infty} \leq \frac{2\delta}{1 - r} \| A^{-1} \|_\infty \| A \|_\infty.
$$

Proof. Since $\| \Delta A \|_\infty \leq \epsilon \| A \|_\infty$ and $\| \Delta b \|_\infty \leq \epsilon \| b \|_\infty$ the conditions of Lemma 2.7.1 are satisfied in the infinity norm. This implies that $A + \Delta A$ is nonsingular and

$$
\frac{\| y \|_\infty}{\| x \|_\infty} \leq \frac{1 + r}{1 - r}.
$$

Now using (2.7.11) we find

$$
|y - x| \leq |A^{-1}| |\Delta b| + |A^{-1}| |\Delta A| |y|
$$

$$
\leq \epsilon|A^{-1}| |b| + \epsilon|A^{-1}| |A| |y| \leq \epsilon|A^{-1}| |A| (|x| + |y|).
$$

If we take norms, then

$$
\| y - x \|_\infty \leq \epsilon \| A^{-1} \|_\infty \| A \|_\infty \left( \| x \|_\infty + \frac{1 + r}{1 - r} \| x \|_\infty \right).
$$
The theorem follows upon division by \( \| x \|_\infty. \) \( \square \)

We refer to the quantity \( \| A^{-1} \| A \| \|_\infty \) as the Skeeol condition number. It has been effectively used in the analysis of several important linear system computations. See §3.5.

Lastly, we report on the results of Oettli and Prager (1964) that indicate when an approximate solution \( \hat{x} \in \mathbb{R}^n \) to the \( n \)-by-\( n \) system \( Ax = b \) satisfies a perturbed system with prescribed structure. In particular, suppose \( E \in \mathbb{R}^{n \times n} \) and \( f \in \mathbb{R}^n \) are given and have nonnegative entries. We seek \( \Delta A \in \mathbb{R}^{n \times n}, \Delta b \in \mathbb{R}^n \), and \( \omega \geq 0 \) such that

\[
(A + \Delta A)\hat{x} = b + \Delta b \quad |\Delta A| \leq \omega E, \quad |\Delta b| \leq \omega f.
\] (2.7.12)

Note that by properly choosing \( E \) and \( f \) the perturbed system can take on certain qualities. For example, if \( E = |A| \) and \( f = |b| \) and \( \omega \) is small, then \( \hat{x} \) satisfies a nearby system in the componentwise sense. Oettli and Prager (1964) show that for a given \( A, b, \hat{x}, E, \) and \( f \) the smallest \( \omega \) possible in (2.7.12) is given by

\[
\omega_{\text{min}} = \max_{1 \leq i \leq n} \frac{|A\hat{x} - b|_i}{(E|\hat{x}| + f)_i}.
\]

If \( A\hat{x} = b \) then \( \omega_{\text{min}} = 0 \). On the other hand, if \( \omega_{\text{min}} = \infty \), then \( \hat{x} \) does not satisfy any system of the prescribed perturbation structure.

Problems

P2.7.1 Show that if \( \| I \| \geq 1 \), then \( \kappa(A) \geq 1 \).

P2.7.2 Show that for a given norm, \( \kappa(AB) \leq \kappa(A)\kappa(B) \) and that \( \kappa(aA) = \kappa(A) \) for all nonzero \( a \).

P2.7.3 Relate the 2-norm condition of \( X \in \mathbb{R}^{m \times n} \) \( (m \geq n) \) to the 2-norm condition of the matrices

\[
B = \begin{bmatrix} I_m & X \\ 0 & I_n \end{bmatrix}
\]

and

\[
C = \begin{bmatrix} X \\ I_n \end{bmatrix}.
\]

Notes and References for Sec. 2.7

The condition concept is thoroughly investigated in

References for componentwise perturbation theory include

The reciprocal of the condition number measures how near a given $Ax = b$ problem is to singularity. The importance of knowing how near a given problem is to a difficult or insoluble problem has come to be appreciated in many computational settings. See

Chapter 3

General Linear Systems

§3.1 Triangular Systems
§3.2 The LU Factorization
§3.3 Roundoff Analysis of Gaussian Elimination
§3.4 Pivoting
§3.5 Improving and Estimating Accuracy

The problem of solving a linear system $Ax = b$ is central in scientific computation. In this chapter we focus on the method of Gaussian elimination, the algorithm of choice when $A$ is square, dense, and unstructured. When $A$ does not fall into this category, then the algorithms of Chapters 4, 5, and 10 are of interest. Some parallel $Ax = b$ solvers are discussed in Chapter 6.

We motivate the method of Gaussian elimination in §3.1 by discussing the ease with which triangular systems can be solved. The conversion of a general system to triangular form via Gauss transformations is then presented in §3.2 where the “language” of matrix factorizations is introduced. Unfortunately, the derived method behaves very poorly on a nontrivial class of problems. Our error analysis in §3.3 pinpoints the difficulty and motivates §3.4, where the concept of pivoting is introduced. In the final section we comment upon the important practical issues associated with scaling, iterative improvement, and condition estimation.

### 3.1 Triangular Systems

Traditional factorization methods for linear systems involve the conversion of the given square system to a triangular system that has the same solution. This section is about the solution of triangular systems.

#### 3.1.1 Forward Substitution

Consider the following 2-by-2 lower triangular system:

$$
\begin{bmatrix}
\ell_{11} & 0 \\
\ell_{21} & \ell_{22}
\end{bmatrix}
\begin{bmatrix}
x_1 \\
x_2
\end{bmatrix}
= 
\begin{bmatrix}
b_1 \\
b_2
\end{bmatrix}.
$$

If $\ell_{11}, \ell_{22} \neq 0$, then the unknowns can be determined sequentially:

$$
x_1 = b_1/\ell_{11}
$$

$$
x_2 = (b_2 - \ell_{21} x_1)/\ell_{22}.
$$

This is the 2-by-2 version of an algorithm known as forward substitution. The general procedure is obtained by solving the ith equation in $L x = b$ for $x_i$:

$$
x_i = \left( b_i - \sum_{j=1}^{i-1} \ell_{ij} x_j \right) / \ell_{ii}
$$
If this is evaluated for \( i = 1:n \), then a complete specification of \( x \) is obtained. Note that at the \( i \)th stage the dot product of \( L(i, 1:i-1) \) and \( x(1:i-1) \) is required. Since \( b_i \) only is involved in the formula for \( x_i \), the former may be overwritten by the latter:

**Algorithm 3.1.1 (Forward Substitution: Row Version)** If \( L \in \mathbb{R}^{n \times n} \) is lower triangular and \( b \in \mathbb{R}^n \), then this algorithm overwrites \( b \) with the solution to \( Lx = b \). \( L \) is assumed to be nonsingular.

\[
b(1) = b(1)/L(1, 1) \\
\text{for } i = 2:n \\
b(i) = \frac{(b(i) - L(i, 1:i-1)b(1:i-1))}{L(i, i)} \\
\text{end}
\]

This algorithm requires \( n^2 \) flops. Note that \( L \) is accessed by row. The computed solution \( \hat{x} \) satisfies:

\[
(L + F)\hat{x} = b \\
|F| \leq nu|L| + O(u^2) \tag{3.1.1}
\]

For a proof, see Higham (1996). It says that the computed solution exactly satisfies a slightly perturbed system. Moreover, each entry in the perturbing matrix \( F \) is small relative to the corresponding element of \( L \).

### 3.1.2 Back Substitution

The analogous algorithm for upper triangular systems \( Ux = b \) is called *back-substitution*. The recipe for \( x_i \) is prescribed by

\[
x_i = \frac{\left(b_i - \sum_{j=i+1}^{n} u_{ij}x_j\right)}{u_{ii}}
\]

and once again \( b_i \) can be overwritten by \( x_i \).

**Algorithm 3.1.2 (Back Substitution: Row Version)** If \( U \in \mathbb{R}^{n \times n} \) is upper triangular and \( b \in \mathbb{R}^n \), then the following algorithm overwrites \( b \) with the solution to \( Ux = b \). \( U \) is assumed to be nonsingular.

\[
b(n) = b(n)/U(n, n) \\
\text{for } i = n-1: -1:1 \\
b(i) = \frac{(b(i) - U(i, i + 1:n)b(i + 1:n))}{U(i, i)} \\
\text{end}
\]

This algorithm requires \( n^2 \) flops and accesses \( U \) by row. The computed solution \( \hat{x} \) obtained by the algorithm can be shown to satisfy

\[
(U + F)\hat{x} = b \\
|F| \leq nu|U| + O(u^2). \tag{3.1.2}
\]
3.1.3 Column Oriented Versions

Column oriented versions of the above procedures can be obtained by reversing loop orders. To understand what this means from the algebraic point of view, consider forward substitution. Once $x_1$ is resolved, it can be removed from equations 2 through $n$ and we proceed with the reduced system $L(2:n, 2:n)x(2:n) = b(2:n) - x(1)L(2:n, 1)$. We then compute $x_2$ and remove it from equations 3 through $n$, etc. Thus, if this approach is applied to

$$\begin{bmatrix}
  2 & 0 & 0 \\
  1 & 5 & 0 \\
  7 & 9 & 8
\end{bmatrix}
\begin{bmatrix}
  x_1 \\
  x_2 \\
  x_3
\end{bmatrix} =
\begin{bmatrix}
  6 \\
  2 \\
  5
\end{bmatrix},$$

we find $x_1 = 3$ and then deal with the 2-by-2 system

$$\begin{bmatrix}
  5 & 0 \\
  9 & 8
\end{bmatrix}
\begin{bmatrix}
  x_2 \\
  x_3
\end{bmatrix} =
\begin{bmatrix}
  2 \\
  5
\end{bmatrix} - 3\begin{bmatrix}
  1 \\
  7
\end{bmatrix} =
\begin{bmatrix}
  -1 \\
  -16
\end{bmatrix}.$$

Here is the complete procedure with overwriting.

Algorithm 3.1.3 (Forward Substitution: Column Version) If $L \in \mathbb{R}^{n \times n}$ is lower triangular and $b \in \mathbb{R}^n$, then this algorithm overwrites $b$ with the solution to $Lx = b$. $L$ is assumed to be nonsingular.

```plaintext
for $j = 1:n - 1$
    $b(j) = b(j)/L(j, j)$
    $b(j + 1:n) = b(j + 1:n) - b(j)L(j + 1:n, j)$
end
$b(n) = b(n)/L(n, n)$
```

It is also possible to obtain a column-oriented saxpy procedure for back-substitution.

Algorithm 3.1.4 (Back Substitution: Column Version) If $U \in \mathbb{R}^{n \times n}$ is upper triangular and $b \in \mathbb{R}^n$, then this algorithm overwrites $b$ with the solution to $Ux = b$. $U$ is assumed to be nonsingular.

```plaintext
for $j = n: -1:2$
    $b(j) = b(j)/U(j, j)$
    $b(1:j - 1) = b(1:j - 1) - b(j)U(1:j - 1, j)$
end
$b(1) = b(1)/U(1, 1)$
```

Note that the dominant operation in both Algorithms 3.1.3 and 3.1.4 is the saxpy operation. The roundoff behavior of these saxpy implementations is essentially the same as for the dot product versions.

The accuracy of a computed solution to a triangular system is often surprisingly good. See Higham (1996).
3.1.4 Multiple Right Hand Sides

Consider the problem of computing a solution \( X \in \mathbb{R}^{n \times q} \) to \( LX = B \) where \( L \in \mathbb{R}^{n \times n} \) is lower triangular and \( B \in \mathbb{R}^{n \times q} \). This is the multiple right hand side forward substitution problem. We show that such a problem can be solved by a block algorithm that is rich in matrix multiplication assuming that \( q \) and \( n \) are large enough. This turns out to be important in subsequent sections where various block factorization schemes are discussed. We mention that although we are considering here just the lower triangular problem, everything we say applies to the upper triangular case as well.

To develop a block forward substitution algorithm we partition the equation \( LX = B \) as follows:

\[
\begin{bmatrix}
L_{11} & 0 & \cdots & 0 \\
L_{21} & L_{22} & \cdots & 0 \\
\vdots & \vdots & \ddots & \vdots \\
L_{N1} & L_{N2} & \cdots & L_{NN}
\end{bmatrix}
\begin{bmatrix}
X_1 \\
X_2 \\
\vdots \\
X_N
\end{bmatrix}
= 
\begin{bmatrix}
B_1 \\
B_2 \\
\vdots \\
B_N
\end{bmatrix}.
\] (3.1.3)

Assume that the diagonal blocks are square. Paralleling the development of Algorithm 3.1.3, we solve the system \( L_{11}X_1 = B_1 \) for \( X_1 \) and then remove \( X_1 \) from block equations 2 through \( N \):

\[
\begin{bmatrix}
L_{22} & 0 & \cdots & 0 \\
L_{32} & L_{33} & \cdots & 0 \\
\vdots & \vdots & \ddots & \vdots \\
L_{N2} & L_{N3} & \cdots & L_{NN}
\end{bmatrix}
\begin{bmatrix}
X_2 \\
X_3 \\
\vdots \\
X_N
\end{bmatrix}
= 
\begin{bmatrix}
B_2 - L_{21}X_1 \\
B_3 - L_{31}X_1 \\
\vdots \\
B_N - L_{N1}X_1
\end{bmatrix}.
\]

Continuing in this way we obtain the following block saxpy forward elimination scheme:

\[
\text{for } j = 1:N \\
\text{Solve } L_{jj}X_j = B_j \\
\text{for } i = j + 1:N \\
B_i = B_i - L_{ij}X_j \\
\text{end} \\
\text{end}
\]

(3.1.4)

Notice that the \( i \)-loop oversees a single block saxpy update of the form

\[
\begin{bmatrix}
B_{j+1} \\
\vdots \\
B_N
\end{bmatrix} = 
\begin{bmatrix}
B_{j+1} \\
\vdots \\
B_N
\end{bmatrix} - 
\begin{bmatrix}
L_{j+1,j} \\
\vdots \\
L_{N,j}
\end{bmatrix}X_j.
\]

For this to be handled as a matrix multiplication in a given architecture it is clear that the blocking in (3.1.3) must give sufficiently "big" \( X_j \). Let us assume that this is the case if each \( X_j \) has at least \( r \) rows. This can be accomplished if \( N = \text{ceil}(n/r) \) and \( X_1, \ldots, X_{N-1} \in \mathbb{R}^{r \times q} \) and \( X_N \in \mathbb{R}^{(n-(N-1)r) \times q} \).
3.1.5 The Level-3 Fraction

It is handy to adopt a measure that quantifies the amount of matrix multiplication in a given algorithm. To this end we define the level-3 fraction of an algorithm to be the fraction of flops that occur in the context of matrix multiplication. We call such flops level-3 flops.

Let us determine the level-3 fraction for (3.1.4) with the simplifying assumption that \( n = rN \). (The same conclusions hold with the unequal blocking described above.) Because there are \( N \) applications of \( r \)-by-\( r \) forward elimination (the level-2 portion of the computation) and \( n^2 \) flops overall, the level-3 fraction is approximately given by

\[
1 - \frac{N r^2}{n^2} = 1 - \frac{1}{n^2} N
\]

Thus, for large \( N \) almost all flops are level-3 flops and it makes sense to choose \( N \) as large as possible subject to the constraint that the underlying architecture can achieve a high level of performance when processing block saxpy’s of width at least \( r = n/N \).

3.1.6 Non-square Triangular System Solving

The problem of solving nonsquare, \( m \)-by-\( n \) triangular systems deserves some mention. Consider first the lower triangular case when \( m \geq n \), i.e.,

\[
\begin{bmatrix}
L_{11} \\
L_{21}
\end{bmatrix} x = \begin{bmatrix}
b_1 \\
b_2
\end{bmatrix}, \quad L_{11} \in \mathbb{R}^{n \times n}, \quad b_1 \in \mathbb{R}^{n} \\
L_{21} \in \mathbb{R}^{(m-n) \times n}, \quad b_2 \in \mathbb{R}^{m-n}
\]

Assume that \( L_{11} \) is lower triangular, and nonsingular. If we apply forward elimination to \( L_{11} x = b_1 \) then \( x \) solves the system provided \( L_{21}(L_{11}^{-1} b_1) = b_2 \). Otherwise, there is no solution to the overall system. In such a case least squares minimization may be appropriate. See Chapter 5.

Now consider the lower triangular system \( L x = b \) when the number of columns \( n \) exceeds the number of rows \( m \). In this case apply forward substitution to the square system \( L(1:m, 1:m)x(1:m, 1:m) = b \) and prescribe an arbitrary value for \( x(m+1:n) \). See §5.7 for additional comments on systems that have more unknowns than equations.

The handling of nonsquare upper triangular systems is similar. Details are left to the reader.

3.1.7 Unit Triangular Systems

A unit triangular matrix is a triangular matrix with ones on the diagonal. Many of the triangular matrix computations that follow have this added bit of structure. It clearly poses no difficulty in the above procedures.
3.1.8 The Algebra of Triangular Matrices

For future reference we list a few properties about products and inverses of triangular and unit triangular matrices.

- The inverse of an upper (lower) triangular matrix is upper (lower) triangular.
- The product of two upper (lower) triangular matrices is upper (lower) triangular.
- The inverse of a unit upper (lower) triangular matrix is unit upper (lower) triangular.
- The product of two unit upper (lower) triangular matrices is unit upper (lower) triangular.

Problems

P3.1.1 Give an algorithm for computing a nonzero $z \in \mathbb{R}^n$ such that $Uz = 0$ where $U \in \mathbb{R}^{n \times n}$ is upper triangular with $u_{nn} = 0$ and $u_{11} \cdots u_{n-1,n-1} \neq 0$.

P3.1.2 Discuss how the determinant of a square triangular matrix could be computed with minimum risk of overflow and underflow.

P3.1.3 Rewrite Algorithm 3.1.4 given that $U$ is stored by column in a length $n(n+1)/2$ array $u_{sec}$.

P3.1.4 Write a detailed version of (3.1.4). Do not assume that $N$ divides $n$.

P3.1.5 Prove all the facts about triangular matrices that are listed in §3.1.8.

P3.1.6 Suppose $S, T \in \mathbb{R}^{n \times n}$ are upper triangular and that $(ST - \lambda I)z = b$ is a nonsingular system. Give an $O(n^3)$ algorithm for computing $z$. Note that the explicit formation of $ST - \lambda I$ requires $O(n^3)$ flops. Hint. Suppose

$$ S_+ = \begin{bmatrix} \sigma & u^T \\ 0 & S_c \end{bmatrix}, \quad T_+ = \begin{bmatrix} \tau & v^T \\ 0 & T_c \end{bmatrix}, \quad b_+ = \begin{bmatrix} \beta \\ b_c \end{bmatrix} $$

where $S_+ = S(k-1:n,k-1:n)$, $T_+ = T(k-1:n,k-1:n)$, $b_+ = b(k-1:n)$ and $\sigma, \tau, \beta \in \mathbb{R}$. Show that if we have a vector $x_c$ such that

$$(S_cT_c - \lambda I)x_c = b_c$$

and $w_c = T_cx_c$ is available, then

$$ x_+ = \begin{bmatrix} \gamma \\ x_c \end{bmatrix}, \quad \gamma = \frac{\beta - \sigma v^T x_c - u^T w_c}{\sigma \tau - \lambda} $$

solves $(S_+T_+ - \lambda I)x_+ = b_+$. Observe that $x_+$ and $w_+ = T_+x_+$ each require $O(n - k)$ flops.

P3.1.7 Suppose the matrices $R_1, \ldots, R_p \in \mathbb{R}^{n \times n}$ are all upper triangular. Give an $O(pn^2)$ algorithm for solving the system $(R_1 \cdots R_p - \lambda I)x = b$ assuming that the matrix of coefficients is nonsingular. Hint. Generalize the solution to the previous problem.

Notes and References for Sec. 3.1

The accuracy of triangular system solvers is analyzed in

3.2 The LU Factorization

As we have just seen, triangular systems are "easy" to solve. The idea behind Gaussian elimination is to convert a given system $Ax = b$ to an equivalent triangular system. The conversion is achieved by taking appropriate linear combinations of the equations. For example, in the system

$$
3x_1 + 5x_2 = 9 \\
6x_1 + 7x_2 = 4
$$

if we multiply the first equation by 2 and subtract it from the second we obtain

$$
3x_1 + 5x_2 = 9 \\
-3x_2 = -14
$$

This is $n = 2$ Gaussian elimination. Our objective in this section is to give a complete specification of this central procedure and to describe what it does in the language of matrix factorizations. This means showing that the algorithm computes a unit lower triangular matrix $L$ and an upper triangular matrix $U$ so that $A = LU$, e.g.,

$$
\begin{bmatrix}
3 & 5 \\
6 & 7
\end{bmatrix} =
\begin{bmatrix}
1 & 0 \\
2 & 1
\end{bmatrix}
\begin{bmatrix}
3 & 5 \\
0 & -3
\end{bmatrix}.
$$

The solution to the original $Ax = b$ problem is then found by a two step triangular solve process:

$$
Ly = b, \quad Ux = y \quad \Rightarrow \quad Ax = LUx = Ly = b.
$$

The LU factorization is a "high-level" algebraic description of Gaussian elimination. Expressing the outcome of a matrix algorithm in the "language" of matrix factorizations is a worthwhile activity. It facilitates generalization and highlights connections between algorithms that may appear very different at the scalar level.

3.2.1 Gauss Transformations

To obtain a factorization description of Gaussian elimination we need a matrix description of the zeroing process. At the $n = 2$ level if $x_1 \neq 0$ and $\tau = x_2/x_1$, then

$$
\begin{bmatrix}
1 & 0 \\
-\tau & 1
\end{bmatrix}
\begin{bmatrix}
x_1 \\
x_2
\end{bmatrix} =
\begin{bmatrix}
x_1 \\
0
\end{bmatrix}
$$

More generally, suppose $x \in \mathbb{R}^n$ with $x_k \neq 0$. If

$$
\tau^T_k = (0, \ldots, 0, \tau_{k+1}, \ldots, \tau_n) \quad \tau_i = \frac{x_i}{x_k} \quad i = k + 1:n
$$
and we define

\[ M_k = I - \tau e_k^T, \]

then

\[
M_k x = \begin{bmatrix}
1 & \cdots & 0 & 0 & \cdots & 0 \\
\vdots & \ddots & \vdots & \vdots & \ddots & \vdots \\
0 & 1 & 0 & 0 & \cdots & 0 \\
0 & -\tau_{k+1} & 1 & 0 & \cdots & 0 \\
\vdots & \vdots & \vdots & \ddots & \ddots & \vdots \\
0 & \cdots & -\tau_n & 0 & \cdots & 1
\end{bmatrix}
\begin{bmatrix}
x_1 \\
x_k \\
x_{k+1} \\
x_n
\end{bmatrix}
= \begin{bmatrix}
x_1 \\
x_k \\
0 \\
x_n
\end{bmatrix}.
\]

In general, a matrix of the form \( M_k = I - \tau e_k^T \in \mathbb{R}^{n \times n} \) is a Gauss transformation if the first \( k \) components of \( \tau \in \mathbb{R}^n \) are zero. Such a matrix is unit lower triangular. The components of \( \tau(k+1:n) \) are called multipliers. The vector \( \tau \) is called the Gauss vector.

### 3.2.2 Applying Gauss Transformations

Multiplication by a Gauss transformation is particularly simple. If \( C \in \mathbb{R}^{n \times r} \) and \( M_k = I - \tau e_k^T \) is a Gauss transform, then

\[
M_k C = (I - \tau e_k^T)C = C - \tau(e_k^T C) = C - \tau C(k,:)\).
\]

is an outer product update. Since \( \tau(1:k) = 0 \) only \( C(k+1:n,:) \) is affected and the update \( C = M_k C \) can be computed row-by-row as follows:

for \( i = k+1:n \)

\[
C(i,:) = C(i,:) - \tau_i C(k,:)
\]

end

This computation requires \( 2(n - 1)r \) flops.

**Example 3.2.1**

\[
C = \begin{bmatrix}
1 & 4 & 7 \\
2 & 5 & 8 \\
3 & 6 & 10
\end{bmatrix}, \quad \tau = \begin{bmatrix}
0 \\
1 \\
-1
\end{bmatrix} \Rightarrow (I - \tau e_1^T)C = \begin{bmatrix}
1 & 4 & 7 \\
1 & 1 & 1 \\
4 & 10 & 17
\end{bmatrix}.
\]

### 3.2.3 Roundoff Properties of Gauss Transforms

If \( \tau \) is the computed version of an exact Gauss vector \( \tau \), then it is easy to verify that

\[ \hat{\tau} = \tau + e \quad |e| \leq u|\tau|. \]
If $\hat{r}$ is used in a Gauss transform update and $fl((I - \hat{r}e_k^T)C)$ denotes the computed result, then

$$fl((I - \hat{r}e_k^T)C) = (I - \tau e_k^T)C + E,$$

where

$$|E| \leq 3u(|C| + |\tau||C(k,:)|) + O(u^2).$$

Clearly, if $\tau$ has large components, then the errors in the update may be large in comparison to $|C|$. For this reason, care must be exercised when Gauss transformations are employed, a matter that is pursued in §3.4.

### 3.2.4 Upper Triangularizing

Assume that $A \in \mathbb{R}^{n \times n}$. Gauss transformations $M_1, \ldots, M_{n-1}$ can usually be found such that $M_{n-1} \cdots M_2M_1A = U$ is upper triangular. To see this we first look at the $n = 3$ case. Suppose

$$A = \begin{bmatrix} 1 & 4 & 7 \\ 2 & 5 & 8 \\ 3 & 6 & 10 \end{bmatrix}.$$ 

If

$$M_1 = \begin{bmatrix} 1 & 0 & 0 \\ -2 & 1 & 0 \\ -3 & 0 & 1 \end{bmatrix},$$

then

$$M_1A = \begin{bmatrix} 1 & 4 & 7 \\ 0 & -3 & -6 \\ 0 & -6 & -11 \end{bmatrix}.$$ 

Likewise,

$$M_2 = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & -2 & 1 \end{bmatrix} \Rightarrow M_2(M_1A) = \begin{bmatrix} 1 & 4 & 7 \\ 0 & -3 & -6 \\ 0 & 0 & 1 \end{bmatrix}.$$ 

Extrapolating from this example observe that during the $k$th step

- We are confronted with a matrix $A^{(k-1)} = M_{k-1} \cdots M_1A$ that is upper triangular in columns 1 to $k - 1$.

- The multipliers in $M_k$ are based on $A^{(k-1)}(k+1:n,k)$. In particular, we need $a_{kk}^{(k-1)} \neq 0$ to proceed.

Noting that complete upper triangularization is achieved after $n - 1$ steps we therefore obtain
\[ k = 1 \]
\[ \text{while } (A(k, k) \neq 0) \& (k \leq n - 1) \]
\[ \tau(k + 1:n) = A(k + 1:n, k)/A(k, k) \]
\[ A(k + 1:n,:) = A(k + 1:n,:) - \tau(k + 1:n)A(k,:) \]
\[ k = k + 1 \]
end

The entry \( A(k, k) \) must be checked to avoid a zero divide. These quantities are referred to as the pivots and their relative magnitude turns out to be critically important.

### 3.2.5 The LU Factorization

In matrix language, if (3.2.2) terminates with \( k = n \), then it computes Gauss transforms \( M_1, \ldots, M_{n-1} \) such that \( M_{n-1} \cdots M_1 A = U \) is upper triangular. It is easy to check that if \( M_k = I - \tau^{(k)} e_k e_k^T \), then its inverse is prescribed by \( M_k^{-1} = I + \tau^{(k)} e_k e_k^T \) and so

\[ A = LU \] (3.2.3)

where

\[ L = M_1^{-1} \cdots M_{n-1}^{-1}. \] (3.2.4)

It is clear that \( L \) is a unit lower triangular matrix because each \( M_k^{-1} \) is unit lower triangular. The factorization (3.2.3) is called the **LU factorization** of \( A \).

As suggested by the need to check for zero pivots in (3.2.2), the LU factorization need not exist. For example, it is impossible to find \( l_{ij} \) and \( u_{ij} \) so

\[
\begin{bmatrix}
1 & 2 & 3 \\
2 & 4 & 7 \\
3 & 5 & 3
\end{bmatrix}
= \begin{bmatrix}
1 & 0 & 0 \\
\ell_{21} & 1 & 0 \\
\ell_{31} & \ell_{32} & 1
\end{bmatrix}
\begin{bmatrix}
u_{11} & u_{12} & u_{13} \\
u_{22} & u_{22} & u_{23} \\
u_{32} & u_{33}
\end{bmatrix}.
\]

To see this equate entries and observe that we must have \( u_{11} = 1, u_{12} = 2, \ell_{21} = 2, u_{22} = 0 \), and \( \ell_{31} = 3 \). But when we then look at the (3,2) entry we obtain the contradictory equation \( 5 = \ell_{31} u_{12} + \ell_{32} u_{22} = 6 \).

As we now show, a zero pivot in (3.2.2) can be identified with a singular leading principal submatrix.

**Theorem 3.2.1** \( A \in \mathbb{R}^{n \times n} \) has an LU factorization if \( \det(A(1:k, 1:k)) \neq 0 \) for \( k = 1:n - 1 \). If the LU factorization exists and \( A \) is nonsingular, then the LU factorization is unique and \( \det(A) = u_{11} \cdots u_{nn} \).

**Proof.** Suppose \( k - 1 \) steps in (3.2.2) have been executed. At the beginning of step \( k \) the matrix \( A \) has been overwritten by \( M_{k-1} \cdots M_1 A = A^{(k-1)} \). Note that \( a_{kk}^{(k-1)} \) is the \( k \)th pivot. Since the Gauss transformations are
unit lower triangular it follows by looking at the leading \( k \)-by-\( k \) portion of this equation that \( \det(A(1:k,1:k)) = a_{11}^{(k-1)} \cdots a_{kk}^{(k-1)} \). Thus, if \( A(1:k,1:k) \) is nonsingular then the \( k \)th pivot is nonzero.

As for uniqueness, if \( A = L_1 U_1 \) and \( A = L_2 U_2 \) are two LU factorizations of a nonsingular \( A \), then \( L_2^{-1} L_1 = U_2 U_1^{-1} \). Since \( L_2^{-1} L_1 \) is unit lower triangular and \( U_2 U_1^{-1} \) is upper triangular, it follows that both of these matrices must equal the identity. Hence, \( L_1 = L_2 \) and \( U_1 = U_2 \).

Finally, if \( A = LU \) then \( \det(A) = \det(LU) = \det(L) \det(U) = \det(U) = u_{11} \cdots u_{nn} \). □

### 3.2.6 Some Practical Details

From the practical point of view there are several improvements that can be made to (3.2.2). First, because zeros have already been introduced in columns 1 through \( k-1 \), the Gauss transform update need only be applied to columns \( k \) through \( n \). Of course, we need not even apply the \( k \)th Gauss transform to \( A(:,k) \) since we know the result. So the efficient thing to do is simply to update \( A(k+1:n,k+1:n) \). Another worthwhile observation is that the multipliers associated with \( M_k \) can be stored in the locations that they zero, i.e., \( A(k+1:n,k) \). With these changes we obtain the following version of (3.2.2):

**Algorithm 3.2.1 (Outer Product Gaussian Elimination)** Suppose \( A \in \mathbb{R}^{n \times n} \) has the property that \( A(1:k,1:k) \) is nonsingular for \( k = 1:n-1 \). This algorithm computes the factorization \( M_{n-1} \cdots M_1 A = U \) where \( U \) is upper triangular and each \( M_k \) is a Gauss transform. \( U \) is stored in the upper triangle of \( A \). The multipliers associated with \( M_k \) are stored in \( A(k+1:n,k) \), i.e., \( A(k+1:n,k) = -M_k(k+1:n,k) \).

for \( k = 1:n-1 \)

\[
\text{rows} = k + 1:n \\
A(\text{rows},k) = A(\text{rows},k)/A(k,k) \\
A(\text{rows,rows}) = A(\text{rows,rows}) - A(\text{rows,k})A(k,\text{rows})
\]

end

This algorithm involves \( 2n^3/3 \) flops and it is one of several formulations of Gaussian Elimination. Note that each pass through the \( k \)-loop involves an outer product.

### 3.2.7 Where is \( L \)?

Algorithm 3.2.3 represents \( L \) in terms of the multipliers. In particular, if \( \tau^{(k)} \) is the vector of multipliers associated with \( M_k \) then upon termination, \( A(k+1:n,k) = \tau^{(k)} \). One of the more happy "coincidences" in matrix
computations is that if $L = M_i^{-1} \cdots M_{n-1}^{-1}$, then $L(k+1:n, k) = \tau^{(k)}$. This follows from a careful look at the product that defines $L$. Indeed,

$$L = \left( I + \tau^{(1)} e_1^T \right) \cdots \left( I + \tau^{(n-1)} e_{n-1}^T \right) = I + \sum_{k=1}^{n-1} \tau^{(k)} e_k^T.$$ 

Since $A(k+1:n, k)$ houses the $k$th vector of multipliers $\tau^{(k)}$, it follows that $A(i, k)$ houses $\ell_{ik}$ for all $i > k$.

### 3.2.8 Solving a Linear System

Once $A$ has been factored via Algorithm 3.2.1, then $L$ and $U$ are represented in the array $A$. We can then solve the system $Ax = b$ via the triangular systems $Ly = b$ and $Ux = y$ by using the methods of §3.1.

**Example 3.2.2** If Algorithm 3.2.1 is applied to

$$A = \begin{bmatrix} 1 & 4 & 7 \\ 2 & 5 & 8 \\ 3 & 6 & 10 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 2 & 1 & 0 \\ 3 & 2 & 1 \end{bmatrix} \begin{bmatrix} 1 & 4 & 7 \\ 0 & -3 & -6 \\ 0 & 0 & 1 \end{bmatrix},$$

then upon completion,

$$A = \begin{bmatrix} 1 & 4 & 7 \\ 2 & -3 & -6 \\ 3 & 2 & 1 \end{bmatrix}.$$ 

If $b = (1, 1, 1)^T$, then $y = (1, -1, 0)^T$ solves $Ly = b$ and $x = (-1/3, 1/3, 0)^T$ solves $Ux = y$.

### 3.2.9 Other Versions

Gaussian elimination, like matrix multiplication, is a triple-loop procedure that can be arranged in several ways. Algorithm 3.2.1 corresponds to the "$kij$" version of Gaussian elimination if we compute the outer product update row-by-row:

for $k = 1:n - 1$

$$A(k+1:n, k) = A(k+1:n, k)/A(k, k)$$

for $i = k + 1:n$

for $j = k + 1:n$

$$A(i, j) = A(i, j) - A(i, k)A(k, j)$$

end

end

There are five other versions: $kji$, $ikj$, $ijk$, $jik$, and $jki$. The last of these results in an implementation that features a sequence of gaxpy's and forward eliminations. In this formulation, the Gauss transformations are not
immediately applied to $A$ as they are in the outer product version. Instead, their application is delayed. The original $A(\cdot, j)$ is untouched until step $j$. At that point in the algorithm $A(\cdot, j)$ is overwritten by $M_{j-1} \cdots M_1 A(\cdot, j)$. The $j$th Gauss transformation is then computed.

To be precise, suppose $1 \leq j \leq n - 1$ and assume that $L(\cdot, 1:j - 1)$ and $U(1:j - 1, 1:j - 1)$ are known. This means that the first $j - 1$ columns of $L$ and $U$ are available. To get the $j$th columns of $L$ and $U$ we equate $j$th columns in the equation $A = LU$: $A(\cdot, j) = LU(\cdot, j)$. From this we conclude that

\[ A(1:j - 1, j) = L(1:j - 1, 1:j - 1)U(1:j - 1, j) \]

and

\[ A(j:n, j) = \sum_{k=1}^{j} L(j:n, k)U(k, j). \]

The first equation is a lower triangular system that can be solved for the vector $U(1:j - 1, j)$. Once this is accomplished, the second equation can be rearranged to produce recipes for $U(j, j)$ and $L(j + 1:n, j)$. Indeed, if we set

\[ v(j:n) = A(j:n, j) - \sum_{k=1}^{j-1} L(j:n, k)U(k, j) \]

\[ = A(j:n, j) - L(j:n, 1:j - 1)U(1:j - 1, j), \]

then $L(j + 1:n, j) = v(j + 1:n)/v(j)$ and $U(j, j) = v(j)$. Thus, $L(j + 1:n, j)$ is a scaled gaxpy and we obtain

\[
L = I; U = 0 \\
\text{for } j = 1:n \\
\hspace{1cm} \text{if } j = 1 \\
\hspace{2cm} v(j:n) = A(j:n, j) \\
\hspace{1cm} \text{else} \\
\hspace{2cm} \text{Solve } L(1:j - 1, 1:j - 1)z = A(1:j - 1, j) \text{ for } z \quad (3.2.5) \\
\hspace{2cm} \text{and set } U(1:j - 1, j) = z. \\
\hspace{2cm} v(j:n) = A(j:n, j) - L(j:n, 1:j - 1)z \\
\hspace{1cm} \text{end} \\
\hspace{1cm} \text{if } j < n \\
\hspace{2cm} L(j + 1:n, j) = v(j + 1:n)/v(j) \\
\hspace{1cm} \text{end} \\
\hspace{1cm} U(j, j) = v(j) \\
\text{end}
\]

This arrangement of Gaussian elimination is rich in forward eliminations and gaxpy operations and, like Algorithm 3.2.1, requires $2n^3/3$ flops.
3.2.10 Block LU

It is possible to organize Gaussian elimination so that matrix multiplication becomes the dominant operation. The key to the derivation of this block procedure is to partition \( A \in \mathbb{R}^{n \times n} \) as follows

\[
A = \begin{bmatrix}
A_{11} & A_{12} \\
A_{21} & A_{22}
\end{bmatrix}
\begin{array}{c}
r \\
r & n-r
\end{array}
\]

where \( r \) is a blocking parameter. Suppose we compute the LU factorization

\( L_{11} U_{11} = A_{11} \) and then solve the multiple right hand side triangular systems \( L_{11} U_{12} = A_{12} \) and \( L_{21} U_{11} = A_{21} \) for \( U_{12} \) and \( L_{21} \) respectively. It follows that

\[
\begin{bmatrix}
A_{11} & A_{12} \\
A_{21} & A_{22}
\end{bmatrix} = \begin{bmatrix}
L_{11} & 0 \\
L_{21} & I_{n-r}
\end{bmatrix}\begin{bmatrix}
I_r & 0 \\
0 & \bar{A}
\end{bmatrix}\begin{bmatrix}
U_{11} & U_{12} \\
0 & I_{n-r}
\end{bmatrix}
\]

where \( \bar{A} = A_{22} - L_{21} U_{12} \). The matrix \( \bar{A} \) is the Schur complement of \( A_{11} \) with respect to \( A \). Note that if \( \bar{A} = L_{22} U_{22} \) is the LU factorization of \( \bar{A} \), then

\[
\begin{bmatrix}
A_{11} & A_{12} \\
A_{21} & A_{22}
\end{bmatrix} = \begin{bmatrix}
L_{11} & 0 \\
L_{21} & L_{22}
\end{bmatrix}\begin{bmatrix}
I_r & 0 \\
0 & \bar{A}
\end{bmatrix}\begin{bmatrix}
U_{11} & U_{12} \\
0 & U_{22}
\end{bmatrix}
\]

is the LU factorization of \( A \). Thus, after \( L_{11}, L_{21}, U_{11} \) and \( U_{22} \), are computed, we repeat the process on the level-3 updated (2,2) block \( \bar{A} \).

Algorithm 3.2.2 (Block Outer Product LU) Suppose \( A \in \mathbb{R}^{n \times n} \) and that \( \det(A(1:k, 1:k)) \) is nonzero for \( k = 1:n-1 \). Assume that \( r \) satisfies \( 1 \leq r \leq n \). The following algorithm computes \( A = LU \) via rank \( r \) updates. Upon completion, \( A(i,j) \) is overwritten with \( L(i,j) \) for \( i > j \) and \( A(i,j) \) is overwritten with \( U(i,j) \) if \( j \geq i \).

\[
\lambda = 1
\]

while \( \lambda \leq n \)

\[
\mu = \min(n, \lambda + r - 1)
\]

Use Algorithm 3.2.1 to overwrite \( A(\lambda:\mu, \lambda:\mu) \) with its \( LU \) factors \( \bar{L} \) and \( \bar{U} \).

Solve \( \bar{L} \bar{Z} = A(\lambda:\mu, \lambda + 1:n) \) for \( \bar{Z} \) and overwrite \( A(\lambda:\mu, \mu + 1:n) \) with \( \bar{Z} \).

Solve \( \bar{W} \bar{U} = A(\mu + 1:n, \lambda:\mu) \) for \( \bar{W} \) and overwrite \( A(\mu + 1:n, \lambda:\mu) \) with \( \bar{W} \).

\[
A(\mu + 1:n, \mu + 1:n) = A(\mu + 1:n, \mu + 1:n) - \bar{W} \bar{Z}
\]

\[
\lambda = \mu + 1
\]

end
This algorithm involves $2n^3/3$ flops.

Recalling the discussion in §3.1.5, let us consider the level-3 fraction for this procedure assuming that $r$ is large enough so that the underlying computer is able to compute the matrix multiply update $A(\mu + 1:n, \mu + 1:n) = A(\mu + 1:n, \mu + 1:n) - WZ$ at "level-3 speed." Assume for clarity that $n = rN$. The only flops that are not level-3 flops occur in the context of the $r$-by-$r$ LU factorizations $A(\lambda; \mu, \lambda; \mu) = \tilde{L}\tilde{U}$. Since there are $N$ such systems solved in the overall computation, we see that the level-3 fraction is given by

$$1 - \frac{N(2r^3/3)}{2n^3/3} = 1 - \frac{1}{N^2}.$$ 

Thus, for large $N$ almost all arithmetic takes place in the context of matrix multiplication. As we have mentioned, this ensures high performance on a wide range of computing environments.

3.2.11 The LU Factorization of a Rectangular Matrix

The LU factorization of a rectangular matrix $A \in \mathbb{R}^{m \times n}$ can also be performed. The $m > n$ case is illustrated by

$$\begin{bmatrix} 1 & 2 \\ 3 & 4 \\ 5 & 6 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 3 & 1 \\ 5 & 2 \end{bmatrix} \begin{bmatrix} 1 & 2 \\ 0 & -2 \end{bmatrix}$$

while

$$\begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ 4 & 1 \end{bmatrix} \begin{bmatrix} 1 & 2 & 3 \\ 0 & -3 & -6 \end{bmatrix}$$

depicts the $m < n$ situation. The LU factorization of $A \in \mathbb{R}^{m \times n}$ is guaranteed to exist if $A(1:k, 1:k)$ is nonsingular for $k = 1:\min(m, n)$.

The square LU factorization algorithms above need only minor modification to handle the rectangular case. For example, to handle the $m > n$ case we modify Algorithm 3.2.1 as follows:

for $k = 1:n$

\begin{verbatim}
rows = k + 1:m
A(rows, k) = A(rows, k)/A(k, k)
if $k < n$
    cols = k + 1:n
    A(rows, cols) = A(rows, cols) - A(rows, k)A(k, cols)
end
end
\end{verbatim}

This algorithm requires $mn^2 - n^3/3$ flops.
3.2.12 A Note on Failure

As we know, Gaussian elimination fails unless the first \( n - 1 \) principal submatrices are nonsingular. This rules out some very simple matrices, e.g.,

\[
A = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}.
\]

While \( A \) has perfect 2-norm condition, it fails to have an LU factorization because it has a singular leading principal submatrix.

Clearly, modifications are necessary if Gaussian elimination is to be effectively used in general linear system solving. The error analysis in the following section suggests the needed modifications.

Problems

P3.2.1 Suppose the entries of \( A(\epsilon) \in \mathbb{R}^{n \times n} \) are continuously differentiable functions of the scalar \( \epsilon \). Assume that \( A = A(0) \) and all its principal submatrices are nonsingular. Show that for sufficiently small \( \epsilon \), the matrix \( A(\epsilon) \) has an LU factorization \( A(\epsilon) = L(\epsilon)U(\epsilon) \) and that \( L(\epsilon) \) and \( U(\epsilon) \) are both continuously differentiable.

P3.2.2 Suppose we partition \( A \in \mathbb{R}^{n \times n} \)

\[
A = \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix}
\]

where \( A_{11} \) is \( r \)-by-\( r \). Assume that \( A_{11} \) is nonsingular. The matrix \( S = A_{22} - A_{21}A_{11}^{-1}A_{12} \) is called the Schur complement of \( A_{11} \) in \( A \). Show that if \( A_{11} \) has an LU factorization, then after \( r \) steps of Algorithm 3.2.1, \( A(r + 1:n, r + 1:n) \) houses \( S \). How could \( S \) be obtained after \( r \) steps of (3.2.5)?

P3.2.3 Suppose \( A \in \mathbb{R}^{n \times n} \) has an LU factorization. Show how \( Ax = b \) can be solved without storing the multipliers by computing the LU factorization of the \( n \)-by-\((n + 1) \) matrix \([A \ b]\).

P3.2.4 Describe a variant of Gaussian elimination that introduces zeros into the columns of \( A \) in the order, \( n; -1:2 \) and which produces the factorization \( A = UL \) where \( U \) is unit upper triangular and \( L \) is lower triangular.

P3.2.5 Matrices in \( \mathbb{R}^{n \times n} \) of the form \( N(y, k) = I - ye_k^T \) where \( y \in \mathbb{R}^n \) are said to be Gauss-Jordan transformations. (a) Give a formula for \( N(y, k)^{-1} \) assuming it exists. (b) Given \( x \in \mathbb{R}^n \), under what conditions can \( y \) be found so \( N(y, k)x = e_k \)? (c) Give an algorithm using Gauss-Jordan transformations that overwrites \( A \) with \( A^{-1} \). What conditions on \( A \) ensure the success of your algorithm?

P3.2.6 Extend (3.2.5) so that it can also handle the case when \( A \) has more rows than columns.

P3.2.7 Show how \( A \) can be overwritten with \( L \) and \( U \) in (3.2.5). Organize the three loops so that unit stride access prevails.

P3.2.8 Develop a version of Gaussian elimination in which the innermost of the three loops oversees a dot product.
Notes and References for Sec. 3.2

Schur complements (P3.2.2) arise in many applications. For a survey of both practical and theoretical interest, see

Schur complements are known as "Gauss transforms" in some application areas. The use of Gauss-Jordan transformations (P3.2.5) is detailed in Fox (1964). See also

As we mentioned, inner product versions of Gaussian elimination have been known and used for some time. The names of Crout and Doolittle are associated with these *ijk* techniques. They were popular during the days of desk calculators because there are far fewer intermediate results than in Gaussian elimination. These methods still have attraction because they can be implemented with accumulated inner products. For remarks along these lines see Fox (1964) as well as Stewart (1973, pp. 131-39). See also:

Loop orderings and block issues in LU computations are discussed in

### 3.3 Roundoff Analysis of Gaussian Elimination

We now assess the effect of rounding errors when the algorithms in the previous two sections are used to solve the linear system $Ax = b$. A much more detailed treatment of roundoff error in Gaussian elimination is given in Higham (1996).

Before we proceed with the analysis, it is useful to consider the nearly ideal situation in which no roundoff occurs during the entire solution process except when $A$ and $b$ are stored. Thus, if $fI(b) = b + e$ and the stored matrix $fI(A) = A + E$ is nonsingular, then we are assuming that the computed solution $\tilde{x}$ satisfies

$$(A + E)\tilde{x} = (b + e) \quad \| E \|_\infty \leq u\| A \|_\infty, \quad \| e \|_\infty \leq u\| b \|_\infty. \quad (3.3.1)$$
3.3. ROUNDOFF ANALYSIS OF GAUSSIAN ELIMINATION

That is, \( \hat{x} \) solves a "nearby" system exactly. Moreover, if \( u\kappa_\infty(A) \leq \frac{1}{2} \) (say), then by using Theorem 2.7.2, it can be shown that

\[
\frac{\| x - \hat{x} \|_\infty}{\| x \|_\infty} \leq 4u\kappa_\infty(A) .
\]  

(3.3.2)

The bounds (3.3.1) and (3.3.2) are "best possible" norm bounds. No general \( \infty \)-norm error analysis of a linear equation solver that requires the storage of \( A \) and \( b \) can render sharper bounds. As a consequence, we cannot justifiably criticize an algorithm for returning an inaccurate \( \hat{x} \) if \( A \) is ill-conditioned relative to the machine precision, e.g., \( u\kappa_\infty(A) \approx 1 \).

3.3.1 Errors in the LU Factorization

Let us see how the error bounds for Gaussian elimination compare with the ideal bounds above. We work with the infinity norm for convenience and focus our attention on Algorithm 3.2.3, the outer product version. The error bounds that we derive also apply to Algorithm 3.2.4, the gaxpy formulation.

Our first task is to quantify the roundoff errors associated with the computed triangular factors.

Theorem 3.3.1 Assume that \( A \) is an \( n \)-by-\( n \) matrix of floating point numbers. If no zero pivots are encountered during the execution of Algorithm 3.2.3, then the computed triangular matrices \( \hat{L} \) and \( \hat{U} \) satisfy

\[
\hat{L} \hat{U} = A + H
\]  

(3.3.3)

\[
|H| \leq 3(n - 1)u (|A| + |\hat{L}| |\hat{U}|) + O(u^2) .
\]  

(3.3.4)

Proof. The proof is by induction on \( n \). The theorem obviously holds for \( n = 1 \). Assume it holds for all \( (n - 1) \)-by-\( (n - 1) \) floating point matrices. If

\[
A = \begin{bmatrix}
\alpha & w^T \\
v & B
\end{bmatrix}
\]

\[
1 \\
n - 1
1 \\
n - 1
\]

then \( \hat{z} = fl(v/\alpha) \) and \( \hat{A}_1 = fl(B - \hat{z}w^T) \) are computed in the first step of the algorithm. We therefore have

\[
\hat{z} = \frac{1}{\alpha} v + f \quad |f| \leq u \frac{|v|}{|\alpha|}
\]  

(3.3.5)

and

\[
\hat{A}_1 = B - \hat{z}w^T + F \quad |F| \leq 2u (|B| + |\hat{z}| |w|^T) + O(u^2) .
\]  

(3.3.6)
The algorithm now proceeds to calculate the LU factorization of $\hat{A}_1$. By induction, we compute approximate factors $\hat{L}_1$ and $\hat{U}_1$ for $\hat{A}_1$ that satisfy

$$ \hat{L}_1 \hat{U}_1 = \hat{A}_1 + H_1 \quad (3.3.7) $$

$$ |H_1| \leq 3(n-2)u \left( |\hat{A}_1| + |\hat{L}_1||\hat{U}_1| \right) + O(u^2). \quad (3.3.8) $$

Thus,

$$ \hat{L}\hat{U} \equiv \begin{bmatrix} 1 & 0 \\ \hat{z} & \hat{L}_1 \end{bmatrix} \begin{bmatrix} \alpha & w^T \\ 0 & \hat{U}_1 \end{bmatrix} = A + \begin{bmatrix} 0 & 0 \\ \alpha f & H_1 + F \end{bmatrix} = A + H. $$

From (3.3.6) it follows that

$$ |\hat{A}_1| \leq (1+2u)(|B| + |\hat{z}| |w|^T) + O(u^2), $$

and therefore by using (3.3.7) and (3.3.8) we have

$$ |H_1 + F| \leq 3(n-1)u \left( |B| + |\hat{z}| |w|^T + |\hat{L}_1||\hat{U}_1| \right) + O(u^2). $$

Since $|\alpha f| \leq u|v|$ it is easy to verify that

$$ |H| \leq 3(n-1)u \left\{ \begin{bmatrix} |\alpha| & |w|^T \\ |v| & |B| \end{bmatrix} + \begin{bmatrix} 1 \\ |\hat{z}| \\ 0 \end{bmatrix} \begin{bmatrix} |\alpha| & |w|^T \\ 0 \\ |\hat{U}_1| \end{bmatrix} \right\} + O(u^2) $$

thereby proving the theorem. \( \square \)

We mention that if $A$ is $m$-by-$n$, then the theorem applies with $n$ in (3.3.4) replaced by the smaller of $n$ and $m$.

### 3.3.2 Triangular Solving with Inexact Triangles

We next examine the effect of roundoff error when $\hat{L}$ and $\hat{U}$ are used by the triangular system solvers of §3.1.

**Theorem 3.3.2** Let $\hat{L}$ and $\hat{U}$ be the computed LU factors of the $n$-by-$n$ floating point matrix $A$ obtained by either Algorithm 3.2.3 or 3.2.4. Suppose the methods of §3.1 are used to produce the computed solution $\hat{y}$ to $\hat{L}\hat{y} = b$ and the computed solution $\hat{x}$ to $\hat{U}\hat{x} = \hat{y}$. Then $(A + E)\hat{x} = b$ with

$$ |E| \leq nu \left( 3|A| + 5|\hat{L}||\hat{U}| \right) + O(u^2). \quad (3.3.9) $$
Proof. From (3.1.1) and (3.1.2) we have
\[
(L + F)\hat{y} = b \quad |F| \leq nu|\hat{L}| + O(u^2)
\]
\[
(\hat{U} + G)\hat{x} = \hat{y} \quad |G| \leq nu|\hat{U}| + O(u^2)
\]
and thus
\[
(L + F)(\hat{U} + G)\hat{x} = (\hat{L}\hat{U} + F\hat{U} + \hat{L}G + FG)\hat{x} = b.
\]

From Theorem 3.3.1
\[
\hat{L}\hat{U} = A + H,
\]
with \(|H| \leq 3(n - 1)u(|A| + |\hat{L}||\hat{U}|) + O(u^2)|, and so by defining
\[
E = H + F\hat{U} + \hat{L}G + FG
\]
we find \((A + E)\hat{x} = b\). Moreover,
\[
|E| \leq |H| + |F| |\hat{U}| + |\hat{L}| |G| + O(u^2)
\]
\[
\leq 3nu \left(|A| + |\hat{L}||\hat{U}|\right) + 2nu \left(|\hat{L}||\hat{U}|\right) + O(u^2). \quad \Box
\]

Were it not for the possibility of a large \(|\hat{L}||\hat{U}|\) term, (3.3.9) would compare favorably with the ideal bound in (3.3.1). (The factor \(n\) is of no consequence, cf. the Wilkinson quotation in §2.4.6.) Such a possibility exists, for there is nothing in Gaussian elimination to rule out the appearance of small pivots. If a small pivot is encountered, then we can expect large numbers to be present in \(\hat{L}\) and \(\hat{U}\).

We stress that small pivots are not necessarily due to ill-conditioning as the example \(A = \begin{bmatrix} \epsilon & 1 \\ 1 & 0 \end{bmatrix}\) bears out. Thus, Gaussian elimination can give arbitrarily poor results, even for well-conditioned problems. The method is unstable.

In order to repair this shortcoming of the algorithm, it is necessary to introduce row and/or column interchanges during the elimination process with the intention of keeping the numbers that arise during the calculation suitably bounded. This idea is pursued in the next section.

Example 3.3.1 Suppose \(\beta = 10, t = 3\), floating point arithmetic is used to solve:
\[
\begin{bmatrix}
0.001 & 1.00 \\
1.00 & 2.00
\end{bmatrix}
\begin{bmatrix}
z_1 \\
z_2
\end{bmatrix}
= \begin{bmatrix}
1.00 \\
3.00
\end{bmatrix}.
\]
Applying Gaussian elimination we get
\[
\hat{L} = \begin{bmatrix}
1 & 0 \\
1000 & 1
\end{bmatrix}, \quad \hat{U} = \begin{bmatrix}
0.001 & 1 \\
0 & -1000
\end{bmatrix}
\]
and a calculation shows
\[
\hat{L}\hat{U} = \begin{bmatrix}
0.001 & 1 \\
1 & 2
\end{bmatrix} + \begin{bmatrix}
0 & 0 \\
0 & -2
\end{bmatrix} \equiv A + H.
\]
Moreover, $\begin{bmatrix} 10^{-4} & .001 \\ 10^{-3} & 1.0001 \end{bmatrix}$ is the bounding matrix in (3.3.4), not a severe overestimate of $|H|$. If we go on to solve the problem using the triangular system solvers of §3.1, then using the same precision arithmetic we obtain a computed solution $\hat{x} = (0, 1)^T$. This is in contrast to the exact solution $x = (1.002..., .998...)^T$.

Problems

P3.3.1 Show that if we drop the assumption that $A$ is a floating point matrix in Theorem 3.3.1, then (3.3.4) holds with the coefficient "3" replaced by "4."

P3.3.2 Suppose $A$ is an $n$-by-$n$ matrix and that $\tilde{L}$ and $\tilde{U}$ are produced by Algorithm 3.2.1. (a) How many flops are required to compute $\| L \| \| U \|_\infty$? (b) Show $f(\| L \| \| U \|) \leq (1 + 2nu)\| L \| \| U \| + O(n^2)$.

P3.3.3 Suppose $x = A^{-1}b$. Show that if $e = x - \hat{x}$ (the error) and $r = b - A\hat{x}$ (the residual), then

$$\frac{\| r \|}{\| A \|} \leq \| e \| \leq \| A^{-1} \| \| r \|.$$ 

Assume consistency between the matrix and vector norm.

P3.3.4 Using 2-digit, base 10, floating point arithmetic, compute the LU factorization of

$$A = \begin{bmatrix} 7 & 6 \\ 9 & 8 \end{bmatrix}.$$ 

For this example, what is the matrix $H$ in (3.3.3)?

Notes and References for Sec. 3.3

The original roundoff analysis of Gaussian elimination appears in

Various improvements in the bounds and simplifications in the analysis have occurred over the years. See

3.4 Pivoting

The analysis in the previous section shows that we must take steps to ensure that no large entries appear in the computed triangular factors \( \hat{L} \) and \( \hat{U} \). The example

\[
A = \begin{bmatrix}
.0001 & 1 \\
1 & 1
\end{bmatrix} = \begin{bmatrix}
1 & 0 \\
.10,000 & 1
\end{bmatrix} \begin{bmatrix}
.0001 & 1 \\
0 & -9999
\end{bmatrix} = LU
\]

correctly identifies the source of the difficulty: relatively small pivots. A way out of this difficulty is to interchange rows. In our example, if \( P \) is the permutation

\[
P = \begin{bmatrix}
0 & 1 \\
1 & 0
\end{bmatrix}
\]

then

\[
PA = \begin{bmatrix}
1 & 1 \\
.0001 & 1
\end{bmatrix} = \begin{bmatrix}
1 & 0 \\
.0001 & 1
\end{bmatrix} \begin{bmatrix}
1 & 1 \\
0 & .9999
\end{bmatrix} = LU.
\]

Now the triangular factors are comprised of acceptably small elements.

In this section we show how to determine a permuted version of \( A \) that has a reasonably stable LU factorization. There are several ways to do this and they each correspond to a different pivoting strategy. We focus on partial pivoting and complete pivoting. The efficient implementation of these strategies and their properties are discussed. We begin with a discussion of permutation matrix manipulation.

3.4.1 Permutation Matrices

The stabilizations of Gaussian elimination that are developed in this section involve data movements such as the interchange of two matrix rows. In keeping with our desire to describe all computations in "matrix terms," it is necessary to acquire a familiarity with permutation matrices. A permutation matrix is just the identity with its rows re-ordered, e.g.,

\[
P = \begin{bmatrix}
0 & 0 & 0 & 1 \\
1 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 \\
0 & 1 & 0 & 0
\end{bmatrix}.
\]

An \( n \)-by-\( n \) permutation matrix should never be explicitly stored. It is much more efficient to represent a general permutation matrix \( P \) with an integer \( n \)-vector \( p \). One way to do this is to let \( p(k) \) be the column index of the sole "1" in \( P \)'s \( k \)th row. Thus, \( p = [4 \ 1 \ 3 \ 2] \) is the appropriate encoding of the above \( P \). It is also possible to encode \( P \) on the basis of where the "1" occurs in each column, e.g., \( p = [2 \ 4 \ 3 \ 1] \).
If $P$ is a permutation and $A$ is a matrix, then $PA$ is a row permuted version of $A$ and $AP$ is a column permuted version of $A$. Permutation matrices are orthogonal and so if $P$ is a permutation, then $P^{-1} = P^T$. A product of permutation matrices is a permutation matrix.

In this section we are particularly interested in interchange permutations. These are permutations obtained by merely swapping two rows in the identity, e.g.,

$$E = \begin{bmatrix} 0 & 0 & 0 & 1 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 1 & 0 & 0 & 0 \end{bmatrix}.$$

Interchange permutations can be used to describe row and column swapping. With the above 4-by-4 example, $EA$ is $A$ with rows 1 and 4 interchanged. Likewise, $AE$ is $A$ with columns 1 and 4 swapped.

If $P = E_n \cdots E_1$ and each $E_k$ is the identity with rows $k$ and $p(k)$ interchanged, then $p(1:n)$ is a useful vector encoding of $P$. Indeed, $x \in \mathbb{R}^n$ can be overwritten by $Px$ as follows:

for $k = 1:n$
\[ x(k) \leftarrow x(p(k)) \]
end

Here, the "\rightarrow" notation means "swap contents." Since each $E_k$ is symmetric and $P^T = E_1 \cdots E_n$, the representation can also be used to overwrite $x$ with $P^Tx$:

for $k = n: -1:1$
\[ x(k) \leftarrow x(p(k)) \]
end

It should be noted that no floating point arithmetic is involved in a permutation operation. However, permutation matrix operations often involve the irregular movement of data and can represent a significant computational overhead.

### 3.4.2 Partial Pivoting: The Basic Idea

We show how interchange permutations can be used in LU computations to guarantee that no multiplier is greater than one in absolute value. Suppose

$$A = \begin{bmatrix} 3 & 17 & 10 \\ 2 & 4 & -2 \\ 6 & 18 & -12 \end{bmatrix}.$$
To get the smallest possible multipliers in the first Gauss transform using row interchanges we need \( a_{11} \) to be the largest entry in the first column. Thus, if \( E_1 \) is the interchange permutation

\[
E_1 = \begin{bmatrix}
  0 & 0 & 1 \\
  0 & 1 & 0 \\
  1 & 0 & 0
\end{bmatrix}
\]

then

\[
E_1 A = \begin{bmatrix}
  6 & 18 & -12 \\
  2 & 4 & -2 \\
  3 & 17 & 10
\end{bmatrix}
\]

and

\[
M_1 = \begin{bmatrix}
  1 & 0 & 0 \\
  -1/3 & 1 & 0 \\
  -1/2 & 0 & 1
\end{bmatrix}
\quad \Rightarrow \quad M_1 E_1 A = \begin{bmatrix}
  6 & 18 & -12 \\
  0 & -2 & 2 \\
  0 & 8 & 16
\end{bmatrix}.
\]

Now to get the smallest possible multiplier in \( M_2 \) we need to swap rows 2 and 3. Thus, if

\[
E_2 = \begin{bmatrix}
  1 & 0 & 0 \\
  0 & 0 & 1 \\
  0 & 1 & 0
\end{bmatrix} \quad \text{and} \quad M_2 = \begin{bmatrix}
  1 & 0 & 0 \\
  0 & 1 & 0 \\
  0 & 1/4 & 1
\end{bmatrix}
\]

then

\[
M_2 E_2 M_1 E_1 A = \begin{bmatrix}
  6 & 18 & -12 \\
  0 & 8 & 16 \\
  0 & 0 & 6
\end{bmatrix}.
\]

The example illustrates the basic idea behind the row interchanges. In general we have:

for \( k = 1:n-1 \)

Determine an interchange matrix \( E_k \) with \( E_k(1:k, 1:k) = I_k \)
such that if \( z \) is the \( k \)th column of \( E_k A \), then

\[
|z(k)| = \| z(k:n) \|_{\infty}.
\]

\[
A = E_k A.
\]

Determine the Gauss transform \( M_k \) such that if \( v \) is the \( k \)th column of \( M_k A \), then \( v(k+1:n) = 0 \).

\[
A = M_k A.
\]

end

This particular row interchange strategy is called partial pivoting. Upon completion we emerge with \( M_{n-1} E_{n-1} \cdots M_1 E_1 A = U \), an upper triangular matrix.
As a consequence of the partial pivoting, no multiplier is larger than one in absolute value. This is because

$$|(E_k M_{k-1} \cdots M_1 E_1 A)_{kk}| = \max_{k \leq i \leq n} |(E_k M_{k-1} \cdots M_1 E_1 A)_{ik}|$$

for $k = 1:n-1$. Thus, partial pivoting effectively guards against arbitrarily large multipliers.

3.4.3 Partial Pivoting Details

We are now set to detail the overall Gaussian Elimination with partial pivoting algorithm.

Algorithm 3.4.1 (Gauss Elimination with Partial Pivoting) If $A \in \mathbb{R}^{n \times n}$, then this algorithm computes Gauss transforms $M_1, \cdots, M_{n-1}$ and interchange permutations $E_1, \cdots, E_{n-1}$ such that $M_{n-1} E_{n-1} \cdots M_1 E_1 A = U$ is upper triangular. No multiplier is bigger than 1 in absolute value. $A(1:k, k)$ is overwritten by $U(1:k, k)$, $k = 1:n$. $A(k+1:n, k)$ is overwritten by $-M_k(k+1:n, k)$, $k = 1:n-1$. The integer vector $p(1:n-1)$ defines the interchange permutations. In particular, $E_k$ interchanges rows $k$ and $p(k)$, $k = 1:n-1$.

for $k = 1:n-1$

Determine $\mu$ with $k \leq \mu \leq n$ so $|A(\mu, k)| = \|A(k:n, k)\|_\infty$

$A(k, k:n) \leftarrow A(\mu, k:n)$

$p(k) = \mu$

if $A(k, k) \neq 0$

rows = $k + 1:n$

$A(rows, k) = A(rows, k)/A(k, k)$

$A(rows, rows) = A(rows, rows) - A(rows, k)A(k, rows)$

end

end

Note that if $\|A(k:n, k)\|_\infty = 0$ in step $k$, then in exact arithmetic the first $k$ columns of $A$ are linearly dependent. In contrast to Algorithm 3.2.1, this poses no difficulty. We merely skip over the zero pivot.

The overhead associated with partial pivoting is minimal from the standpoint of floating point arithmetic as there are only $O(n^2)$ comparisons associated with the search for the pivots. The overall algorithm involves $2n^3/3$ flops.

To solve the linear system $Ax = b$ after invoking Algorithm 3.4.1 we

- Compute $y = M_{n-1} E_{n-1} \cdots M_1 E_1 b$.
- Solve the upper triangular system $Ux = y$. 

All the information necessary to do this is contained in the array $A$ and the pivot vector $p$. Indeed, the calculation

\[
\text{for } k = 1:n - 1 \\
\quad b(k) \leftarrow b(p(k)) \\
\quad b(k + 1:n) = b(k + 1:n) - b(k)A(k + 1:n, k)
\]

ends and overwrites $b$ with $M_{n-1}E_{n-1} \cdots M_1E_1$.

Example 3.4.1 If Algorithm 3.4.1 is applied to

\[
A = \begin{bmatrix}
3 & 17 & 10 \\
2 & 4 & -2 \\
6 & 18 & -12
\end{bmatrix},
\]

then upon exit

\[
A = \begin{bmatrix}
6 & 18 & -12 \\
1/3 & 8 & 16 \\
1/2 & -1/4 & 6
\end{bmatrix}
\]

and $p = [3, 3]$. These two quantities encode all the information associated with the reduction:

\[
\begin{bmatrix}
1 & 0 & 0 \\
0 & 1 & 0 \\
0 & 1/4 & 1
\end{bmatrix}
\begin{bmatrix}
1 & 0 & 0 \\
0 & 0 & 1 \\
0 & 1 & 0
\end{bmatrix}
\begin{bmatrix}
1 & 0 & 0 \\
-1/3 & 1 & 0 \\
-1/2 & 0 & 1
\end{bmatrix}
\begin{bmatrix}
0 & 0 & 1 \\
0 & 1 & 0 \\
1 & 0 & 0
\end{bmatrix}
= \begin{bmatrix}
6 & 18 & -12 \\
0 & 8 & 16 \\
0 & 0 & 6
\end{bmatrix}.
\]

3.4.4 Where is $L$?

Gaussian elimination with partial pivoting computes the LU factorization of a row permuted version of $A$. The proof is a messy subscriptsing argument.

Theorem 3.4.1 If Gaussian elimination with partial pivoting is used to compute the upper triangularization

\[
M_{n-1}E_{n-1} \cdots M_1E_1A = U
\]

via Algorithm 3.4.1, then

\[
PA = LU
\]

where $P = E_{n-1} \cdots E_1$ and $L$ is a unit lower triangular matrix with $|l_{ij}| \leq 1$. The $k$th column of $L$ below the diagonal is a permuted version of the $k$th Gauss vector. In particular, if $M_k = I - \tau(k)e_k^T$, then $L(k + 1:n, k) = g(k + 1:n)$ where $g = E_{n-1} \cdots E_{k+1}\tau(k)$.

Proof. A manipulation of (3.4.1) reveals that $\tilde{M}_{n-1} \cdots \tilde{M}_1PA = U$ where $\tilde{M}_{n-1} = M_{n-1}$ and

\[
\tilde{M}_k = E_{n-1} \cdots E_{k+1}M_kE_{k+1} \cdots E_{n-1} \quad k \leq n - 2.
\]
Since each $E_j$ is an interchange permutation involving row $j$ and a row $\mu$ with $\mu \geq j$ we have $E_j(1:j - 1,1:j - 1) = I_{j-1}$. It follows that each $\tilde{M}_k$ is a Gauss transform with Gauss vector $\tilde{r}^{(k)} = E_{n-1} \cdots E_{k+1} r^{(k)}$. □

As a consequence of the theorem, it is easy to see how to change Algorithm 3.4.1 so that upon completion, $A(i,j)$ houses $L(i,j)$ for all $i > j$. We merely apply each $E_k$ to all the previously computed Gauss vectors. This is accomplished by changing the line “$A(k,k:n) \leftrightarrow A(\mu,k:n)$” in Algorithm 3.4.1 to “$A(k,1:n) \leftrightarrow A(\mu,1:n)$.”

Example 3.4.2 The factorization $PA = LU$ of the matrix in Example 3.4.1 is given by
\[
\begin{bmatrix}
0 & 0 & 1 \\
1 & 0 & 0 \\
0 & 1 & 0
\end{bmatrix}
\begin{bmatrix}
3 & 17 & 10 \\
2 & 4 & -2 \\
6 & 18 & -12
\end{bmatrix}
= \begin{bmatrix}
1 & 0 & 0 \\
1/2 & 1 & 0 \\
1/3 & -1/4 & 1
\end{bmatrix}
\begin{bmatrix}
6 & 18 & -12 \\
0 & 8 & 16 \\
0 & 0 & 6
\end{bmatrix}.
\]

3.4.5 The Gaxpy Version

In §3.2 we developed outer product and gaxpy schemes for computing the LU factorization. Having just incorporated pivoting in the outer product version, it is natural to do the same with the gaxpy approach. Recall from (3.2.5) the general structure of the gaxpy LU process:

\begin{align*}
L &= I \\
U &= 0 \\
\text{for } j &= 1:n \\
&\quad \text{if } j = 1 \\
&\quad \quad v(j:n) = A(j:n,j) \\
&\quad \text{else} \\
&\quad \quad \text{Solve } L(1:j - 1,1:j - 1)z = A(1:j - 1,j) \text{ for } z \\
&\quad \quad \quad \text{and set } U(1:j - 1,j) = z. \\
&\quad \quad \quad v(j:n) = A(j:n,j) - L(j:n,1:j - 1)z \\
&\quad \text{end} \\
&\quad \text{if } j < n \\
&\quad \quad L(j + 1:n,j) = v(j + 1:n)/v(j) \\
&\quad \text{end} \\
&\quad U(j,j) = v(j) \\
\end{align*}

With partial pivoting we search $|v(j:n)|$ for its maximal element and proceed accordingly. Assuming $A$ is nonsingular so no zero pivots are encountered we obtain
\[ L = I; U = 0 \]
for \( j = 1:n \)
  if \( j = 1 \)
    \[ v(j:n) = A(j:n, j) \]
  else
    Solve \( L(1:j - 1, 1:j - 1)z = A(1:j - 1, j) \)
    for \( z \) and set \( U(1:j - 1, j) = z \).
    \[ v(j:n) = A(j:n, j) - L(j:n, 1:j - 1)z \]
  end
if \( j < n \)
  Determine \( \mu \) with \( k \leq \mu \leq n \) so \( |v(\mu)| = \| v(j:n) \|_\infty \).
  \[ p(j) = \mu \]
  \[ v(j) \leftrightarrow v(\mu) \]
  \[ A(j, j + 1:n) \leftrightarrow A(\mu, j + 1:n) \]
  \[ L(j + 1:n, j) = v(j + 1:n)/v(j) \]
  if \( j > 1 \)
    \[ L(j, 1:j - 1) \leftrightarrow L(\mu, 1:j - 1) \]
  end
end
\[ U(j, j) = v(j) \]
end

In this implementation, we emerge with the factorization \( PA = LU \) where \( P = E_{n-1} \cdots E_1 \) where \( E_k \) is obtained by interchanging rows \( k \) and \( p(k) \) of the \( n \)-by-\( n \) identity. As with Algorithm 3.4.1, this procedure requires \( 2n^3/3 \) flops and \( O(n^2) \) comparisons.

### 3.4.6 Error Analysis

We now examine the stability that is obtained with partial pivoting. This requires an accounting of the rounding errors that are sustained during elimination and during the triangular system solving. Bearing in mind that there are no rounding errors associated with permutation, it is not hard to show using Theorem 3.3.2 that the computed solution \( \hat{x} \) satisfies \( (A + E)\hat{x} = b \) where

\[
|E| \leq nu \left( 3|A| + 5\hat{P}^T|\hat{L}||\hat{U}| \right) + O(u^2) .
\]  

(3.4.3)

Here we are assuming that \( \hat{P} \), \( \hat{L} \), and \( \hat{U} \) are the computed analogs of \( P \), \( L \), and \( U \) as produced by the above algorithms. Pivoting implies that the elements of \( \hat{L} \) are bounded by one. Thus \( \| \hat{L} \|_\infty \leq n \) and we obtain the bound

\[
\| E \|_\infty \leq nu \left( 3\| A \|_\infty + 5n\| \hat{U} \|_\infty \right) + O(u^2) .
\]  

(3.4.4)
The problem now is to bound $\| \tilde{U} \|_\infty$. Define the growth factor $\rho$ by

$$\rho = \max_{i,j,k} \frac{|\tilde{a}_{ij}^{(k)}|}{\|A\|_\infty}$$  \hspace{1cm} (3.4.5)

where $\tilde{a}_{ij}^{(k)}$ is the computed version of the matrix $A^{(k)} = M_k E_k \cdots M_1 E_1 A$.

It follows that

$$\| E \|_\infty \leq 8n^3 \rho \| A \|_\infty u + O(u^2).$$  \hspace{1cm} (3.4.6)

Whether or not this compares favorably with the ideal bound (3.3.1) hinges upon the size of the growth factor of $\rho$. (The factor $n^3$ is not an operating factor in practice and may be ignored in this discussion.) The growth factor measures how large the numbers become during the process of elimination. In practice, $\rho$ is usually of order 10 but it can also be as large as $2^{n-1}$. Despite this, most numerical analysts regard the occurrence of serious element growth in Gaussian elimination with partial pivoting as highly unlikely in practice. The method can be used with confidence.

**Example 3.4.3** If Gaussian elimination with partial pivoting is applied to the problem

$$\begin{bmatrix}
.001 & 1.00 \\
1.00 & 2.00
\end{bmatrix}
\begin{bmatrix}
z_1 \\
z_2
\end{bmatrix}
= \begin{bmatrix}
1.00 \\
3.00
\end{bmatrix}$$

with $\beta = 10$, $t = 3$, floating point arithmetic, then

$$P = \begin{bmatrix}
0 & 1 \\
1 & 0
\end{bmatrix}, \quad \hat{L} = \begin{bmatrix}
1.00 & 0 \\
.001 & 1.00
\end{bmatrix}, \quad \hat{U} = \begin{bmatrix}
1.00 & 2.00 \\
0 & 1.00
\end{bmatrix}$$

and $\hat{z} = (1.00, .996)^T$. Compare with Example 3.3.1.

**Example 3.4.2** If $A \in \mathbb{R}^{n \times n}$ is defined by

$$a_{ij} = \begin{cases}
1 & \text{if } i = j \text{ or } j = n \\
-1 & \text{if } i > j \\
0 & \text{otherwise}
\end{cases}$$

then $A$ has an LU factorization with $|\ell_{ij}| \leq 1$ and $u_{nn} = 2^{n-1}$.  

### 3.4.7 Block Gaussian Elimination

Gaussian Elimination with partial pivoting can be organized so that it is rich in level-3 operations. We detail a block outer product procedure but block gaupxy and block dot product formulations are also possible. See Dayde and Duff (1988).

Assume $A \in \mathbb{R}^{n \times n}$ and for clarity that $n = rN$. Partition $A$ as follows:

$$A = \begin{bmatrix}
A_{11} & A_{12} \\
A_{21} & A_{22}
\end{bmatrix} \begin{bmatrix}
r \\
r & n-r
\end{bmatrix}$$
The first step in the block reduction is typical and proceeds as follows:

- Use scalar Gaussian elimination with partial pivoting (e.g. a rectangular version of Algorithm 3.4.1) to compute permutation \( P_1 \in \mathbb{R}^{n \times n} \), unit lower triangular \( L_{11} \in \mathbb{R}^{r \times r} \) and upper triangular \( U_{11} \in \mathbb{R}^{r \times r} \) so

\[
P_1 \begin{bmatrix} A_{11} \\ A_{21} \end{bmatrix} = \begin{bmatrix} L_{11} \\ L_{21} \end{bmatrix} U_{11}.
\]

- Apply the \( P_1 \) across the rest of \( A \):

\[
\begin{bmatrix} \tilde{A}_{12} \\ \tilde{A}_{22} \end{bmatrix} = P_1 \begin{bmatrix} A_{12} \\ A_{22} \end{bmatrix}.
\]

- Solve the lower triangular multiple right hand side problem

\[
L_{11} U_{12} = \tilde{A}_{12}.
\]

- Perform the level-3 update

\[
\tilde{A} = \tilde{A}_{22} - L_{21} U_{12}.
\]

With these computations we obtain the factorization

\[
P_1 A = \begin{bmatrix} L_{11} & 0 \\ L_{21} & I_{n-r} \end{bmatrix} \begin{bmatrix} I_r & 0 \\ 0 & \tilde{A} \end{bmatrix} \begin{bmatrix} U_{11} & U_{12} \\ 0 & I_{n-r} \end{bmatrix}.
\]

The process is then repeated on the first \( r \) columns of \( \tilde{A} \).

In general, during step \( k \) (1 \( \leq k \leq N - 1 \)) of the block algorithm we apply scalar Gaussian elimination to a matrix of size \((n - (k - 1)r)\)-by-\( r \). An \( r \)-by-\((n - kr)\) multiple right hand side system is solved and a level 3 update of size \((n - kr)\)-by-\((n - kr)\) is performed. The level 3 fraction for the overall process is approximately given by \( 1 - 3/(2N) \). Thus, for large \( N \) the procedure is rich in matrix multiplication.

### 3.4.8 Complete Pivoting

Another pivot strategy called complete pivoting has the property that the associated growth factor bound is considerably smaller than \( 2^{n-1} \). Recall that in partial pivoting, the \( k \)th pivot is determined by scanning the current subcolumn \( A(k:n,k) \). In complete pivoting, the largest entry in the current submatrix \( A(k:n,k:n) \) is permuted into the \((k,k)\) position. Thus, we compute the upper triangularization \( M_{n-1} E_{n-1} \cdots M_1 E_1 A F_1 \cdots F_{n-1} = U \) with the property that in step \( k \) we are confronted with the matrix

\[
A^{(k-1)} = M_{k-1} E_{k-1} \cdots M_1 E_1 A F_1 \cdots F_{k-1}
\]
and determine interchange permutations $E_k$ and $F_k$ such that

$$\left| \left( E_kA^{(k-1)}F_k \right)_{kk} \right| = \max_{k\leq i,j \leq n} \left| \left( E_kA^{(k-1)}F_k \right)_{ij} \right|.$$

We have the analog of Theorem 3.4.1

**Theorem 3.4.2** If Gaussian elimination with complete pivoting is used to compute the upper triangularization

$$M_{n-1}E_{n-1} \cdots M_1E_1AF_1 \cdots F_{n-1} = U$$

then

$$PAQ = LU$$

where $P = E_{n-1} \cdots E_1$, $Q = F_1 \cdots F_{n-1}$ and $L$ is a unit lower triangular matrix with $|l_{ij}| \leq 1$. The $k$th column of $L$ below the diagonal is a permuted version of the $k$th Gauss vector. In particular, if $M_k = I - \tau(k)e_k^T$ then $L(k+1:n,k) = g(k+1:n)$ where $g = E_{n-1} \cdots E_{k+1}\tau(k)$.

**Proof.** The proof is similar to the proof of Theorem 3.4.1. Details are left to the reader. □

Here is Gaussian elimination with complete pivoting in detail:

**Algorithm 3.4.2 (Gaussian Elimination with Complete Pivoting)**

This algorithm computes the complete pivoting factorization $PAQ = LU$ where $L$ is unit lower triangular and $U$ is upper triangular. $P = E_{n-1} \cdots E_1$ and $Q = F_1 \cdots F_{n-1}$ are products of interchange permutations. $A(1:k, k)$ is overwritten by $U(1:k, k), k = 1:n$. $A(k+1:n,k)$ is overwritten by $L(k+1:n,k), k = 1:n-1$. $E_k$ interchanges rows $k$ and $p(k)$. $F_k$ interchanges columns $k$ and $q(k)$.

```
for k = 1:n - 1
  Determine \( \mu \) with \( k \leq \mu \leq n \) and \( \lambda \) with \( k \leq \lambda \leq n \) so
  \( |A(\mu, \lambda)| = \max\{ |A(i, j)| : i = k:n, j = k:n \} \)
  \( A(k, 1:n) \leftarrow A(\mu, 1:n) \)
  \( A(1:n, k) \leftarrow A(1:n, \lambda) \)
  \( p(k) = \mu \)
  \( q(k) = \lambda \)
  if \( A(k, k) \neq 0 \)
    \( \text{rows} = k + 1:n \)
    \( A(\text{rows}, k) = A(\text{rows}, k)/A(k, k) \)
    \( A(\text{rows}, \text{rows}) = A(\text{rows}, \text{rows}) - A(\text{rows}, k)A(k, \text{rows}) \)
end
```
This algorithm requires \(2n^3/3\) flops and \(O(n^3)\) comparisons. Unlike partial pivoting, complete pivoting involves a significant overhead because of the two-dimensional search at each stage.

### 3.4.9 Comments on Complete Pivoting

Suppose rank\((A) = r < n\). It follows that at the beginning of step \(r + 1\), \(A(r+1:n, r+1:n) = 0\). This implies that \(E_k = F_k = M_k = I\) for \(k = r + 1:n\) and so the algorithm can be terminated after step \(r\) with the following factorization in hand:

\[
P AQ = LU = \begin{bmatrix} L_{11} & 0 \\ L_{21} & I_{n-r} \end{bmatrix} \begin{bmatrix} U_{11} & U_{12} \\ 0 & 0 \end{bmatrix}.
\]

Here \(L_{11}\) and \(U_{11}\) are \(r\)-by-\(r\) and \(L_{21}\) and \(U_{12}^T\) are \((n - r)\)-by-\(r\). Thus, Gaussian elimination with complete pivoting can in principle be used to determine the rank of a matrix. Yet roundoff errors make the probability of encountering an exactly zero pivot remote. In practice one would have to “declare” \(A\) to have rank \(k\) if the pivot element in step \(k+1\) was sufficiently small. The numerical rank determination problem is discussed in detail in §5.4.

Wilkinson (1961) has shown that in exact arithmetic the elements of the matrix \(A^{(k)} = M_k E_k \cdots M_1 E_1 A F_1 \cdots F_k\) satisfy

\[
|a^{(k)}_{ij}| \leq k^{1/2} (2 \cdot 3^{1/2} \cdots k^{1/(k-1)})^{1/2} \max|a_{ij}|.
\]

The upper bound is a rather slow-growing function of \(k\). This fact coupled with vast empirical evidence suggesting that \(\rho\) is always modestly sized (e.g., \(\rho = 10\)) permit us to conclude that Gaussian elimination with complete pivoting is stable. The method solves a nearby linear system \((A + E)x = b\) exactly in the sense of (3.3.1). However, there appears to be no practical justification for choosing complete pivoting over partial pivoting except in cases where rank determination is an issue.

**Example 3.4.6** If Gaussian elimination with complete pivoting is applied to the problem

\[
\begin{bmatrix} .001 & 1.00 \\ 1.00 & 2.00 \end{bmatrix} \begin{bmatrix} z_1 \\ z_2 \end{bmatrix} = \begin{bmatrix} 1.00 \\ 3.00 \end{bmatrix}
\]

with \(\beta = 10, t = 3\), floating arithmetic, then

\[
P = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad Q = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}, \quad L = \begin{bmatrix} 1.00 & 0.00 \\ .500 & 1.00 \end{bmatrix}, \quad U = \begin{bmatrix} 2.00 & 1.00 \\ 0.00 & .499 \end{bmatrix}
\]

and \(\hat{x} = [1.00, 1.00]^T\). Compare with Examples 3.3.1 and 3.4.3.

### 3.4.10 The Avoidance of Pivoting

For certain classes of matrices it is not necessary to pivot. It is important to identify such classes because pivoting usually degrades performance. To
illustrate the kind of analysis required to prove that pivoting can be safely avoided, we consider the case of diagonally dominant matrices. We say that \( A \in \mathbb{R}^{n \times n} \) is strictly diagonally dominant if
\[
|a_{ii}| > \sum_{j \neq i}^{n} |a_{ij}| \quad i = 1:n.
\]

The following theorem shows how this property can ensure a nice, no-pivoting LU factorization.

**Theorem 3.4.3** If \( A^T \) is strictly diagonally dominant, then \( A \) has an LU factorization and \( |l_{ij}| \leq 1 \). In other words, if Algorithm 3.4.1 is applied, then \( P = I \).

**Proof.** Partition \( A \) as follows
\[
A = \begin{bmatrix}
\alpha & w^T \\
v & C
\end{bmatrix}
\]

where \( \alpha \) is 1-by-1 and note that after one step of the outer product LU process we have the factorization
\[
\begin{bmatrix}
\alpha & w^T \\
v & C
\end{bmatrix} = \begin{bmatrix}
1 & 0 \\
v/\alpha & I
\end{bmatrix} \begin{bmatrix}
1 & 0 \\
0 & C - vw^T/\alpha
\end{bmatrix} \begin{bmatrix}
\alpha & w^T \\
0 & I
\end{bmatrix}.
\]

The theorem follows by induction on \( n \) if we can show that the transpose of \( B = C - vw^T/\alpha \) is strictly diagonally dominant. This is because we may then assume that \( B \) has an LU factorization \( B = L_1 U_1 \) and that implies
\[
A = \begin{bmatrix}
1 & 0 \\
v/\alpha & L_1
\end{bmatrix} \begin{bmatrix}
\alpha & w^T \\
0 & U_1
\end{bmatrix} \equiv LU.
\]

But the proof that \( B^T \) is strictly diagonally dominant is straightforward. From the definitions we have
\[
\sum_{i=1}^{n-1} |b_{ij}| = \sum_{i=1}^{n-1} |c_{ij} - v_i w_j/\alpha| \leq \sum_{i=1}^{n-1} |c_{ij}| + \frac{|w_j|}{|\alpha|} \sum_{i=1}^{n-1} |v_i|
\]
\[
\leq (|c_{jj}| - |w_j|) + \frac{|w_j|}{|\alpha|} (|\alpha| - |v_j|)
\]
\[
\leq |c_{jj} - \frac{w_j v_j}{\alpha}| = |b_{jj}|. \square
\]
3.4.11 Some Applications

We conclude with some examples that illustrate how to think in terms of matrix factorizations when confronted with various linear equation situations.

Suppose \( A \) is nonsingular and \( n \)-by-\( n \) and that \( B \) is \( n \)-by-\( p \). Consider the problem of finding \( X \) (\( n \)-by-\( p \)) so \( AX = B \), i.e., the multiple right hand side problem. If \( X = [x_1, \ldots, x_p] \) and \( B = [b_1, \ldots, b_p] \) are column partitions, then

\[
\text{Compute } PA = LU. \\
\text{for } k = 1:p \\
\quad \text{Solve } Ly = Pb_k \\
\quad \text{Solve } Ux_k = y
\]  
\[\text{end} \tag{3.4.9}\]

Note that \( A \) is factored just once. If \( B = I_n \) then we emerge with a computed \( A^{-1} \).

As another example of getting the LU factorization “outside the loop,” suppose we want to solve the linear system \( A^k x = b \) where \( A \in \mathbb{R}^{n \times n} \), \( b \in \mathbb{R}^n \), and \( k \) is a positive integer. One approach is to compute \( C = A^k \) and then solve \( Cx = b \). However, the matrix multiplications can be avoided altogether:

\[
\text{Compute } PA = LU \\
\text{for } j = 1:k \\
\quad \text{Overwrite } b \text{ with the solution to } Ly = Pb. \\
\quad \text{Overwrite } b \text{ with the solution to } Ux = b.
\]  
\[\text{end} \tag{3.4.10}\]

As a final example we show how to avoid the pitfall of explicit inverse computation. Suppose we are given \( A \in \mathbb{R}^{n \times n} \), \( d \in \mathbb{R}^n \), and \( c \in \mathbb{R}^n \) and that we want to compute \( s = c^T A^{-1} d \). One approach is to compute \( X = A^{-1} \) as suggested above and then compute \( s = c^T X d \). A more economical procedure is to compute \( PA = LU \) and then solve the triangular systems \( Ly = Pd \) and \( Ux = y \). It follows that \( s = c^T x \). The point of this example is to stress that when a matrix inverse is encountered in a formula, we must think in terms of solving equations rather than in terms of explicit inverse formation.

Problems

P3.4.1 Let \( A = LU \) be the LU factorization of \( n \)-by-\( n \) \( A \) with \( |\ell_{ij}| \leq 1 \). Let \( a_i^T \) and \( u_i^T \) denote the \( i \)th rows of \( A \) and \( U \), respectively. Verify the equation

\[
u_i^T = a_i^T - \sum_{j=1}^{i-1} \ell_{ij} u_j^T\]
and use it to show that \( \| U \|_\infty \leq 2^{n-1} \| A \|_\infty \). (Hint: Take norms and use induction.)

P3.4.2 Show that if \( PAQ = LU \) is obtained via Gaussian elimination with complete pivoting, then no element of \( U(i, i:n) \) is larger in absolute value than \( |u_{ii}| \).

P3.4.3 Suppose \( A \in \mathbb{R}^{n \times n} \) has an \( LU \) factorization and that \( L \) and \( U \) are known. Give an algorithm which can compute the \( (i, j) \) entry of \( A^{-1} \) in approximately \( (n-j)^2 + (n-i)^2 \) flops.

P3.4.4 Suppose \( \hat{X} \) is the computed inverse obtained via (3.4.9). Give an upper bound for \( \| A\hat{X} - I \|_F \).

P3.4.5 Prove Theorem 3.4.2.

P3.4.6 Extend Algorithm 3.4.3 so that it can factor an arbitrary rectangular matrix.

P3.4.7 Write a detailed version of the block elimination algorithm outlined in §3.4.7.

Notes and References for Sec. 3.4

An Algol version of Algorithm 3.4.1 is given in

The conjecture that \( |a_{ik}^{(k)}| \leq n \max |a_{ij}| \) when complete pivoting is used has been proven in the real \( n = 4 \) case in

Other papers concerned with element growth and pivoting include

3.5. Improving and Estimating Accuracy

The designers of sparse Gaussian elimination codes are interested in the topic of element growth because multipliers greater than unity are sometimes tolerated for the sake of minimizing fill-in. See

The connection between small pivots and near singularity is reviewed in

A pivot strategy that we did not discuss is pairwise pivoting. In this approach, 2-by-2 Gauss transformations are used to zero the lower triangular portion of $A$. The technique is appealing in certain multiprocessor environments because only adjacent rows are combined in each step. See

As a sample paper in which a class of matrices is identified that require no pivoting, see

Just as there are six "conventional" versions of scalar Gaussian elimination, there are also six conventional block formulations of Gaussian elimination. For a discussion of these procedures and their implementation see

3.5 Improving and Estimating Accuracy

Suppose Gaussian elimination with partial pivoting is used to solve the $n$-by-$n$ system $Ax = b$. Assume $t$-digit, base $\beta$ floating point arithmetic is used. Equation (3.4.6) essentially says that if the growth factor is modest then the computed solution $\hat{x}$ satisfies

\[(A + E)\hat{x} = b, \quad \| E \|_{\infty} \approx u \| A \|_{\infty}, \quad u = \frac{1}{2} \beta^{-t}. \tag{3.5.1} \]

In this section we explore the practical ramifications of this result. We begin by stressing the distinction that should be made between residual size and accuracy. This is followed by a discussion of scaling, iterative improvement, and condition estimation. See Higham (1996) for a more detailed treatment of these topics.

We make two notational remarks at the outset. The infinity norm is used throughout since it is very handy in roundoff error analysis and in practical
error estimation. Second, whenever we refer to "Gaussian elimination" in
this section we really mean Gaussian elimination with some stabilizing pivot
strategy such as partial pivoting.

3.5.1 Residual Size Versus Accuracy

The residual of a computed solution \( \hat{x} \) to the linear system \( Ax = b \) is the
vector \( b - A\hat{x} \). A small residual means that \( A\hat{x} \) effectively "predicts" the
right hand side \( b \). From (3.5.1) we have
\[
\| b - A\hat{x} \|_{\infty} \approx u \| A \|_{\infty} \| \hat{x} \|_{\infty}
\]
and so we obtain

Heuristic I. Gaussian elimination produces a solution \( \hat{x} \) with a relatively
small residual.

Small residuals do not imply high accuracy. Combining (3.3.2) and (3.5.1),
we see that
\[
\frac{\| \hat{x} - x \|_{\infty}}{\| x \|_{\infty}} \approx u \kappa_{\infty}(A).
\] (3.5.2)

This justifies a second guiding principle.

Heuristic II. If the unit roundoff and condition satisfy \( u \approx 10^{-d} \) and
\( \kappa_{\infty}(A) \approx 10^{q} \), then Gaussian elimination produces a solution \( \hat{x} \) that
has about \( d - q \) correct decimal digits.

If \( u \kappa_{\infty}(A) \) is large, then we say that \( A \) is ill-conditioned with respect to
the machine precision.

As an illustration of the Heuristics I and II, consider the system
\[
\begin{bmatrix}
.986 & .579 \\
.409 & .237
\end{bmatrix}
\begin{bmatrix}
x_1 \\
x_2
\end{bmatrix}
= \begin{bmatrix}
.235 \\
.107
\end{bmatrix}
\]
in which \( \kappa_{\infty}(A) \approx 700 \) and \( x = (2, -3)^T \). Here is what we find for various
machine precisions:

<table>
<thead>
<tr>
<th>( \beta )</th>
<th>( t )</th>
<th>( \hat{x}_1 )</th>
<th>( \hat{x}_2 )</th>
<th>( \frac{| \hat{x} - x |<em>{\infty}}{| x |</em>{\infty}} )</th>
<th>( \frac{| b - A\hat{x} |<em>{\infty}}{| A |</em>{\infty} | \hat{x} |_{\infty}} )</th>
</tr>
</thead>

</tbody>
</table>

Whether or not one is content with the computed solution \( \hat{x} \) depends on
the requirements of the underlying source problem. In many applications
accuracy is not important but small residuals are. In such a situation, the
\( \hat{x} \) produced by Gaussian elimination is probably adequate. On the other
hand, if the number of correct digits in \( \hat{x} \) is an issue then the situation
is more complicated and the discussion in the remainder of this section is
relevant.
3.5.2 Scaling

Let $\beta$ be the machine base and define the diagonal matrices $D_1$ and $D_2$ by

\[
D_1 = \text{diag}(\beta^1 \ldots \beta^n), \\
D_2 = \text{diag}(\beta^{c_1} \ldots \beta^{c_n}).
\]

The solution to the $n$-by-$n$ linear system $Ax = b$ can be found by solving the scaled system $(D_1^{-1}AD_2)y = D_1^{-1}b$ using Gaussian elimination and then setting $x = D_2y$. The scalings of $A$, $b$, and $y$ require only $O(n^2)$ flops and may be accomplished without roundoff. Note that $D_1$ scales equations and $D_2$ scales unknowns.

It follows from Heuristic II that if $\hat{x}$ and $\hat{y}$ are the computed versions of $x$ and $y$, then

\[
\frac{\|D_2^{-1}(\hat{x} - x)\|_{\infty}}{\|D_2^{-1}x\|_{\infty}} = \frac{\|\hat{y} - y\|_{\infty}}{\|y\|_{\infty}} \approx w\kappa_\infty(D_1^{-1}AD_2).
\]  

(3.5.3)

Thus, if $\kappa_\infty(D_1^{-1}AD_2)$ can be made considerably smaller than $\kappa_\infty(A)$, then we might expect a correspondingly more accurate $\hat{x}$, provided errors are measured in the "$D_2$" norm defined by $\|z\|_{D_2} = \|D_2^{-1}z\|_{\infty}$. This is the objective of scaling. Note that it encompasses two issues: the condition of the scaled problem and the appropriateness of appraising error in the $D_2$-norm.

An interesting but very difficult mathematical problem concerns the exact minimization of $\kappa_p(D_1^{-1}AD_2)$ for general diagonal $D_1$ and various $p$. What results there are in this direction are not very practical. This is hardly discouraging, however, when we recall that (3.5.3) is heuristic and it makes little sense to minimize exactly a heuristic bound. What we seek is a fast, approximate method for improving the quality of the computed solution $\hat{x}$.

One technique of this variety is simple row scaling. In this scheme $D_2$ is the identity and $D_1$ is chosen so that each row in $D_1^{-1}A$ has approximately the same $\infty$-norm. Row scaling reduces the likelihood of adding a very small number to a very large number during elimination—an event that can greatly diminish accuracy.

Slightly more complicated than simple row scaling is row-column equilibration. Here, the object is to choose $D_1$ and $D_2$ so that the $\infty$-norm of each row and column of $D_1^{-1}AD_2$ belongs to the interval $[1/\beta, 1]$ where $\beta$ is the base of the floating point system. For work along these lines see McKeeman (1962).

It cannot be stressed too much that simple row scaling and row-column equilibration do not "solve" the scaling problem. Indeed, either technique can render a worse $\hat{x}$ than if no scaling whatever is used. The ramifications of this point are thoroughly discussed in Forsythe and Moler (1967, chapter 11). The basic recommendation is that the scaling of equations and
unknowns must proceed on a problem-by-problem basis. General scaling strategies are unreliable. It is best to scale (if at all) on the basis of what the source problem proclaims about the significance of each $a_{ij}$. Measurement units and data error may have to be considered.

**Example 3.5.1** (Forsythe and Moler (1967, pp. 34, 40)). If 

$$
\begin{bmatrix}
10 & 100,000 \\
1 & 1 \\
\end{bmatrix}
\begin{bmatrix}
x_1 \\
x_2 \\
\end{bmatrix}
= 
\begin{bmatrix}
100,000 \\
2 \\
\end{bmatrix}
$$

and the equivalent row-scaled problem

$$
\begin{bmatrix}
.0001 & 1 \\
1 & 1 \\
\end{bmatrix}
\begin{bmatrix}
x_1 \\
x_2 \\
\end{bmatrix}
= 
\begin{bmatrix}
1 \\
2 \\
\end{bmatrix}
$$

are each solved using $\beta = 10, t = 3$ arithmetic, then solutions $\hat{x} = (0.00, 1.00)^T$ and $\hat{\hat{x}} = (1.00, 1.00)^T$ are respectively computed. Note that $x = (1.0001\ldots, .9999\ldots)^T$ is the exact solution.

### 3.5.3 Iterative Improvement

Suppose $Ax = b$ has been solved via the partial pivoting factorization $PA = LU$ and that we wish to improve the accuracy of the computed solution $\hat{x}$. If we execute

$$
r = b - A\hat{x}
$$

Solve $Ly = Pr$.

Solve $Uz = y$.

$x_{new} = \hat{x} + z$

then in exact arithmetic $Ax_{new} = A\hat{x} + Ax = (b - r) + r = b$. Unfortunately, the naive floating point execution of these formulae renders an $x_{new}$ that is no more accurate than $\hat{x}$. This is to be expected since $\hat{r} = fl(b - A\hat{x})$ has few, if any, correct significant digits. (Recall Heuristic 1.) Consequently, $\hat{\hat{x}} = fl(A^{-1}r) \approx A^{-1} \cdot r$. Noise $\approx$ Noise is a very poor correction from the standpoint of improving the accuracy of $\hat{x}$. However, Skeel (1980) has done an error analysis that indicates when (3.5.4) gives an improved $x_{new}$ from the standpoint of backwards error. In particular, if the quantity

$$
\tau = (||A|| |A^{-1}| \infty) \left( \max_i (|A||x|)_i / \min_i (|A||x|)_i \right)
$$

is not too big, then (3.5.4) produces an $x_{new}$ such that $(A + E)x_{new} = b$ for very small $E$. Of course, if Gaussian elimination with partial pivoting is used then the computed $\hat{x}$ already solves a nearby system. However, this may not be the case for some of the pivot strategies that are used to preserve sparsity. In this situation, the fixed precision iterative improvement
step (3.5.4) can be very worthwhile and cheap. See Arioli, Demmel, and Duff (1988).

For (3.5.4) to produce a more accurate $z$, it is necessary to compute the residual $b - A\hat{x}$ with extended precision floating point arithmetic. Typically, this means that if $t$-digit arithmetic is used to compute $PA = LU$, $x$, $y$, and $z$, then $2t$-digit arithmetic is used to form $b - A\hat{x}$, i.e., double precision. The process can be iterated. In particular, once we have computed $PA = LU$ and initialize $x = 0$, we repeat the following:

\[
\begin{align*}
  r &= b - Ax \quad \text{(Double Precision)} \\
  \text{Solve } Ly &= Pr \text{ for } y. \\
  \text{Solve } Uz &= y \text{ for } z. \\
  x &= x + z
\end{align*}
\]

(3.5.5)

We refer to this process as *mixed precision iterative improvement*. The original $A$ must be used in the double precision computation of $r$. The basic result concerning the performance of (3.5.5) is summarized in the following heuristic:

**Heuristic III.** If the machine precision $u$ and condition satisfy $u = 10^{-d}$ and $\kappa_{\infty}(A) \approx 10^q$, then after $k$ executions of (3.5.5), $x$ has approximately $\min(d, k(d - q))$ correct digits.

Roughly speaking, if $u \kappa_{\infty}(A) \leq 1$, then iterative improvement can ultimately produce a solution that is correct to full (single) precision. Note that the process is relatively cheap. Each improvement costs $O(n^2)$, to be compared with the original $O(n^3)$ investment in the factorization $PA = LU$. Of course, no improvement may result if $A$ is badly enough conditioned with respect to the machine precision.

The primary drawback of mixed precision iterative improvement is that its implementation is somewhat machine-dependent. This discourages its use in software that is intended for wide distribution. The need for retaining an original copy of $A$ is another aggravation associated with the method.

On the other hand, mixed precision iterative improvement is usually very easy to implement on a given machine that has provision for the accumulation of inner products, i.e., provision for the double precision calculation of inner products between the rows of $A$ and $x$. In a short mantissa computing environment the presence of an iterative improvement routine can significantly widen the class of solvable $Ax = b$ problems.

**Example 3.5.2** If (3.5.5) is applied to the system

\[
\begin{bmatrix}
  .986 & .579 \\
  .409 & .237
\end{bmatrix}
\begin{bmatrix}
  x_1 \\
  x_2
\end{bmatrix} =
\begin{bmatrix}
  .235 \\
  .107
\end{bmatrix}
\]

and $\beta = 10$ and $t = 3$, then iterative improvement produces the following sequence of computed solutions:

\[
\hat{x} =
\begin{bmatrix}
  2.11 \\
  -3.17
\end{bmatrix},
\begin{bmatrix}
  1.99 \\
  -2.99
\end{bmatrix},
\begin{bmatrix}
  2.00 \\
  -3.00
\end{bmatrix}, \ldots
\]
The exact solution is \( x = [2, -3]^T \).

### 3.5.4 Condition Estimation

Suppose that we have solved \( Ax = b \) via \( PA = LU \) and that we now wish to ascertain the number of correct digits in the computed solution \( \hat{x} \). It follows from Heuristic \( \Pi \) that in order to do this we need an estimate of the condition \( \kappa_\infty(\hat{A}) = \| A \|_\infty \| A^{-1} \|_\infty \). Computing \( \| A \|_\infty \) poses no problem as we merely use the formula

\[
\| A \|_\infty = \max_{1 \leq i \leq n} \sum_{j=1}^{n} |a_{ij}|.
\]

The challenge is with respect to the factor \( \| A^{-1} \|_\infty \). Conceivably, we could estimate this quantity by \( \| \hat{X} \|_\infty \), where \( \hat{X} = [\hat{x}_1, \ldots, \hat{x}_n] \) and \( \hat{x}_i \) is the computed solution to \( A x_i = e_i \). (See §3.4.9.) The trouble with this approach is its expense: \( \hat{\kappa}_\infty = \| A \|_\infty \| \hat{X} \|_\infty \) costs about three times as much as \( \hat{x} \).

The central problem of condition estimation is how to estimate the condition number in \( O(n^2) \) flops assuming the availability of \( PA = LU \) or some other factorizations that are presented in subsequent chapters. An approach described in Forsythe and Moler (SLE, p. 51) is based on iterative improvement and the heuristic \( \hat{\kappa}_\infty(\hat{A}) \approx \| z \|_\infty / \| x \|_\infty \) where \( z \) is the first correction of \( x \) in (3.5.5). While the resulting condition estimator is \( O(n^2) \), it suffers from the shortcoming of iterative improvement, namely, machine dependency.

Cline, Moler, Stewart, and Wilkinson (1979) have proposed a very successful approach to the condition estimation problem without this flaw. It is based on exploitation of the implication

\[
Ay = d \quad \implies \quad \| A^{-1} \|_\infty \geq \| y \|_\infty / \| d \|_\infty.
\]

The idea behind their estimator is to choose \( d \) so that the solution \( y \) is large in norm and then set

\[
\hat{\kappa}_\infty = \| A \|_\infty \| y \|_\infty / \| d \|_\infty.
\]

The success of this method hinges on how close the ratio \( \| y \|_\infty / \| d \|_\infty \) is to its maximum value \( \| A^{-1} \|_\infty \).

Consider the case when \( A = T \) is upper triangular. The relation between \( d \) and \( y \) is completely specified by the following column version of back substitution:

\[
p(1:n) = 0
\]
for \( k = n - 1:1 \)

\[
\text{Choose } d(k).
\]

\[
y(k) = (d(k) - p(k))/T(k, k)
\]

\[
p(1:k - 1) = p(1:k - 1) + y(k)T(1:k - 1, k)
\]

end

Normally, we use this algorithm to solve a given triangular system \( Ty = d \). Now, however, we are free to pick the right-hand side \( d \) subject to the "constraint" that \( y \) is large relative to \( d \).

One way to encourage growth in \( y \) is to choose \( d(k) \) from the set \( \{-1, +1\} \) so as to maximize \( y(k) \). If \( p(k) \geq 0 \), then set \( d(k) = -1 \). If \( p(k) < 0 \), then set \( d(k) = +1 \). In other words, (3.5.6) is invoked with \( d(k) = \text{sign}(p(k)) \). Since \( d \) is then a vector of the form \( d(1:n) = (\pm 1, \ldots, \pm 1)^T \), we obtain the estimator \( \kappa_\infty = \| T \|_\infty \| y \|_\infty \).

A more reliable estimator results if \( d(k) \in \{-1, +1\} \) is chosen so as to encourage growth both in \( y(k) \) and the updated running sum given by \( p(1:k - 1, k) + T(1:k - 1, k)y(k) \). In particular, at step \( k \) we compute

\[
y(k)^+ = (1 - p(k))/T(k, k)
\]

\[
s(k)^+ = |y(k)^+| + \| p(1:k - 1) + T(1:k - 1, k)y(k)^+ \|_1
\]

\[
y(k)^- = (-1 - p(k))/T(k, k)
\]

\[
s(k)^- = |y(k)^-| + \| p(1:k - 1) + T(1:k - 1, k)y(k)^- \|_1
\]

and set

\[
y(k) = \begin{cases} 
  y(k)^+ & \text{if } s(k)^+ \geq s(k)^-
  \\
  y(k)^- & \text{if } s(k)^+ < s(k)^-
\end{cases}
\]

This gives

Algorithm 3.5.1 (Condition Estimator) Let \( T \in \mathbb{R}^{n \times n} \) be a nonsingular upper triangular matrix. This algorithm computes unit \( \infty \)-norm \( y \) and a scalar \( \kappa \) so \( \| Ty \|_\infty \approx 1/\| T^{-1} \|_\infty \) and \( \kappa \approx \kappa_\infty(T) \)

\[
p(1:n) = 0
\]

for \( k = n - 1:1 \)

\[
y(k)^+ = (1 - p(k))/T(k, k)
\]

\[
y(k)^- = (-1 - p(k))/T(k, k)
\]

\[
p(k)^+ = p(1:k - 1) + T(1:k - 1, k)y(k)^+
\]

\[
p(k)^- = p(1:k - 1) + T(1:k - 1, k)y(k)^-
\]
if $|y(k)^+| + \| p(k)^+ \|_1 \geq |y(k)^-| + \| p(k)^- \|_1$

$y(k) = y(k)^+$

$p(1:k-1) = p(k)^+$

else

$y(k) = y(k)^-$

$p(1:k-1) = p(k)^-$

end

$\kappa = \| y \|_\infty T \|_\infty$

$y = y/\| y \|_\infty$

The algorithm involves several times the work of ordinary back substitution.

We are now in a position to describe a procedure for estimating the condition of a square nonsingular matrix $A$ whose $PA = LU$ factorization we know:

- Apply the lower triangular version of Algorithm 3.5.1 to $U^T$ and obtain a large norm solution to $U^T y = d$.

- Solve the triangular systems $L^T r = y$, $L w = P r$, and $U z = w$.

- $\kappa_\infty = \| A \|_\infty \| z \|_\infty / \| r \|_\infty$.

Note that $\| z \|_\infty \leq \| A^{-1} \|_\infty \| r \|_\infty$. The method is based on several heuristics. First, if $A$ is ill-conditioned and $PA = LU$, then it is usually the case that $U$ is correspondingly ill-conditioned. The lower triangle $L$ tends to be fairly well-conditioned. Thus, it is more profitable to apply the condition estimator to $U$ than to $L$. The vector $r$, because it solves $A^T P^T r = d$, tends to be rich in the direction of the left singular vector associated with $\sigma_{\min}(A)$. Righthand sides with this property render large solutions to the problem $A z = r$.

In practice, it is found that the condition estimation technique that we have outlined produces good order-of-magnitude estimates of the actual condition number.

Problems

P3.5.1 Show by example that there may be more than one way to equilibrate a matrix.

P3.5.2 Using $\beta = 10, t = 2$ arithmetic, solve

$$
\begin{bmatrix}
11 & 15 \\
5 & 7 \\
\end{bmatrix}
\begin{bmatrix}
x_1 \\
x_2 \\
\end{bmatrix}
= 
\begin{bmatrix}
7 \\
3 \\
\end{bmatrix}
$$

using Gaussian elimination with partial pivoting. Do one step of iterative improvement using $t = 4$ arithmetic to compute the residual. (Do not forget to round the computed residual to two digits.)

P3.5.3 Suppose $P (A + E) = \tilde{L} \tilde{U}$, where $P$ is a permutation, $\tilde{L}$ is lower triangular with $|\tilde{l}_{ij}| \leq 1$, and $\tilde{U}$ is upper triangular. Show that $\kappa_\infty(A) \geq \| A \|_\infty / (\| E \|_\infty + \mu)$ where
3.5. Improving and Estimating Accuracy

\( \mu = \min |u_{ii}| \). Conclude that if a small pivot is encountered when Gaussian elimination with pivoting is applied to \( A \), then \( A \) is ill-conditioned. The converse is not true. (Let \( A = B_n \).

P3.5.4 (Kahan 1966) The system \( Ax = b \)

\[
A = \begin{bmatrix}
2 & -1 & 1 \\
-1 & 10^{-10} & 10^{-10} \\
1 & 10^{-10} & 10^{-10}
\end{bmatrix}, \quad 
\begin{bmatrix}
2(1 + 10^{-10}) \\
-10^{-10} \\
10^{-10}
\end{bmatrix}
\]

has solution \( x = (10^{-10} - 1)T \). (a) Show that if \( (A + E)y = b \) and \( |E| \leq 10^{-8}|A| \), then \( |x - y| \leq 10^{-7}|x| \). That is, small relative changes in \( A \)'s entries do not induce large changes in \( x \) even though \( \kappa_{\infty}(A) = 10^{10} \). (b) Define \( D = \text{diag}(10^{-6}, 10^6, 10^5) \). Show \( \kappa_{\infty}(DAD) \leq 5 \). (c) Explain what is going on in terms of Theorem 2.7.3.

P3.5.5 Consider the matrix:

\[
T = \begin{bmatrix}
1 & 0 & M & -M \\
0 & 1 & -M & M \\
0 & 0 & 1 & 0 \\
0 & 0 & 0 & 1
\end{bmatrix}, \quad M \in \mathbb{R}.
\]

What estimate of \( \kappa_{\infty}(T) \) is produced when (3.5.6) is applied with \( d(k) = -\text{sign}(p(k)) \)?

What estimate does Algorithm 3.5.1 produce? What is the true \( \kappa_{\infty}(T) \)?

P3.5.6 What does Algorithm 3.5.1 produce when applied to the matrix \( B_{n} \) given in (2.7.9)?

Notes and References for Sec. 3.5

The following papers are concerned with the scaling of \( Ax = b \) problems:

Part of the difficulty in scaling concerns the selection of a norm in which to measure errors. An interesting discussion of this frequently overlooked point appears in

§4.5 Block Systems
§4.6 Vandermonde Systems and the FFT
§4.7 Toeplitz and Related Systems

It is a basic tenet of numerical analysis that structure should be exploited whenever solving a problem. In numerical linear algebra, this translates into an expectation that algorithms for general matrix problems can be streamlined in the presence of such properties as symmetry, definiteness, and sparsity. This is the central theme of the current chapter, where our principal aim is to devise special algorithms for computing special variants of the LU factorization.

We begin by pointing out the connection between the triangular factors $L$ and $U$ when $A$ is symmetric. This is achieved by examining the LDM$^T$ factorization in §4.1. We then turn our attention to the important case when $A$ is both symmetric and positive definite, deriving the stable Cholesky factorization in §4.2. Unsymmetric positive definite systems are also investigated in this section. In §4.3, banded versions of Gaussian elimination and other factorization methods are discussed. We then examine the interesting situation when $A$ is symmetric but indefinite. Our treatment of this problem in §4.4 highlights the numerical analyst's ambivalence towards pivoting. We love pivoting for the stability it induces but despise it for the
structure that it can destroy. Fortunately, there is a happy resolution to this conflict in the symmetric indefinite problem.

Any block banded matrix is also banded and so the methods of §4.3 are applicable. Yet, there are occasions when it pays not to adopt this point of view. To illustrate this we consider the important case of block tridiagonal systems in §4.5. Other block systems are discussed as well.

In the final two sections we examine some very interesting $O(n^2)$ algorithms that can be used to solve Vandermonde and Toeplitz systems.

4.1 The LDM$^T$ and LDL$^T$ Factorizations

We want to develop a structure-exploiting method for solving symmetric $Ax = b$ problems. To do this we establish a variant of the LU factorization in which $A$ is factored into a three-matrix product $LDM^T$ where $D$ is diagonal and $L$ and $M$ are unit lower triangular. Once this factorization is obtained, the solution to $Ax = b$ may be found in $O(n^2)$ flops by solving $Ly = b$ (forward elimination), $Dz = y$, and $MTx = z$ (back substitution). The reason for developing the $LDM^T$ factorization is to set the stage for the symmetric case for if $A = A^T$ then $L = M$ and the work associated with the factorization is half of that required by Gaussian elimination. The issue of pivoting is taken up in subsequent sections.

4.1.1 The LDM$^T$ Factorization

Our first result connects the LDM$^T$ factorization with the LU factorization.
Theorem 4.1.1 If all the leading principal submatrices of $A \in \mathbb{R}^{n \times n}$ are nonsingular, then there exist unique unit lower triangular matrices $L$ and $M$ and a unique diagonal matrix $D = \text{diag}(d_1, \ldots, d_n)$ such that $A = LDM^T$.

Proof. By Theorem 3.2.1 we know that $A$ has an LU factorization $A = LU$. Set $D = \text{diag}(d_1, \ldots, d_n)$ with $d_i = u_{ii}$ for $i = 1:n$. Notice that $D$ is nonsingular and that $M^T = D^{-1}U$ is unit upper triangular. Thus, $A = LU = LD(D^{-1}U) = LDM^T$. Uniqueness follows from the uniqueness of the LU factorization as described in Theorem 3.2.1. □

The proof shows that the $LDM^T$ factorization can be found by using Gaussian elimination to compute $A = LU$ and then determining $D$ and $M$ from the equation $U = DM^T$. However, an interesting alternative algorithm can be derived by computing $L$, $D$, and $M$ directly.

Assume that we know the first $j - 1$ columns of $L$, diagonal entries $d_1, \ldots, d_{j-1}$ of $D$, and the first $j - 1$ rows of $M$ for some $j$ with $1 \leq j \leq n$. To develop recipes for $L(j + 1:n, j)$, $M(j, 1:j - 1)$, and $d_j$ we equate $j$th columns in the equation $A = LDM^T$. In particular,

$$A(1:n, j) = Lu \tag{4.1.1}$$

where $u = DM^Te_j$. The "top" half of (4.1.1) defines $v(1:j)$ as the solution of a known lower triangular system:

$$L(1:j, 1:j)v(1:j) = A(1:j, j).$$

Once we know $v$ then we compute

$$d(j) = v(j)$$
$$M(j, i) = v(i)/d(i) \quad i = 1:j - 1.$$\hspace{1cm} (4.1.2)

The "bottom" half of (4.1.1) says $L(j + 1:n, 1:j)v(1:j) = A(j + 1:n, j)$ which can be rearranged to obtain a recipe for the $j$th column of $L$:

$$L(j + 1:n, j)v(j) = A(j + 1:n, j) - L(j + 1:n, 1:j - 1)v(1:j - 1).$$

Thus, $L(j + 1:n, j)$ is a scaled gaxpy operation and overall we obtain

for $j = 1:n$

Solve $L(1:j, 1:j)v(1:j) = A(1:j, j)$ for $v(1:j)$.

for $i = 1:j - 1$

$$M(j, i) = v(i)/d(i) \hspace{1cm} (4.1.2)$$

end

$d(j) = v(j)$

$L(j + 1:n, j) =$

$$(A(j + 1:n, j) - L(j + 1:n, 1:j - 1)v(1:j - 1))/v(j)$$

end
As with the LU factorization, it is possible to overwrite \( A \) with the \( L, D, \) and \( M \) factors. If the column version of forward elimination is used to solve for \( v(1:j) \) then we obtain the following procedure:

**Algorithm 4.1.1 (LDM\(^T\))** If \( A \in \mathbb{R}^{n \times n} \) has an LU factorization then this algorithm computes unit lower triangular matrices \( L \) and \( M \) and a diagonal matrix \( D = \text{diag}(d_1, \ldots, d_n) \) such that \( A = LDM^T \). The entry \( a_{ij} \) is overwritten with \( l_{ij} \) if \( i > j \), with \( d_i \) if \( i = j \), and with \( m_{ji} \) if \( i < j \).

\[
\text{for } j = 1:n \\
\quad \{ \text{Solve } L(1:j,1:j)v(1:j) = A(1:j,j). \} \\
\quad v(1:j) = A(1:j,j) \\
\quad \text{for } k = 1:j - 1 \\
\quad \qquad v(k + 1:j) = v(k + 1:j) - v(k)A(k + 1:j,k) \\
\quad \text{end} \\
\quad \{ \text{Compute } M(j,1:j - 1) \text{ and store in } A(1:j - 1,j). \} \\
\quad \text{for } i = 1:j - 1 \\
\quad \quad A(i,j) = v(i)/A(i,i) \\
\quad \text{end} \\
\quad \{ \text{Store } d(j) \text{ in } A(j,j). \} \\
\quad A(j,j) = v(j) \\
\quad \{ \text{Compute } L(j + 1:n,j) \text{ and store in } A(j + 1:n,j) \} \\
\quad \text{for } k = 1:j - 1 \\
\quad \quad A(j + 1:n) = A(j + 1:n,j) - v(k)A(j + 1:n,k) \\
\quad \text{end} \\
\quad A(j + 1:n,j) = A(j + 1:n,j)/v(j) \\
\text{end}
\]

This algorithm involves the same amount of work as the LU factorization, about \( 2n^3/3 \) flops.

The computed solution \( \hat{x} \) to \( Ax = b \) obtained via Algorithm 4.1.1 and the usual triangular system solvers of §3.1 can be shown to satisfy a perturbed system \((A + E)\hat{x} = b\), where

\[
|E| \leq nu \left( 3|A| + 5|\hat{L}||\hat{D}||\hat{M}^T| \right) + O(u^2) \tag{4.1.3}
\]

and \( \hat{L}, \hat{D}, \) and \( \hat{M} \) are the computed versions of \( L, D, \) and \( M \), respectively.

As in the case of the LU factorization considered in the previous chapter, the upper bound in (4.1.3) is without limit unless some form of pivoting is done. Hence, for Algorithm 4.1.1 to be a practical procedure, it must be modified so as to compute a factorization of the form \( PA = LDM^T \), where \( P \) is a permutation matrix chosen so that the entries in \( L \) satisfy \( |l_{ij}| \leq 1 \). The details of this are not pursued here since they are straightforward and since our main object for introducing the LDM\(^T\) factorization is to motivate
special methods for symmetric systems.

Example 4.1.1

\[
A = \begin{bmatrix}
10 & 10 & 20 \\
20 & 25 & 40 \\
30 & 50 & 61
\end{bmatrix} = \begin{bmatrix}
1 & 0 & 0 \\
2 & 1 & 0 \\
3 & 4 & 1
\end{bmatrix} \begin{bmatrix}
10 & 0 & 0 \\
0 & 5 & 0 \\
0 & 0 & 1
\end{bmatrix} = \begin{bmatrix}
1 & 1 & 2 \\
0 & 1 & 0 \\
0 & 0 & 1
\end{bmatrix}
\]

and upon completion, Algorithm 4.1.1 overwrites \( A \) as follows:

\[
A = \begin{bmatrix}
10 & 1 & 2 \\
2 & 5 & 0 \\
3 & 4 & 1
\end{bmatrix}.
\]

4.1.2 Symmetry and the \( LDL^T \) Factorization

There is redundancy in the \( LDM^T \) factorization if \( A \) is symmetric.

Theorem 4.1.2 If \( A = LDM^T \) is the \( LDM^T \) factorization of a nonsingular symmetric matrix \( A \), then \( L = M \).

Proof. The matrix \( M^{-1}AM^{-T} = M^{-1}LD \) is both symmetric and lower triangular and therefore diagonal. Since \( D \) is nonsingular, this implies that \( M^{-1}L \) is also diagonal. But \( M^{-1}L \) is unit lower triangular and so \( M^{-1}L = I \). \( \square \)

In view of this result, it is possible to halve the work in Algorithm 4.1.1 when it is applied to a symmetric matrix. In the \( j \)th step we already know \( M(j, 1:j - 1) \) since \( M = L \) and we presume knowledge of \( L \)'s first \( j - 1 \) columns. Recall that in the \( j \)th step of (4.1.2) the vector \( v(1:j) \) is defined by the first \( j \) components of \( DM^Te_j \). Since \( M = L \), this says that

\[
v(1:j) = \begin{bmatrix}
d(1)L(j, 1) \\
\vdots \\
d(j - 1)L(j, j - 1) \\
d(j)
\end{bmatrix}.
\]

Hence, the vector \( v(1:j - 1) \) can be obtained by a simple scaling of \( L \)'s \( j \)th row. The formula \( v(j) = A(j, j) - L(j, 1:j - 1)v(1:j - 1) \) can be derived from the \( j \)th equation in \( L(1:j, 1:j)v = A(1:j, j) \) rendering

for \( j = 1:n \)

for \( i = 1:j - 1 \)

\[
v(i) = L(j, i)d(i)
\]

end

\[
v(j) = A(j, j) - L(j, 1:j - 1)v(1:j - 1)
\]

\[
d(j) = v(j)
\]

\[
L(j + 1:n, j) = (A(j + 1:n, j) - L(j + 1:n, 1:j - 1)v(1:j - 1))/v(j)
\]

end
With overwriting this becomes

Algorithm 4.1.2 (LDL^T) If \( A \in \mathbb{R}^{n \times n} \) is symmetric and has an LU factorization then this algorithm computes a unit lower triangular matrix \( L \) and a diagonal matrix \( D = \text{diag}(d_1, \ldots, d_n) \) so \( A = LDL^T \). The entry \( a_{ij} \) is overwritten with \( \ell_{ij} \) if \( i > j \) and with \( d_i \) if \( i = j \).

\[
\begin{align*}
\text{for } j &= 1:n \\
\{ \text{Compute } v(1:j). \} & \\
\text{for } i &= 1:j - 1 \\
\quad v(i) &= A(j, i)A(i, i) \\
\text{end} & \\
\quad v(j) &= A(j, j) - A(j, 1:j - 1)v(1:j - 1) \\
\{ \text{Store } d(j) \text{ and compute } L(j + 1:n, j). \} & \\
A(j, j) &= v(j) \\
A(j + 1:n, j) &= \\
& \quad (A(j + 1:n, j) - A(j + 1:n, 1:j - 1)v(1:j - 1))/v(j)
\end{align*}
\]

end

This algorithm requires \( n^3/3 \) flops, about half the number of flops involved in Gaussian elimination.

In the next section, we show that if \( A \) is both symmetric and positive definite, then Algorithm 4.1.2 not only runs to completion, but is extremely stable. If \( A \) is symmetric but not positive definite, then pivoting may be necessary and the methods of \( \S 4.4 \) are relevant.

Example 4.1.2

\[
A = \begin{bmatrix}
10 & 20 & 30 \\
20 & 45 & 80 \\
30 & 80 & 171
\end{bmatrix} = \begin{bmatrix}
1 & 0 & 0 \\
2 & 1 & 0 \\
3 & 4 & 1
\end{bmatrix}
\begin{bmatrix}
10 & 0 & 0 \\
0 & 5 & 0 \\
0 & 0 & 1
\end{bmatrix}
\begin{bmatrix}
1 & 2 & 3 \\
0 & 1 & 4 \\
0 & 0 & 1
\end{bmatrix}
\]

and so if Algorithm 4.1.2 is applied, \( A \) is overwritten by

\[
A = \begin{bmatrix}
10 & 20 & 30 \\
2 & 5 & 80 \\
3 & 4 & 1
\end{bmatrix}
\]

Problems

P4.1.1 Show that the LDL^T factorization of a nonsingular \( A \) is unique if it exists.

P4.1.2 Modify Algorithm 4.1.1 so that it computes a factorization of the form \( PA = LDL^T \), where \( L \) and \( M \) are both unit lower triangular, \( D \) is diagonal, and \( P \) is a permutation that is chosen so \( |\ell_{ij}| \leq 1 \).

P4.1.3 Suppose the \( n \)-by-\( n \) symmetric matrix \( A = (a_{ij}) \) is stored in a vector \( c \) as follows: \( c = (a_{11}, a_{21}, \ldots, a_{n1}, a_{22}, \ldots, a_{n2}, \ldots, a_{nn}) \). Rewrite Algorithm 4.1.2 with \( A \) stored in this fashion. Get as much indexing outside the inner loops as possible.
P4.1.4 Rewrite Algorithm 4.1.2 for $A$ stored by diagonal. See §1.2.8.

Notes and References for Sec. 4.1

See also

Just as algorithms can be tailored to exploit structure, so can error analysis and perturbation theory:

### 4.2 Positive Definite Systems

A matrix $A \in \mathbb{R}^{n \times n}$ is positive definite if $x^T Ax > 0$ for all nonzero $x \in \mathbb{R}^n$. Positive definite systems constitute one of the most important classes of special $Ax = b$ problems. Consider the 2-by-2 symmetric case. If

$$A = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix}$$

is positive definite then

$$x = (1, 0)^T \Rightarrow x^T Ax = a_{11} > 0$$
$$x = (0, 1)^T \Rightarrow x^T Ax = a_{22} > 0$$
$$x = (1, 1)^T \Rightarrow x^T Ax = a_{11} + 2a_{12} + a_{22} > 0$$
$$x = (1, -1)^T \Rightarrow x^T Ax = a_{11} - 2a_{12} + a_{22} > 0.$$  

The last two equations imply $|a_{12}| \leq (a_{11} + a_{22})/2$. From these results we see that the largest entry in $A$ is on the diagonal and that it is positive. This turns out to be true in general. A symmetric positive definite matrix has a "weighty" diagonal. The mass on the diagonal is not blatantly obvious
as in the case of diagonal dominance but it has the same effect in that it
precludes the need for pivoting. See §3.4.10.

We begin with a few comments about the property of positive definiteness
and what it implies in the unsymmetric case with respect to pivoting.
We then focus on the efficient organization of the Cholesky procedure which
can be used to safely factor a symmetric positive definite $A$. Gaxpy, outer
product, and block versions are developed. The section concludes with a
few comments about the semidefinite case.

4.2.1 Positive Definiteness

Suppose $A \in \mathbb{R}^{n \times n}$ is positive definite. It is obvious that a positive definite
matrix is nonsingular for otherwise we could find a nonzero $x$ so $x^T A x = 0$.
However, much more is implied by the positivity of the quadratic form
$x^T A x$ as the following results show.

Theorem 4.2.1 If $A \in \mathbb{R}^{n \times n}$ is positive definite and $X \in \mathbb{R}^{n \times k}$ has rank
$k$, then $B = X^T A X \in \mathbb{R}^{k \times k}$ is also positive definite.

Proof. If $z \in \mathbb{R}^k$ satisfies $0 \geq z^T B z = (Xz)^T A (Xz)$ then $Xz = 0$. But
since $X$ has full column rank, this implies that $z = 0$. □

Corollary 4.2.2 If $A$ is positive definite then all its principal submatrices
are positive definite. In particular, all the diagonal entries are positive.

Proof. If $v \in \mathbb{R}^k$ is an integer vector with $1 \leq v_1 < \cdots < v_k \leq n$, then
$X = I_n(:,v)$ is a rank $k$ matrix made up columns $v_1, \ldots, v_k$ of the identity.
It follows from Theorem 4.2.1 that $A(v,v) = X^T A X$ is positive definite. □

Corollary 4.2.3 If $A$ is positive definite then the factorization $A = L D M^T$
exists and $D = \text{diag}(d_1, \ldots, d_n)$ has positive diagonal entries.

Proof. From Corollary 4.2.2, it follows that the submatrices $A(1:k,1:k)$
are nonsingular for $k = 1:n$ and so from Theorem 4.1.1 the factorization
$A = L D M^T$ exists. If we apply Theorem 4.2.1 with $X = L^{-T}$ then $B =
D M^T L^{-T} = L^{-1} A L^{-T}$ is positive definite. Since $M^T L^{-T}$ is unit upper
triangular, $B$ and $D$ have the same diagonal and it must be positive. □

There are several typical situations that give rise to positive definite matrices in practice:

- The quadratic form is an energy function whose positivity is guaranteed from physical principles.
- The matrix $A$ equals a cross-product $X^T X$ where $X$ has full column rank. (Positive definiteness follows by setting $A = I_n$ in Theorem 4.2.1.)
- Both $A$ and $A^T$ are diagonally dominant and each $a_{ii}$ is positive.
4.2.2 Unsymmetric Positive Definite Systems

The mere existence of an LDM\(^T\) factorization does not mean that its computation is advisable because the resulting factors may have unacceptably large elements. For example, if \(\epsilon > 0\) then the matrix

\[
A = \begin{bmatrix}
\epsilon & m \\
-m & \epsilon
\end{bmatrix} = \begin{bmatrix}
1 & 0 \\
-m/\epsilon & 1
\end{bmatrix} \begin{bmatrix}
\epsilon & 0 \\
0 & \epsilon + m^2/\epsilon
\end{bmatrix} \begin{bmatrix}
1 & m/\epsilon \\
0 & 1
\end{bmatrix}
\]

is positive definite. But if \(m/\epsilon \gg 1\), then pivoting is recommended.

The following result suggests when to expect element growth in the LDM\(^T\) factorization of a positive definite matrix.

**Theorem 4.2.4** Let \(A \in \mathbb{R}^{n \times n}\) be positive definite and set \(T = (A+A^T)/2\) and \(S = (A - A^T)/2\). If \(A = LDM^T\), then

\[
\| L \| D \| M^T \|_F \leq n \left( \| T \|_2 + \| ST^{-1}S \|_2 \right) \quad (4.2.1)
\]

**Proof.** See Golub and Van Loan (1979). \(\Box\)

The theorem suggests when it is safe not to pivot. Assume that the computed factors \(\hat{L}, \hat{D}, \hat{M}\) satisfy:

\[
\| \hat{L} \| \hat{D} \| \hat{M}^T \|_F \leq c \| L \| D \| M^T \|_F, \quad (4.2.2)
\]

where \(c\) is a constant of modest size. It follows from (4.2.1) and the analysis in §3.3 that if these factors are used to compute a solution to \(Ax = b\), then the computed solution \(\hat{x}\) satisfies \((A + E)\hat{x} = b\) with

\[
\| E \|_F \leq u \left( 3n \| A \|_F + 5cn^2 \left( \| T \|_2 + \| ST^{-1}S \|_2 \right) \right) + O(u^2). \quad (4.2.3)
\]

It is easy to show that \(\| T \|_2 \leq \| A \|_2\), and so it follows that if

\[
\Omega = \frac{\| ST^{-1}S \|_2}{\| A \|_2} \quad (4.2.4)
\]

is not too large then it is safe not to pivot. In other words, the norm of the skew part \(S\) has to be modest relative to the condition of the symmetric part \(T\). Sometimes it is possible to estimate \(\Omega\) in an application. This is trivially the case when \(A\) is symmetric for then \(\Omega = 0\).

4.2.3 Symmetric Positive Definite Systems

When we apply the above results to a symmetric positive definite system we know that the factorization \(A = LDL^T\) exists and moreover is stable to compute. However, in this situation another factorization is available.
Theorem 4.2.5 (Cholesky Factorization) If \( A \in \mathbb{R}^{n \times n} \) is symmetric positive definite, then there exists a unique lower triangular \( G \in \mathbb{R}^{n \times n} \) with positive diagonal entries such that \( A = GG^T \).

Proof. From Theorem 4.1.2, there exists a unit lower triangular \( L \) and a diagonal \( D = \text{diag}(d_1, \ldots, d_n) \) such that \( A = LDL^T \). Since the \( d_k \) are positive, the matrix \( G = L \text{diag}(\sqrt{d_1}, \ldots, \sqrt{d_n}) \) is real lower triangular with positive diagonal entries. It also satisfies \( A = GG^T \). Uniqueness follows from the uniqueness of the \( LDL^T \) factorization. \( \square \)

The factorization \( A = GG^T \) is known as the Cholesky factorization and \( G \) is referred to as the Cholesky triangle. Note that if we compute the Cholesky factorization and solve the triangular systems \( Gy = b \) and \( G^Tx = y \), then \( b = Gy = G(G^Tx) = (GG^T)x = Ax \).

Our proof of the Cholesky factorization in Theorem 4.2.5 is constructive. However, more effective methods for computing the Cholesky triangle can be derived by manipulating the equation \( A = GG^T \). This can be done in several ways as we show in the next few subsections.

Example 4.2.1 The matrix

\[
\begin{bmatrix}
2 & -2 \\
-2 & 5 \\
\end{bmatrix} = \begin{bmatrix}
1 & 0 \\
-1 & 1 \\
\end{bmatrix} \begin{bmatrix}
2 & 0 \\
0 & 3 \\
\end{bmatrix} \begin{bmatrix}
1 & -1 \\
0 & 1 \\
\end{bmatrix} = \begin{bmatrix}
\sqrt{2} & 0 \\
-\sqrt{2} & \sqrt{3} \\
\end{bmatrix} \begin{bmatrix}
\sqrt{2} & -\sqrt{2} \\
0 & \sqrt{3} \\
\end{bmatrix}
\]

is positive definite.

4.2.4 Gaxpy Cholesky

We first derive an implementation of Cholesky that is rich in the gaxpy operation. If we compare \( j \)th columns in the equation \( A = GG^T \) then we obtain

\[
A(:, j) = \sum_{k=1}^{j} G(j, k)G(:, k).
\]

This says that

\[
G(j, j)G(:, j) = A(:, j) - \sum_{k=1}^{j-1} G(j, k)G(:, k) \equiv v. \tag{4.2.5}
\]

If we know the first \( j - 1 \) columns of \( G \), then \( v \) is computable. It follows by equating components in (4.2.5) that

\[
G(j:n, j) = v(j:n)/\sqrt{v(j)}.
\]

This is a scaled gaxpy operation and so we obtain the following gaxpy-based method for computing the Cholesky factorization:
for \( j = 1:n \)
\[
v(j:n) = A(j:n, j)
\]
\[\text{for } k = 1:j - 1\]
\[
v(j:n) = v(j:n) - G(j, k)G(j:n, k)
\]
end
\[
G(j:n, j) = v(j:n)/\sqrt{v(j)}
\]
end

It is possible to arrange the computations so that \( G \) overwrites the lower triangle of \( A \).

Algorithm 4.2.1 (Cholesky: Gaxpy Version) Given a symmetric positive definite \( A \in \mathbb{R}^{n \times n} \), the following algorithm computes a lower triangular \( G \in \mathbb{R}^{n \times n} \) such that \( A = GG^T \). For all \( i \geq j \), \( G(i, j) \) overwrites \( A(i, j) \).

\[
\text{for } j = 1:n
\]
\[\text{if } j > 1\]
\[
A(j:n, j) = A(j:n, j) - A(j:n, 1:j - 1)A(j, 1:j - 1)^T
\]
end
\[
A(j:n, j) = A(j:n, j)/\sqrt{A(j,j)}
\]
end

This algorithm requires \( n^3/3 \) flops.

4.2.5 Outer Product Cholesky

An alternative Cholesky procedure based on outer product (rank-1) updates can be derived from the partitioning

\[
A = \begin{bmatrix}
\alpha & v^T \\
v & B
\end{bmatrix} = \begin{bmatrix}
\beta & 0 \\
v/\beta & I_{n-1}
\end{bmatrix} \begin{bmatrix}
1 & 0 \\
0 & B - vv^T/\alpha
\end{bmatrix} \begin{bmatrix}
\beta & v^T/\beta \\
v/\beta & I_{n-1}
\end{bmatrix}.
\]

(4.2.6)

Here, \( \beta = \sqrt{\alpha} \) and we know that \( \alpha > 0 \) because \( A \) is positive definite. Note that \( B - vv^T/\alpha \) is positive definite because it is a principal submatrix of \( X^TAX \) where

\[
X = \begin{bmatrix}
1 & -v^T/\alpha \\
0 & I_{n-1}
\end{bmatrix}.
\]

If we have the Cholesky factorization \( G_1G_1^T = B - vv^T/\alpha \), then from (4.2.6) it follows that \( A = GG^T \) with

\[
G = \begin{bmatrix}
\beta & 0 \\
v/\beta & G_1
\end{bmatrix}.
\]

Thus, the Cholesky factorization can be obtained through the repeated application of (4.2.6), much in the the style of \( kji \) Gaussian elimination.
Algorithm 4.2.2 (Cholesky: Outer product Version) Given a symmetric positive definite $A \in \mathbb{R}^{n \times n}$, the following algorithm computes a lower triangular $G \in \mathbb{R}^{n \times n}$ such that $A = GG^T$. For all $i \geq j$, $G(i, j)$ overwrites $A(i, j)$.

for $k = 1:n$
    $A(k, k) = \sqrt{A(k, k)}$
    $A(k + 1:n, k) = A(k + 1:n, k)/A(k, k)$
    for $j = k + 1:n$
        $A(j:n, j) = A(j:n, j) - A(j:n, k)A(j, k)$
    end
end

This algorithm involves $n^3/3$ flops. Note that the $j$-loop computes the lower triangular part of the outer product update

\[ A(k + 1:n, k + 1:n) = A(k + 1:n, k + 1:n) - A(k + 1:n, k)A(k + 1:n, k)^T. \]

Recalling our discussion in §1.4.8 about gaxpy versus outer product updates, it is easy to show that Algorithm 4.2.1 involves fewer vector touches than Algorithm 4.2.2 by a factor of two.

4.2.6 Block Dot Product Cholesky

Suppose $A \in \mathbb{R}^{n \times n}$ is symmetric positive definite. Regard $A = (A_{ij})$ and its Cholesky factor $G = (G_{ij})$ as $N$-by-$N$ block matrices with square diagonal blocks. By equating $(i, j)$ blocks in the equation $A = GG^T$ with $i \geq j$ it follows that

\[ A_{ij} = \sum_{k=1}^{j} G_{ik}G_{jk}^T. \]

Defining

\[ S = A_{ij} - \sum_{k=1}^{j-1} G_{ik}G_{jk}^T, \]

we see that $G_{jj}G_{jj}^T = S$ if $i = j$ and that $G_{ij}G_{jj}^T = S$ if $i > j$. Properly sequenced, these equations can be arranged to compute all the $G_{ij}$:

Algorithm 4.2.3 (Cholesky: Block Dot Product Version) Given a symmetric positive definite $A \in \mathbb{R}^{n \times n}$, the following algorithm computes a lower triangular $G \in \mathbb{R}^{n \times n}$ such that $A = GG^T$. The lower triangular part of $A$ is overwritten by the lower triangular part of $G$. $A$ is regarded as an $N$-by-$N$ block matrix with square diagonal blocks.
for $j = 1:N$
  for $i = j:N$
    
    $$S = A_{ij} - \sum_{k=1}^{j-1} G_{ik}G_{jk}^T$$
    
    if $i = j$
      Compute Cholesky factorization $S = G_{jj}G_{jj}^T$.
    else
      Solve $G_{ij}G_{jj}^T = S$ for $G_{ij}$
    end
  end
  Overwrite $A_{ij}$ with $G_{ij}$.
end

The overall process involves $n^3/3$ flops like the other Cholesky procedures that we have developed. The procedure is rich in matrix multiplication assuming a suitable blocking of the matrix $A$. For example, if $n = rN$ and each $A_{ij}$ is $r$-by-$r$, then the level-3 fraction is approximately $1 - (1/N^2)$.

Algorithm 4.2.3 is incomplete in the sense that we have not specified how the products $G_{ik}G_{jk}$ are formed or how the $r$-by-$r$ Cholesky factorizations $S = G_{jj}G_{jj}^T$ are computed. These important details would have to be worked out carefully in order to extract high performance.

Another block procedure can be derived from the gaxpy Cholesky algorithm. After $r$ steps of Algorithm 4.2.1 we know the matrices $G_{11} \in \mathbb{R}^{r \times r}$ and $G_{21} \in \mathbb{R}^{(n-r) \times r}$ in

$$\begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix} = \begin{bmatrix} G_{11} & 0 \\ G_{21} & I_{n-r} \end{bmatrix} \begin{bmatrix} I_r & 0 \\ 0 & \tilde{A} \end{bmatrix} \begin{bmatrix} G_{11} & 0 \\ G_{21} & I_{n-r} \end{bmatrix}^T.$$

We then perform $r$ more steps of gaxpy Cholesky not on $A$ but on the reduced matrix $\tilde{A} = A_{22} - G_{21}G_{21}^T$ which we explicitly form exploiting symmetry. Continuing in this way we obtain a block Cholesky algorithm whose $k$th step involves $r$ gaxpy Cholesky steps on a matrix of order $n - (k-1)r$ followed a level-3 computation having order $n - kr$. The level-3 fraction is approximately equal to $1 - 3/(2N)$ if $n \approx rN$.

4.2.7 Stability of the Cholesky Process

In exact arithmetic, we know that a symmetric positive definite matrix has a Cholesky factorization. Conversely, if the Cholesky process runs to completion with strictly positive square roots, then $A$ is positive definite. Thus, to find out if a matrix $A$ is positive definite, we merely try to compute its Cholesky factorization using any of the methods given above.

The situation in the context of roundoff error is more interesting. The numerical stability of the Cholesky algorithm roughly follows from the in-
equality
\[ g_{ij}^2 \leq \sum_{k=1}^{i} g_{ik}^2 = a_{ii}. \]

This shows that the entries in the Cholesky triangle are nicely bounded. The same conclusion can be reached from the equation \( \|G\|_2^2 = \|A\|_2. \)

The roundoff errors associated with the Cholesky factorization have been extensively studied in a classical paper by Wilkinson (1968). Using the results in this paper, it can be shown that if \( \hat{x} \) is the computed solution to \( Ax = b \), obtained via any of our Cholesky procedures then \( \hat{x} \) solves the perturbed system \( (A + E)\hat{x} = b \) where \( \|E\|_2 \leq c_n u \|A\|_2 \) and \( c_n \) is a small constant depending upon \( n \). Moreover, Wilkinson shows that if \( q_n u_2(A) \leq 1 \) where \( q_n \) is another small constant, then the Cholesky process runs to completion, i.e. no square roots of negative numbers arise.

Example 4.2.2 If Algorithm 4.2.2 is applied to the positive definite matrix
\[
A = \begin{bmatrix}
100 & 15 & .01 \\
15 & 2.3 & .01 \\
.01 & .01 & 1.00
\end{bmatrix}
\]
and \( \beta = 10, t = 2 \), rounded arithmetic used, then \( \hat{y}_{11} = 10, \hat{y}_{21} = 1.5, \hat{y}_{31} = .001 \) and \( \hat{y}_{22} = 0.00 \). The algorithm then breaks down trying to compute \( g_{32} \).  

4.2.8 The Semidefinite Case

A matrix is said to be positive semidefinite if \( x^T Ax \geq 0 \) for all vectors \( x \). Symmetric positive semidefinite (sps) matrices are important and we briefly discuss some Cholesky-like manipulations that can be used to solve various sps problems. Results about the diagonal entries in an sps matrix are needed first.

Theorem 4.2.6 If \( A \in \mathbb{R}^{n \times n} \) is symmetric positive semidefinite, then
\[
\begin{align*}
|a_{ij}| & \leq (a_{ii} + a_{jj})/2 \quad (4.2.7) \\
|a_{ij}| & \leq \sqrt{a_{ii} a_{jj}} \quad (i \neq j) \quad (4.2.8) \\
\max_{i,j} |a_{ij}| & = \max_{i} a_{ii} \quad (4.2.9)
\end{align*}
\]
\[
a_{ii} = 0 \Rightarrow A(i, :) = 0, \quad A(:, i) = 0 \quad (4.2.10)
\]

Proof. If \( x = e_i + e_j \) then \( 0 \leq x^T Ax = a_{ii} + a_{jj} + 2a_{ij} \) while \( x = e_i - e_j \) implies \( 0 \leq x^T Ax = a_{ii} + a_{jj} - 2a_{ij} \). Inequality (4.2.7) follows from these two results. Equation (4.2.9) is an easy consequence of (4.2.7).

To prove (4.2.8) assume without loss of generality that \( i = 1 \) and \( j = 2 \) and consider the inequality
\[
0 \leq \begin{bmatrix} x \\ 1 \end{bmatrix}^T \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix} \begin{bmatrix} x \\ 1 \end{bmatrix} = a_{11}x^2 + 2a_{12}x + a_{22}
\]
which holds since $A(1:2,1:2)$ is also semidefinite. This is a quadratic equation in $z$ and for the inequality to hold, the discriminant $4a_{12}^2 - 4a_{11}a_{22}$ must be negative. Implication (4.2.10) follows from (4.2.8).

Consider what happens when outer product Cholesky is applied to an $sp$ matrix. If a zero $A(k,k)$ is encountered then from (4.2.10) $A(k:n,k)$ is zero and there is “nothing to do” and we obtain

\[
\begin{align*}
\text{for } k = 1:n \\
\text{if } A(k,k) > 0 \\
A(k,k) &= \sqrt{A(k,k)} \\
A(k+1:n,k) &= A(k+1:n,k)/A(k,k) \\
\text{for } j = k+1:n \\
A(j:n,j) &= A(j:n,j) - A(j:n,k)A(j,k)
\end{align*}
\]

Thus, a simple change makes Algorithm 4.2.2 applicable to the semidefinite case. However, in practice rounding errors preclude the generation of exact zeros and it may be preferable to incorporate pivoting.

### 4.2.9 Symmetric Pivoting

To preserve symmetry in a symmetric $A$ we only consider data reorderings of the form $PAP^T$ where $P$ is a permutation. Row permutations ($A \leftarrow PA$) or column permutations ($A \leftarrow AP$) alone destroy symmetry. An update of the form

\[
A \leftarrow PAP^T
\]

is called a symmetric permutation of $A$. Note that such an operation does not move off-diagonal elements to the diagonal. The diagonal of $PAP^T$ is a reordering of the diagonal of $A$.

Suppose at the beginning of the $k$th step in (4.2.11) we symmetrically permute the largest diagonal entry of $A(k:n,k:n)$ into the lead position. If that largest diagonal entry is zero then $A(k:n,k:n) = 0$ by virtue of (4.2.10). In this way we can compute the factorization $PAP^T = GG^T$ where $G \in \mathbb{R}^{n \times (k-1)}$ is lower triangular.

**Algorithm 4.2.4** Suppose $A \in \mathbb{R}^{n \times n}$ is symmetric positive semidefinite and that $\text{rank}(A) = r$. The following algorithm computes a permutation $P$, the index $r$, and an $n$-by-$r$ lower triangular matrix $G$ such that $PAP^T = GG^T$. The lower triangular part of $A(:,1:r)$ is overwritten by the lower triangular part of $G$. $P = P_r \cdots P_1$ where $P_k$ is the identity with rows $k$ and $\text{piv}(k)$ interchanged.
In practice, a tolerance is used to detect small \( A(k, k) \). However, the situation is quite tricky and the reader should consult Higham (1989). In addition, §5.5 has a discussion of tolerances in the rank detection problem. Finally, we remark that a truly efficient implementation of Algorithm 4.2.4 would only access the lower triangular portion of \( A \).

### 4.2.10 The Polar Decomposition and Square Root

Let \( A = U_1 \Sigma_1 V^T \) be the thin SVD of \( A \in \mathbb{R}^{m \times n} \) where \( m \geq n \). Note that

\[
A = (U_1 V^T)(V \Sigma_1 V^T) = ZP
\]

where \( Z = U_1 V^T \) and \( P = V \Sigma_1 V^T \). \( Z \) has orthonormal columns and \( P \) is symmetric positive semidefinite because

\[
x^T P x = (V^T x)^T \Sigma_1 (V^T x) = \sum_{k=1}^{n} \sigma_k y_k^2 \geq 0
\]

where \( y = V^T x \). The decomposition (4.2.12) is called the polar decomposition because it is analogous to the complex number factorization \( z = e^{i \arg(z)} |z| \). See §12.4.1 for further discussion.

Another important decomposition is the matrix square root. Suppose \( A \in \mathbb{R}^{n \times n} \) is symmetric positive semidefinite and that \( A = GG^T \) is its Cholesky factorization. If \( G = U \Sigma V^T \) is \( G \)'s SVD and \( X = U \Sigma U^T \), then \( X \) is symmetric positive semidefinite and

\[
A = GG^T = (U \Sigma V^T)(U \Sigma V^T)^T = U \Sigma^2 U^T = (U \Sigma U^T)(U \Sigma U^T) = X^2.
\]

Thus, \( X \) is a square root of \( A \). It can be shown (most easily with eigenvalue theory) that a symmetric positive semidefinite matrix has a unique symmetric positive semidefinite square root.
Problems

P4.2.1 Suppose that $H = A + iB$ is Hermitian and positive definite with $A, B \in \mathbb{R}^{n \times n}$. This means that $x^H H x > 0$ whenever $x \neq 0$. (a) Show that

$$C = \begin{bmatrix} A & -B \\ B & A \end{bmatrix}$$

is symmetric and positive definite. (b) Formulate an algorithm for solving $(A + iB)(x + iy) = (b + ic)$, where $b, c, x,$ and $y$ are in $\mathbb{R}^n$. It should involve $8n^3/3$ flops. How much storage is required?

P4.2.2 Suppose $A \in \mathbb{R}^{n \times n}$ is symmetric and positive definite. Give an algorithm for computing an upper triangular matrix $R \in \mathbb{R}^{n \times n}$ such that $A = RR^T$.

P4.2.3 Let $A \in \mathbb{R}^{n \times n}$ be positive definite and set $T = (A + A^T)/2$ and $S = (A - A^T)/2$. (a) Show that $\|A^{-1}\|_2 \leq \|T^{-1}\|_2$ and $x^T A^{-1} x \leq x^T T^{-1} x$ for all $x \in \mathbb{R}^n$. (b) Show that if $A = LDL^T$, then $d_k \geq 1/\|T^{-1}\|_2$ for $k = 1:n$.

P4.2.4 Find a 2-by-2 real matrix $A$ with the property that $x^T Ax > 0$ for all real nonzero 2-vectors but which is not positive definite when regarded as a member of $\mathbb{C}^{2 \times 2}$.

P4.2.5 Suppose $A \in \mathbb{R}^{n \times n}$ has a positive diagonal. Show that if both $A$ and $A^T$ are strictly diagonally dominant, then $A$ is positive definite.

P4.2.6 Show that the function $f(x) = (x^T Ax)/2$ is a vector norm on $\mathbb{R}^n$ if and only if $A$ is positive definite.

P4.2.7 Modify Algorithm 4.2.1 so that if the square root of a negative number is encountered, then the algorithm finds a unit vector $z$ so $z^T A z < 0$ and terminates.

P4.2.8 The numerical range $W(A)$ of a complex matrix $A$ is defined to be the set $W(A) = \{x^H A x : x^H x = 1\}$. Show that if $0 \notin W(A)$, then $A$ has an LU factorization.

P4.2.9 Formulate an $m < n$ version of the polar decomposition for $A \in \mathbb{R}^{n \times n}$.

P4.2.10 Suppose $A = I + uu^T$ where $A \in \mathbb{R}^{n \times n}$ and $\|u\|_2 = 1$. Give explicit formulae for the diagonal and subdiagonal of $A$'s Cholesky factor.

P4.2.11 Suppose $A \in \mathbb{R}^{n \times n}$ is symmetric positive definite and that its Cholesky factor is available. Let $e_k = I_n(:, k)$. For $1 \leq i < j \leq n$, let $\alpha_{ij}$ be the smallest real that makes $A + \alpha (e_i e_j^T + e_j e_i^T)$ singular. Likewise, let $\alpha_{ii}$ be the smallest real that makes $(A + \alpha e_i e_i^T)$ singular. Show how to compute these quantities using the Sherman-Morrison-Woodbury formula. How many flops are required to find all the $\alpha_{ij}$?

Notes and References for Sec. 4.2

The definiteness of the quadratic form $x^T A x$ can frequently be established by considering the mathematics of the underlying problem. For example, the discretization of certain partial differential operators gives rise to provably positive definite matrices. Aspects of the unsymmetric positive definite problem are discussed in

4.2. POSITIVE DEFINITE SYSTEMS

Symmetric positive definite systems constitute the most important class of special $Ax = b$ problems. Algol programs for these problems are given in

The roundoff errors associated with the method are analyzed in

The question of how the Cholesky triangle $G$ changes when $A = GG^T$ is perturbed is analyzed in

Nearness/sensitivity issues associated with positive semi-definiteness and the polar decomposition are presented in

Computationally-oriented references for the polar decomposition and the square root are given in §8.6 and §11.2 respectively.
4.3 Banded Systems

In many applications that involve linear systems, the matrix of coefficients is banded. This is the case whenever the equations can be ordered so that each unknown \( x_i \) appears in only a few equations in a "neighborhood" of the \( i \)th equation. Formally, we say that \( A = (a_{ij}) \) has upper bandwidth \( q \) if \( a_{ij} = 0 \) whenever \( j > i + q \) and lower bandwidth \( p \) if \( a_{ij} = 0 \) whenever \( i > j + p \). Substantial economies can be realized when solving banded systems because the triangular factors in \( LU, GG^T, LDM^T \), etc., are also banded.

Before proceeding the reader is advised to review §1.2 where several aspects of band matrix manipulation are discussed.

4.3.1 Band LU Factorization

Our first result shows that if \( A \) is banded and \( A = LU \) then \( L(U) \) inherits the lower (upper) bandwidth of \( A \).

Theorem 4.3.1 Suppose \( A \in \mathbb{R}^{n \times n} \) has an \( LU \) factorization \( A = LU \). If \( A \) has upper bandwidth \( q \) and lower bandwidth \( p \), then \( U \) has upper bandwidth \( q \) and \( L \) has lower bandwidth \( p \).

Proof. The proof is by induction on \( n \). From (3.2.6) we have the factorization

\[
A = \begin{bmatrix} \alpha & w^T \\ v & B \end{bmatrix} = \begin{bmatrix} 1 & 0 \\ v/\alpha & I_{n-1} \end{bmatrix} \begin{bmatrix} 1 & 0 \\ 0 & B - vw^T/\alpha \end{bmatrix} \begin{bmatrix} \alpha & w^T \\ 0 & I_{n-1} \end{bmatrix}.
\]

It is clear that \( B - vw^T/\alpha \) has upper bandwidth \( q \) and lower bandwidth \( p \) because only the first \( q \) components of \( w \) and the first \( p \) components of \( v \) are nonzero. Let \( L_1U_1 \) be the \( LU \) factorization of this matrix. Using the induction hypothesis and the sparsity of \( w \) and \( v \), it follows that

\[
L = \begin{bmatrix} 1 & 0 \\ v/\alpha & L_1 \end{bmatrix} \quad \text{and} \quad U = \begin{bmatrix} \alpha & w^T \\ 0 & U_1 \end{bmatrix}
\]

have the desired bandwidth properties and satisfy \( A = LU \). □

The specialization of Gaussian elimination to banded matrices having an \( LU \) factorization is straightforward.

Algorithm 4.3.1 (Band Gaussian Elimination: Outer Product Version) Given \( A \in \mathbb{R}^{n \times n} \) with upper bandwidth \( q \) and lower bandwidth \( p \), the following algorithm computes the factorization \( A = LU \), assuming it exists. \( A(i, j) \) is overwritten by \( L(i, j) \) if \( i > j \) and by \( U(i, j) \) otherwise.
for $k = 1:n - 1$
  for $i = k + 1: \min(k + p, n)$
    $A(i, k) = A(i, k) / A(k, k)$
  end
  for $j = k + 1: \min(k + q, n)$
    for $i = k + 1: \min(k + p, n)$
      $A(i, j) = A(i, j) - A(i, k) A(k, j)$
    end
  end
end

If $n \gg p$ and $n \gg q$ then this algorithm involves about $2npq$ flops. Band versions of Algorithm 4.1.1 (LDM$^T$) and all the Cholesky procedures also exist, but we leave their formulation to the exercises.

### 4.3.2 Band Triangular System Solving

Analogous savings can also be made when solving banded triangular systems.

**Algorithm 4.3.2 (Band Forward Substitution: Column Version)**

Let $L \in \mathbb{R}^{n \times n}$ be a unit lower triangular matrix having lower bandwidth $p$. Given $b \in \mathbb{R}^n$, the following algorithm overwrites $b$ with the solution to $Lx = b$.

for $j = 1:n$
  for $i = j + 1: \min(j + p, n)$
    $b(i) = b(i) - L(i, j) b(j)$
  end
end

If $n \gg p$ then this algorithm requires about $2np$ flops.

**Algorithm 4.3.3 (Band Back-Substitution: Column Version)**

Let $U \in \mathbb{R}^{n \times n}$ be a nonsingular upper triangular matrix having upper bandwidth $q$. Given $b \in \mathbb{R}^n$, the following algorithm overwrites $b$ with the solution to $Ux = b$.

for $j = n: -1: 1$
  $b(j) = b(j) / U(j, j)$
  for $i = \max(1, j - q): j - 1$
    $b(i) = b(i) - U(i, j) b(j)$
  end
end

If $n \gg q$ then this algorithm requires about $2nq$ flops.
4.3.3 Band Gaussian Elimination with Pivoting

Gaussian elimination with partial pivoting can also be specialized to exploit band structure in $A$. If, however, $PA = LU$, then the band properties of $L$ and $U$ are not quite so simple. For example, if $A$ is tridiagonal and the first two rows are interchanged at the very first step of the algorithm, then $u_{13}$ is nonzero. Consequently, row interchanges expand bandwidth. Precisely how the band enlarges is the subject of the following theorem.

Theorem 4.3.2 Suppose $A \in \mathbb{R}^{n \times n}$ is nonsingular and has upper and lower bandwidths $q$ and $p$, respectively. If Gaussian elimination with partial pivoting is used to compute Gauss transformations

$$M_j = I - \alpha^{(j)} e_j^T \quad j = 1:n - 1$$

and permutations $P_1, \ldots, P_{n-1}$ such that $M_{n-1} P_{n-1} \cdots M_1 P_1 A = U$ is upper triangular, then $U$ has upper bandwidth $p + q$ and $\alpha^{(j)}_i = 0$ whenever $i \leq j$ or $i > j + p$.

Proof. Let $PA = LU$ be the factorization computed by Gaussian elimination with partial pivoting and recall that $P = P_{n-1} \cdots P_1$. Write $P^T = \{ e_{s_1}, \ldots, e_{s_n} \}$, where $\{s_1, \ldots, s_n\}$ is a permutation of $\{1, 2, \ldots, n\}$. If $s_i > i + p$ then it follows that the leading $i$-by-$i$ principal submatrix of $PA$ is singular, since $(PA)_{ij} = \alpha_{s_i,j}$ for $j = 1:s_i - p - 1$ and $s_i - p - 1 \geq i$. This implies that $U$ and $A$ are singular, a contradiction. Thus, $s_i \leq i + p$ for $i = 1:n$ and therefore, $PA$ has upper bandwidth $p + q$. It follows from Theorem 4.3.1 that $U$ has upper bandwidth $p + q$.

The assertion about the $\alpha^{(j)}$ can be verified by observing that $M_j$ need only zero elements $(j + 1, j), \ldots, (j + p, j)$ of the partially reduced matrix $P_j M_{j-1} P_{j-1} \cdots P_1 A$. □

Thus, pivoting destroys band structure in the sense that $U$ becomes "wider" than $A$'s upper triangle, while nothing at all can be said about the bandwidth of $L$. However, since the $j$th column of $L$ is a permutation of the $j$th Gauss vector $\alpha_j$, it follows that $L$ has at most $p + 1$ nonzero elements per column.

4.3.4 Hessenberg LU

As an example of an unsymmetric band matrix computation, we show how Gaussian elimination with partial pivoting can be applied to factor an upper Hessenberg matrix $H$. (Recall that if $H$ is upper Hessenberg then $h_{ij} = 0$, $i > j + 1$). After $k - 1$ steps of Gaussian elimination with partial pivoting
we are left with an upper Hessenberg matrix of the form:

\[
\begin{bmatrix}
  x & x & x & x & x \\
  0 & x & x & x & x \\
  0 & 0 & x & x & x \\
  0 & 0 & x & x & x \\
  0 & 0 & 0 & 0 & x \\
\end{bmatrix}
\]

\(k = 3, n = 5\)

By virtue of the special structure of this matrix, we see that the next permutation, \(P_3\), is either the identity or the identity with rows 3 and 4 interchanged. Moreover, the next Gauss transformation \(M_k\) has a single nonzero multiplier in the \((k + 1, k)\) position. This illustrates the \(k\)th step of the following algorithm.

Algorithm 4.3.4 (Hessenberg LU) Given an upper Hessenberg matrix \(H \in \mathbb{R}^{n \times n}\), the following algorithm computes the upper triangular matrix \(M_{n-1}P_{n-1} \cdots M_1P_1H = U\) where each \(P_k\) is a permutation and each \(M_k\) is a Gauss transformation whose entries are bounded by unity. \(H(i, k)\) is overwritten with \(U(i, k)\) if \(i \leq k\) and by \((M_k)_{k+1,k}\) if \(i = k + 1\). An integer vector \(\text{piv}(1:n - 1)\) encodes the permutations. If \(P_k = I\), then \(\text{piv}(k) = 0\). If \(P_k\) interchanges rows \(k\) and \(k + 1\), then \(\text{piv}(k) = 1\).

\[
\begin{align*}
\text{for } k &= 1:n - 1 \\
\text{if } |H(k, k)| &< |H(k + 1, k)| \\
\text{piv}(k) &= 1; \ H(k:k:n) \leftrightarrow H(k + 1, k:n) \\
\text{else} \\
\text{piv}(k) &= 0 \\
\text{end} \\
\text{if } H(k, k) &\neq 0 \\
t &= -H(k + 1, k)/H(k, k) \\
\text{for } j &= k + 1:n \\
H(k + 1, j) &= H(k + 1, j) + tH(k, j) \\
\text{end} \\
H(k + 1, k) &= t \\
\text{end}
\end{align*}
\]

This algorithm requires \(n^2\) flops.

### 4.3.5 Band Cholesky

The rest of this section is devoted to banded \(Ax = b\) problems where the matrix \(A\) is also symmetric positive definite. The fact that pivoting is unnecessary for such matrices leads to some very compact, elegant algorithms. In particular, it follows from Theorem 4.3.1 that if \(A = GGT^T\) is the Cholesky factorization of \(A\), then \(G\) has the same lower bandwidth as \(A\).
This leads to the following banded version of Algorithm 4.2.1, gaxpy-based Cholesky

**Algorithm 4.3.5 (Band Cholesky: Gaxpy Version)** Given a symmetric positive definite \( A \in \mathbb{R}^{n \times n} \) with bandwidth \( p \), the following algorithm computes a lower triangular matrix \( G \) with lower bandwidth \( p \) such that \( A = GG^T \). For all \( i \geq j \), \( G(i, j) \) overwrites \( A(i, j) \).

\[
\begin{align*}
\text{for } j = 1:n \\
\quad \text{for } k = \max(1, j - p):j - 1 \\
\quad \quad \lambda = \min(k + p, n) \\
\quad \quad A(j:j, j) = A(j:j, j) - A(j, k)A(j:j, k) \\
\quad \text{end} \\
\quad \lambda = \min(j + p, n) \\
\quad A(j:j, j) = A(j:j, j)/\sqrt{A(j,j)} \\
\text{end}
\end{align*}
\]

If \( n \gg p \) then this algorithm requires about \( n(p^2 + 3p) \) flops and \( n \) square roots. Of course, in a serious implementation an appropriate data structure for \( A \) should be used. For example, if we just store the nonzero lower triangular part, then a \((p + 1)\)-by-\( n \) array would suffice. (See §1.2.6)

If our band Cholesky procedure is coupled with appropriate band triangular solve routines then approximately \( np^2 + 7np + 2n \) flops and \( n \) square roots are required to solve \( Ax = b \). For small \( p \) it follows that the square roots represent a significant portion of the computation and it is preferable to use the \( LDL^T \) approach. Indeed, a careful flop count of the steps \( A = LDL^T \), \( Ly = b \), \( Dx = y \), and \( L^T x = z \) reveals that \( np^2 + 8np + n \) flops and no square roots are needed.

### 4.3.6 Tridiagonal System Solving

As a sample narrow band \( LDL^T \) solution procedure, we look at the case of symmetric positive definite tridiagonal systems. Setting

\[
L = \begin{bmatrix}
1 & & & 0 \\
e_1 & 1 & & \\
& \ddots & \ddots & \\
& & \ddots & \\
0 & \cdots & e_{n-1} & 1
\end{bmatrix}
\]
and $D = \text{diag}(d_1, \ldots, d_n)$ we deduce from the equation $A = LDL^T$ that:

\[
\begin{align*}
    a_{11} &= d_1 \\
    a_{k,k-1} &= e_{k-1}d_{k-1} \\
    a_{kk} &= d_k + e_{k-1}^2d_{k-1} = d_k + e_{k-1}a_{k,k-1}
\end{align*}
\quad k = 2:n
\]

Thus, the $d_i$ and $e_i$ can be resolved as follows:

\[
\begin{align*}
    d_1 &= a_{11} \\
    \text{for } k = 2:n \\
    e_{k-1} &= a_{k,k-1}/d_{k-1}; \\
    d_k &= a_{kk} - e_{k-1}a_{k,k-1}
\end{align*}
\]

To obtain the solution to $Ax = b$ we solve $Ly = b$, $Dz = y$, and $L^Tz = z$. With overwriting we obtain

Algorithm 4.3.6 (Symmetric, Tridiagonal, Positive Definite System Solver) Given an $n$-by-$n$ symmetric, tridiagonal, positive definite matrix $A$ and $b \in \mathbb{R}^n$, the following algorithm overwrites $b$ with the solution to $Ax = b$. It is assumed that the diagonal of $A$ is stored in $d(1:n)$ and the superdiagonal in $e(1:n-1)$.

\[
\begin{align*}
    \text{for } k = 2:n \\
    t &= e(k-1); \\
    e(k-1) &= t/d(k-1); \\
    d(k) &= d(k) - te(k-1)
\end{align*}
\]

\[
\begin{align*}
    \text{end} \\
    \text{for } k = 2:n \\
    b(k) &= b(k) - e(k-1)b(k-1)
\end{align*}
\]

\[
\begin{align*}
    \text{end} \\
    b(n) &= b(n)/d(n) \\
    \text{for } k = n-1:1:1 \\
    b(k) &= b(k)/d(k) - e(k)b(k+1)
\end{align*}
\]

This algorithm requires $8n$ flops.

4.3.7 Vectorization Issues

The tridiagonal example brings up a sore point: narrow band problems and vector/pipeline architectures do not mix well. The narrow band implies short vectors. However, it is sometimes the case that large, independent sets of such problems must be solved at the same time. Let us look at how such a computation should be arranged in light of the issues raised in §1.4.

For simplicity, assume that we must solve the $n$-by-$n$ unit lower bidiagonal systems

\[A^{(k)}x^{(k)} = b^{(k)} \quad k = 1:m\]
and that \( m \geq n \). Suppose we have arrays \( E(1:n-1, 1:m) \) and \( B(1:n, 1:m) \) with the property that \( E(1:n - 1, k) \) houses the subdiagonal of \( A^{(k)} \) and \( B(1:n, k) \) houses the \( k \)th right hand side \( b^{(k)} \). We can overwrite \( b^{(k)} \) with the solution \( x^{(k)} \) as follows:

\[
\text{for } k = 1:m \\
\quad \text{for } i = 2:n \\
\quad \quad B(i, k) = B(i, k) - E(i - 1, k)B(i - 1, k) \\
\quad \text{end} \\
\text{end}
\]

The problem with this algorithm, which sequentially solves each bidiagonal system in turn, is that the inner loop does not vectorize. This is because of the dependence of \( B(i, k) \) on \( B(i - 1, k) \). If we interchange the \( k \) and \( i \) loops we get

\[
\text{for } i = 2:n \\
\quad \text{for } k = 1:m \\
\quad \quad B(i, k) = B(i, k) - E(i - 1, k)B(i - 1, k) \\
\quad \text{end} \\
\text{end}
\]

(4.3.1)

Now the inner loop vectorizes well as it involves a vector multiply and a vector add. Unfortunately, (4.3.1) is not a unit stride procedure. However, this problem is easily rectified if we store the subdiagonals and right-hand-sides by row. That is, we use the arrays \( E(1:m, 1:n - 1) \) and \( B(1:m, 1:n - 1) \) and store the subdiagonal of \( A^{(k)} \) in \( E(k, 1:n - 1) \) and \( b^{(k)^T} \) in \( B(k, 1:n) \). The computation (4.3.1) then transforms to

\[
\text{for } i = 2:n \\
\quad \text{for } k = 1:m \\
\quad \quad B(k, i) = B(k, i) - E(k, i - 1)B(k, i - 1) \\
\quad \text{end} \\
\text{end}
\]

illustrating once again the effect of data structure on performance.

### 4.3.8 Band Matrix Data Structures

The above algorithms are written as if the matrix \( A \) is conventionally stored in an \( n \)-by-\( n \) array. In practice, a band linear equation solver would be organized around a data structure that takes advantage of the many zeroes in \( A \). Recall from §1.2.6 that if \( A \) has lower bandwidth \( p \) and upper bandwidth \( q \) it can be represented in a \( (p + q + 1) \)-by-\( n \) array \( A.band \) where band entry \( a_{ij} \) is stored in \( A.band(i - j + q + 1, j) \). In this arrangement, the nonzero portion of \( A \)'s \( j \)th column is housed in the \( j \)th column of \( A.band \). Another possible band matrix data structure that we discussed in §1.2.8
involves storing \( A \) by diagonal in a 1-dimensional array \( A_{\text{diag}} \). Regardless of the data structure adopted, the design of a matrix computation with a band storage arrangement requires care in order to minimize subscripting overheads.

Problems

P4.3.1 Derive a banded LDM* procedure similar to Algorithm 4.3.1.

P4.3.2 Show how the output of Algorithm 4.3.4 can be used to solve the upper Hessenberg system \( Hx = b \).

P4.3.3 Give an algorithm for solving an unsymmetric tridiagonal system \( Ax = b \) that uses Gaussian elimination with partial pivoting. It should require only four \( n \)-vectors of floating point storage for the factorization.

P4.3.4 For \( C \in \mathbb{R}^{n \times n} \) define the profile indices \( m(C, i) = \min\{j : c_{ij} \neq 0\} \), where \( i = 1:n \). Show that if \( A = GG^T \) is the Cholesky factorization of \( A \), then \( m(A, i) = m(C, i) \) for \( i = 1:n \). (We say that \( G \) has the same profile as \( A \).)

P4.3.5 Suppose \( A \in \mathbb{R}^{n \times n} \) is symmetric positive definite with profile indices \( m_i = m(A, i) \) where \( i = 1:n \). Assume that \( A \) is stored in a one-dimensional array \( v \) as follows: \( v = (a_{11}, a_{22}, a_{33}, \ldots, a_{n-1, n-1}, a_{nn}) \). Write an algorithm that overwrites \( v \) with the corresponding entries of the Cholesky factor \( G \) and then uses this factorization to solve \( Ax = b \). How many flops are required?

P4.3.6 For \( C \in \mathbb{R}^{n \times n} \) define \( p(C, i) = \max\{j : c_{ij} \neq 0\} \). Suppose that \( A \in \mathbb{R}^{n \times n} \) has an LU factorization \( A = LU \) and that:

\[
\begin{align*}
m(A, 1) & \leq m(A, 2) \leq \cdots \leq m(A, n) \\
p(A, 1) & \leq p(A, 2) \leq \cdots \leq p(A, n)
\end{align*}
\]

Show that \( m(A, i) = m(L, i) \) and \( p(A, i) = p(U, i) \) for \( i = 1:n \). Recall the definition of \( m(A, i) \) from P4.3.4.

P4.3.7 Develop a gaxpy version of Algorithm 4.3.1.

P4.3.8 Develop a unit stride, vectorizable algorithm for solving the symmetric positive definite tridiagonal systems \( A^{(k)}x^{(k)} = b^{(k)} \). Assume that the diagonals, superdiagonals, and right hand sides are stored by row in arrays \( D \), \( E \), and \( B \) and that \( b^{(k)} \) is overwritten with \( x^{(k)} \).

P4.3.9 Develop a version of Algorithm 4.3.1 in which \( A \) is stored by diagonal.

P4.3.10 Give an example of a 3-by-3 symmetric positive definite matrix whose tridiagonal part is not positive definite.

P4.3.11 Consider the \( Ax = b \) problem where

\[
A = \begin{bmatrix}
2 & -1 & 0 & \cdots & 0 & -1 \\
-1 & 2 & -1 & \ddots & \vdots & 0 \\
0 & -1 & 2 & \ddots & \ddots & \vdots \\
\vdots & \ddots & \ddots & \ddots & \ddots & \vdots \\
0 & \cdots & \cdots & \cdots & 2 & -1 \\
-1 & 0 & \cdots & 0 & -1 & 2
\end{bmatrix}
\]

This kind of matrix arises in boundary value problems with periodic boundary conditions.

(a) Show \( A \) is singular. (b) Give conditions that \( b \) must satisfy for there to exist a solution and specify an algorithm for solving it. (c) Assume that \( n \) is even and consider the permutation

\[
P = [e_1, e_n, e_2, e_{n-1}, e_3, \ldots]
\]
where $e_k$ is the $k$th column of $I_n$. Describe the transformed system $P^T A P(P^T x) = P^T b$ and show how to solve it. Assume that there is a solution and ignore pivoting.

Notes and References for Sec. 4.3

The literature concerned with banded systems is immense. Some representative papers include

A topic of considerable interest in the area of banded matrices deals with methods for reducing the width of the band. See

As we mentioned, tridiagonal systems arise with particular frequency. Thus, it is not surprising that a great deal of attention has been focused on special methods for this class of banded problems.

Chapter 4 of George and Liu (1981) contains a nice survey of band methods for positive definite systems.
4.4 Symmetric Indefinite Systems

A symmetric matrix whose quadratic form $x^T Ax$ takes on both positive and negative values is called indefinite. Although an indefinite $A$ may have an $LDL^T$ factorization, the entries in the factors can have arbitrary magnitude:

$$
\begin{bmatrix}
\epsilon & 1 \\
1 & 0
\end{bmatrix} = 
\begin{bmatrix}
1 & 0 \\
1/\epsilon & 1
\end{bmatrix}
\begin{bmatrix}
\epsilon & 0 \\
0 & -1/\epsilon
\end{bmatrix}
\begin{bmatrix}
1 & 0
\end{bmatrix}^T.
$$

Of course, any of the pivot strategies in §3.4 could be invoked. However, they destroy symmetry and with it, the chance for a "Cholesky speed" indefinite system solver. Symmetric pivoting, i.e., data reshufflings of the form $A \leftarrow PAP^T$, must be used as we discussed in §4.2.9. Unfortunately, symmetric pivoting does not always stabilize the $LDL^T$ computation. If $\epsilon_1$ and $\epsilon_2$ are small then regardless of $P$, the matrix

$$
\tilde{A} = P \begin{bmatrix}
\epsilon_1 & 1 \\
1 & \epsilon_2
\end{bmatrix} P^T
$$

has small diagonal entries and large numbers surface in the factorization. With symmetric pivoting, the pivots are always selected from the diagonal and trouble results if these numbers are small relative to what must be zeroed off the diagonal. Thus, $LDL^T$ with symmetric pivoting cannot be recommended as a reliable approach to symmetric indefinite system solving. It seems that the challenge is to involve the off-diagonal entries in the pivoting process while at the same time maintaining symmetry.

In this section we discuss two ways to do this. The first method is due to Aasen(1971) and it computes the factorization

$$
PAP^T = LTL^T \quad (4.4.1)
$$

where $L = (\ell_{ij})$ is unit lower triangular and $T$ is tridiagonal. $P$ is a permutation chosen such that $|\ell_{ij}| \leq 1$. In contrast, the diagonal pivoting method due to Bunch and Parlett (1971) computes a permutation $P$ such that

$$
PAP^T = LDL^T \quad (4.4.2)
$$

where $D$ is a direct sum of 1-by-1 and 2-by-2 pivot blocks. Again, $P$ is chosen so that the entries in the unit lower triangular $L$ satisfy $|\ell_{ij}| \leq 1$. Both factorizations involve $n^3/3$ flops and once computed, can be used to solve $Ax = b$ with $O(n^2)$ work:

$$
PAP^T = LTL^T, \quad Lz = Pb, Tw = z, L^Ty = w, x = Py \quad \Rightarrow \quad Ax = b
$$

$$
PAP^T = LDL^T, \quad Lz = Pb, Dw = z, L^Ty = w, x = Py \quad \Rightarrow \quad Ax = b
$$

The only thing "new" to discuss in these solution procedures are the $Tw = z$ and $Dw = z$ systems.
In Aasen’s method, the symmetric indefinite tridiagonal system $Tw = z$ is solved in $O(n)$ time using band Gaussian elimination with pivoting. Note that there is no serious price to pay for the disregard of symmetry at this level since the overall process is $O(n^3)$.

In the diagonal pivoting approach, the $Dw = z$ system amounts to a set of 1-by-1 and 2-by-2 symmetric indefinite systems. The 2-by-2 problems can be handled via Gaussian elimination with pivoting. Again, there is no harm in disregarding symmetry during this $O(n)$ phase of the calculation.

Thus, the central issue in this section is the efficient computation of the factorizations (4.4.1) and (4.4.2).

### 4.4.1 The Parlett-Reid Algorithm

Parlett and Reid (1970) show how to compute (4.4.1) using Gauss transforms. Their algorithm is sufficiently illustrated by displaying the $k = 2$ step for the case $n = 5$. At the beginning of this step the matrix $A$ has been transformed to

$$A^{(1)} = M_1 P_1 A P_1^T M_1^T = \begin{bmatrix}
\alpha_1 & \beta_1 & 0 & 0 & 0 \\
\beta_1 & \alpha_2 & v_3 & v_4 & v_5 \\
0 & v_3 & x & x & x \\
0 & v_4 & x & x & x \\
0 & v_5 & x & x & x
\end{bmatrix}$$

where $P_1$ is a permutation chosen so that the entries in the Gauss transformation $M_1$ are bounded by unity in modulus. Scanning the vector $(v_3 \ v_4 \ v_5)^T$ for its largest entry, we now determine a 3-by-3 permutation $P_2$ such that

$$P_2 \begin{bmatrix} v_3 \\ v_4 \\ v_5 \end{bmatrix} = \begin{bmatrix} \tilde{v}_3 \\ \tilde{v}_4 \\ \tilde{v}_5 \end{bmatrix} \Rightarrow |\tilde{v}_3| = \max\{|\tilde{v}_3|, |\tilde{v}_4|, |\tilde{v}_5|\}.$$

If this maximal element is zero, we set $M_2 = P_2 = I$ and proceed to the next step. Otherwise, we set $P_2 = \text{diag}(I_2, \tilde{P}_2)$ and $M_2 = I - \alpha^{(2)} e_3^T$ with

$$\alpha^{(2)} = (0 \ 0 \ 0 \ \tilde{v}_4/\tilde{v}_3 \ \tilde{v}_5/\tilde{v}_3)^T$$

and observe that

$$A^{(2)} = M_2 P_2 A^{(1)} P_2^T M_2^T = \begin{bmatrix}
\alpha_1 & \beta_1 & 0 & 0 & 0 \\
\beta_1 & \alpha_2 & \tilde{v}_3 & 0 & 0 \\
0 & \tilde{v}_3 & x & x & x \\
0 & 0 & x & x & x \\
0 & 0 & x & x & x
\end{bmatrix}.$$

In general, the process continues for $n - 2$ steps leaving us with a tridiagonal matrix

$$T = A^{(n-2)} = (M_{n-2} P_{n-2} \cdots M_1 P_1) A (M_{n-2} P_{n-2} \cdots M_1 P_1)^T.$$
It can be shown that (4.4.1) holds with $P = P_{n-2} \cdots P_1$ and
\[
L = (M_{n-2} P_{n-2} \cdots M_1 P_1 P^T)^{-1}.
\]
Analysis of $L$ reveals that its first column is $e_1$ and that its subdiagonal entries in column $k$ with $k > 1$ are "made up" of the multipliers in $M_{k-1}$.

The efficient implementation of the Parlett-Reid method requires care when computing the update
\[
A^{(k)} = M_k (P_k A^{(k-1)} P_k^T) M_k^T. \tag{4.4.3}
\]
To see what is involved with a minimum of notation, suppose $B = B^T$ has order $n - k$ and that we wish to form: $B_+ = (I - we_1^T)B(I - we_1^T)^T$ where $w \in \mathbb{R}^{n-k}$ and $e_1$ is the first column of $I_{n-k}$. Such a calculation is at the heart of (4.4.3). If we set
\[
u = Be_1 - \frac{b_{11}}{2} w,
\]
then the lower half of the symmetric matrix $B_+ = B - wu^T - uw^T$ can be formed in $2(n - k)^2$ flops. Summing this quantity as $k$ ranges from 1 to $n - 2$ indicates that the Parlett-Reid procedure requires $2n^3/3$ flops—twice what we would like.

**Example 4.4.1** If the Parlett-Reid algorithm is applied to
\[
A = \begin{bmatrix}
0 & 1 & 2 & 3 \\
1 & 2 & 2 & 2 \\
2 & 2 & 3 & 3 \\
3 & 2 & 3 & 4
\end{bmatrix}
\]
then
\[
P_1 = [e_1 \ e_4 \ e_2 \ e_2] \\
M_1 = I_4 - (0, 0, 2/3, 1/3, 1)^T e_2^T \\
P_2 = [e_1 \ e_2 \ e_4 \ e_3] \\
M_2 = I_4 - (0, 0, 1/12)^T e_3^T
\]
and $PAP^T = LTL^T$, where $P = \{e_1, e_3, e_4, e_2\}$,
\[
L = \begin{bmatrix}
1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 \\
0 & 1/3 & 1 & 0 \\
0 & 2/3 & 1/2 & 1
\end{bmatrix}
\text{ and } T = \begin{bmatrix}
0 & 3 & 0 & 0 \\
3 & 4 & 2/3 & 0 \\
0 & 2/3 & 10/9 & 0 \\
0 & 0 & 0 & 1/2
\end{bmatrix}.
\]

### 4.4.2 The Method of Aasen

An $n^3/3$ approach to computing (4.4.1) due to Aasen (1971) can be derived by reconsidering some of the computations in the Parlett-Reid approach.
We need a notation for the tridiagonal $T$:

$$
T = \begin{bmatrix}
\alpha_1 & \beta_1 & \cdots & 0 \\
\beta_1 & \alpha_2 & \cdots & \\
& \ddots & \ddots & \vdots \\
& & \ddots & \beta_{n-1} \\
0 & \cdots & \beta_{n-1} & \alpha_n \\
\end{bmatrix}.
$$

For clarity, we temporarily ignore pivoting and assume that the factorization $A = LTL^T$ exists where $L$ is unit lower triangular with $L(:,1) = e_1$. Aasen’s method is organized as follows:

for $j = 1:n$

Compute $h(1:j)$ where $h = TL^T e_j = He_j$.

Compute $\alpha(j)$.

if $j \leq n - 1$

Compute $\beta(j)$

end

if $j \leq n - 2$

Compute $L(j + 2:n, j + 1)$.

end

end

Thus, the mission of the $j$th Aasen step is to compute the $j$th column of $T$ and the $(j + 1)$-st column of $L$. The algorithm exploits the fact that the matrix $H = TL^T$ is upper Hessenberg. As can be deduced from (4.4.4), the computation of $\alpha(j)$, $\beta(j)$, and $L(j + 2:n, j + 1)$ hinges upon the vector $h(1:j) = H(1:j, j)$. Let us see why.

Consider the $j$th column of the equation $A = LH$:

$$
A(:,j) = L(:,1:j+1)h(1:j+1).
$$

(4.4.5)

This says that $A(:,j)$ is a linear combination of the first $j + 1$ columns of $L$. In particular,

$$
A(j+1:n,j) = L(j+1:n,1:j)h(1:j) + L(j+1:n,j+1)h(j+1).
$$

It follows that if we compute

$$
v(j+1:n) = A(j+1:n,j) - L(j+1:n,1:j)h(1:j),
$$

then

$$
L(j+1:n,j+1)h(j+1) = v(j+1:n).
$$

(4.4.6)
Thus, \( L(j+2:n, j+1) \) is a scaling of \( v(j+2:n) \). Since \( L \) is unit lower triangular we have from (4.4.6) that

\[
v(j + 1) = h(j + 1)
\]

and so from that same equation we obtain the following recipe for the \((j + 1)\)-st column of \( L \):

\[
L(j + 2:n, j + 1) = v(j + 2:n)/v(j + 1).
\]

Note that \( L(j + 2:n, j + 1) \) is a scaled gaxpy.

We next develop formulae for \( \alpha(j) \) and \( \beta(j) \). Compare the \((j, j)\) and \((j + 1, j)\) entries in the equation \( H = TL^T \). With the convention \( \beta(0) = 0 \) we find that \( h(j) = \beta(j - 1)L(j, j - 1) + \alpha(j) \) and \( h(j + 1) = v(j + 1) \) and so

\[
\begin{align*}
\alpha(j) &= h(j) - \beta(j - 1)L(j, j - 1) \\
\beta(j) &= v(j + 1).
\end{align*}
\]

With these recipes we can completely describe the Aasen procedure:

\begin{verbatim}
for j = 1:n
    Compute h(1:j) where h = TL^T e_j.
    if j = 1 \lor j = 2
        \alpha(j) = h(j)
    else
        \alpha(j) = h(j) - \beta(j - 1)L(j, j - 1)
    end
    if j \leq n - 1
        v(j + 1:n) = A(j + 1:n, j) - L(j + 1:n, 1:j)h(1:j)
        \beta(j) = v(j + 1)
    end
    if j \leq n - 2
        L(j + 2:n, j + 1) = v(j + 2:n)/v(j + 1)
    end
end
\end{verbatim}

To complete the description we must detail the computation of \( h(1:j) \). From (4.4.5) it follows that

\[
A(1:j, j) = L(1:j, 1:j)h(1:j).
\]  

This lower triangular system can be solved for \( h(1:j) \) since we know the first \( j \) columns of \( L \). However, a much more efficient way to compute \( H(1:j, j) \)
is obtained by exploiting the \(j\)th column of the equation \(H = TLT^T\). In particular, with the convention that \(\beta(0)L(j, 0) = 0\) we have

\[
h(k) = \beta(k - 1)L(j, k - 1) + \alpha(k)L(j, k) + \beta(k)L(j, k + 1).
\]

for \(k = 1:j\). These are working formulae except in the case \(k = j\) because we have not yet computed \(\alpha(j)\) and \(\beta(j)\). However, once \(h(1:j - 1)\) is known we can obtain \(h(j)\) from the last row of the triangular system (4.4.8), i.e.,

\[
h(j) = A(j, j) - \sum_{k=1}^{j-1} L(j, k)h(k).
\]

Collecting results and using a work array \(\ell(1:n)\) for \(L(j, 1:j)\) we see that the computation of \(h(1:j)\) in (4.4.7) can be organized as follows:

\[
\begin{align*}
\text{if } j &= 1 \\
h(1) &= A(1, 1) \\
\text{elseif } j &= 2 \\
h(1) &= \beta(1); \ h(2) = A(2, 2) \\
\text{else} \\
\ell(0) &= 0; \ \ell(1) = 0; \ \ell(2:j - 1) = L(j, 2:j - 1); \ \ell(j) = 1 \\
h(j) &= A(j, j) \\
\text{for } k &= 1:j - 1 \\
h(k) &= \beta(k - 1)\ell(k - 1) + \alpha(k)\ell(k) + \beta(k)\ell(k + 1) \\
h(j) &= h(j) - \ell(k)h(k) \\
\text{end}
\end{align*}
\]

Note that with this \(O(j)\) method for computing \(h(1:j)\), the \(\text{gaxpy}\) calculation of \(v(j + 1:n)\) is the dominant operation in (4.4.7). During the \(j\)th step this \(\text{gaxpy}\) involves about \(2j(n - j)\) flops. Summing this for \(j = 1:n\) shows that Aasen's method requires \(n^3/3\) flops. Thus, the Aasen and Cholesky algorithms entail the same amount of arithmetic.

### 4.4.3 Pivoting in Aasen's Method

As it now stands, the columns of \(L\) are scalings of the \(v\)-vectors in (4.4.7). If any of these scalings are large, i.e., if any of the \(v(j + 1)\)'s are small, then we are in trouble. To circumvent this problem we need only permute the largest component of \(v(j + 1:n)\) to the top position. Of course, this permutation must be suitably applied to the unreduced portion of \(A\) and the previously computed portion of \(L\).

**Algorithm 4.4.1 (Aasen's Method)** If \(A \in \mathbb{R}^{n \times n}\) is symmetric then the following algorithm computes a permutation \(P\), a unit lower triangular
4.4. Symmetric Indefinite Systems

$L$, and a tridiagonal $T$ such that $PAP^T = LTL^T$ with $|L(i,j)| \leq 1$. The permutation $P$ is encoded in an integer vector $piv$. In particular, $P = P_1 \cdots P_{n-2}$ where $P_j$ is the identity with rows $piv(j)$ and $j+1$ interchanged. The diagonal and subdiagonal of $T$ are stored in $\alpha(1:n)$ and $\beta(1:n-1)$, respectively. Only the subdiagonal portion of $L(2:n, 2:n)$ is computed.

\begin{verbatim}
for j = 1:n
    Compute h(1:j) via (4.4.9).
    if j = 1 \lor j = 2
        $\alpha(j) = h(j)$
    else
        $\alpha(j) = h(j) - \beta(j-1)L(j, j-1)$
    end
    if j \leq n - 1
        $v(j + 1:n) = A(j + 1:n, j) - L(j + 1:n, 1:j)h(1:j)$
        Find $q$ so $|v(q)| = \| v(j + 1:n) \|_\infty$ with $j + 1 \leq q \leq n$.
        $piv(j) = q$; $v(j + 1) \leftrightarrow v(q)$; $L(j + 1, 2:j) \leftrightarrow L(q, 2:j)$
        $A(j + 1, j + 1:n) \leftrightarrow A(q, j + 1:n)$
        $A(j + 1:n, j + 1) \leftrightarrow A(j + 1:n, q)$
        $\beta(j) = v(j + 1)$
    end
    if j \leq n - 2
        $L(j + 2:n, j + 1) = v(j + 2:n)$
        if $v(j + 1) \neq 0$
            $L(j + 2:n, j + 1) = L(j + 2:n, j + 1)/v(j + 1)$
        end
    end
end
\end{verbatim}

Aasen's method is stable in the same sense that Gaussian elimination with partial pivoting is stable. That is, the exact factorization of a matrix near $A$ is obtained provided $\| \hat{T} \|_2/\| A \|_2 \approx 1$, where $\hat{T}$ is the computed version of the tridiagonal matrix $T$. In general, this is almost always the case.

In a practical implementation of the Aasen algorithm, the lower triangular portion of $A$ would be overwritten with $L$ and $T$. Here is $n = 5$ case:

\[
A \leftarrow \begin{bmatrix}
\alpha_1 & \beta_1 & \alpha_2 \\
\ell_{32} & \beta_2 & \alpha_3 \\
\ell_{42} & \ell_{43} & \beta_3 & \alpha_4 \\
\ell_{52} & \ell_{53} & \ell_{54} & \beta_4 & \alpha_5
\end{bmatrix}
\]

Notice that the columns of $L$ are shifted left in this arrangement.
4.4.4 Diagonal Pivoting Methods

We next describe the computation of the block $LDL^T$ factorization (4.4.2). We follow the discussion in Bunch and Parlett (1971). Suppose

$$P_1 A P_1^T = \begin{bmatrix} E & C^T \\ C & B \end{bmatrix} s \begin{bmatrix} n-s \\ s \end{bmatrix}$$

where $P_1$ is a permutation matrix and $s = 1$ or $2$. If $A$ is nonzero, then it is always possible to choose these quantities so that $E$ is nonsingular thereby enabling us to write

$$P_1 A P_1^T = \begin{bmatrix} I_s & 0 \\ CE^{-1} & I_{n-s} \end{bmatrix} \begin{bmatrix} E & 0 \\ 0 & B - CE^{-1}C^T \end{bmatrix} \begin{bmatrix} I_s & E^{-1}C^T \\ 0 & I_{n-s} \end{bmatrix}$$

For the sake of stability, the $s$-by-$s$ "pivot" $E$ should be chosen so that the entries in

$$\tilde{A} = (\tilde{a}_{ij}) \equiv B - CE^{-1}C^T$$

are suitably bounded. To this end, let $\alpha \in (0, 1)$ be given and define the size measures

$$\mu_0 = \max_{i,j} |a_{ij}|$$

$$\mu_1 = \max_i |a_{ii}| .$$

The Bunch-Parlett pivot strategy is as follows:

if $\mu_1 \geq \alpha \mu_0$

$s = 1$

Choose $P_1$ so $|e_{11}| = \mu_1$.

else

$s = 2$

Choose $P_1$ so $|e_{21}| = \mu_0$.

end

It is easy to verify from (4.4.10) that if $s = 1$ then

$$|\tilde{a}_{ij}| \leq (1 + \alpha^{-1})\mu_0$$

while $s = 2$ implies

$$|\tilde{a}_{ij}| \leq \frac{3 - \alpha}{1 - \alpha} \mu_0 .$$
By equating \((1 + \alpha^{-1})^2\), the growth factor associated with two \(s = 1\) steps, and \((3 - \alpha)/(1 - \alpha)\), the corresponding \(s = 2\) factor, Bunch and Parlett conclude that \(\alpha = (1 + \sqrt{17})/8\) is optimum from the standpoint of minimizing the bound on element growth.

The reductions outlined above are then repeated on the \(n - s\) order symmetric matrix \(\tilde{A}\). A simple induction argument establishes that the factorization (4.4.2) exists and that \(n^3/3\) flops are required if the work associated with pivot determination is ignored.

### 4.4.5 Stability and Efficiency

Diagonal pivoting with the above strategy is shown by Bunch (1971) to be as stable as Gaussian elimination with complete pivoting. Unfortunately, the overall process requires between \(n^3/12\) and \(n^3/6\) comparisons, since \(\mu_0\) involves a two-dimensional search at each stage of the reduction. The actual number of comparisons depends on the total number of 2-by-2 pivots but in general the Bunch-Parlett method for computing (4.4.2) is considerably slower than the technique of Aasen. See Barwell and George (1976).

This is not the case with the diagonal pivoting method of Bunch and Kaufman (1977). In their scheme, it is only necessary to scan two columns at each stage of the reduction. The strategy is fully illustrated by considering the very first step in the reduction:

\[
\alpha = (1 + \sqrt{17})/8; \quad \lambda = |a_{r1}| = \max\{|a_{21}|, \ldots, |a_{n1}|\}
\]

if \(\lambda > 0\)

if \(|a_{11}| \geq \alpha \lambda\)

\(s = 1; P_1 = I\)

else

\(\sigma = |a_{pr}| = \max\{|a_{1r}, \ldots, |a_{r-1,r}|, |a_{r+1,r}|, \ldots, |a_{nr}|\}\)

if \(\sigma|a_{11}| \geq \alpha \lambda^2\)

\(s = 1, P_1 = I\)

elseif \(|a_{rr}| \geq \alpha \sigma\)

\(s = 1\) and choose \(P_1\) so \((P_1^T A P_1)_{11} = a_{rr}\).

else

\(s = 2\) and choose \(P_1\) so \((P_1^T A P_1)_{21} = a_{rp}\).

end

end

Overall, the Bunch-Kaufman algorithm requires \(n^3/3\) flops, \(O(n^2)\) comparisons, and, like all the methods of this section, \(n^2/2\) storage.
Example 4.4.2  If the Bunch-Kaufman algorithm is applied to

\[ A = \begin{bmatrix} 1 & 10 & 20 \\ 10 & 1 & 30 \\ 20 & 30 & 1 \end{bmatrix} \]

then in the first step \( \lambda = 20, r = 3, \sigma = 30, \) and \( p = 2 \). The permutation \( P = [ e_3 \ e_2 \ e_1 ] \) is applied giving

\[ PAP^T = \begin{bmatrix} 1 & 30 & 20 \\ 30 & 1 & 10 \\ 20 & 10 & 1 \end{bmatrix}. \]

A 2-by-2 pivot is then used to produce the reduction

\[ PAP^T = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -11.7920 \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & -11.7920 \end{bmatrix}. \]

4.4.6  A Note on Equilibrium Systems

A very important class of symmetric indefinite matrices have the form

\[ A = \begin{bmatrix} C & B \\ B^T & 0 \end{bmatrix} \begin{bmatrix} n \\ p \end{bmatrix} \]

where \( C \) is symmetric positive definite and \( B \) has full column rank. These conditions ensure that \( A \) is nonsingular.

Of course, the methods of this section apply to \( A \). However, they do not exploit its structure because the pivot strategies “wipe out” the zero (2,2) block. On the other hand, here is a tempting approach that does exploit \( A \)’s block structure:

(a) Compute the Cholesky factorization of \( C, C = GG^T \).

(b) Solve \( GK = B \) for \( K \in \mathbb{R}^{n \times p} \).

(c) Compute the Cholesky factorization of \( K^TK = B^T C^{-1} B, HH^T = K^TK \).

From this it follows that

\[ A = \begin{bmatrix} G & \begin{bmatrix} \begin{bmatrix} G^T & K \\ K^T & H \end{bmatrix} \end{bmatrix} \begin{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} f \\ g \end{bmatrix} \end{bmatrix} \end{bmatrix} \]

In principle, this triangular factorization can be used to solve the equilibrium system

\[ \begin{bmatrix} C & B \\ B^T & 0 \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix} = \begin{bmatrix} f \\ g \end{bmatrix}. \]
However, it is clear by considering steps (b) and (c) above that the accuracy of the computed solution depends upon $\kappa(C)$ and this quantity may be much greater than $\kappa(A)$. The situation has been carefully analyzed and various structure-exploiting algorithms have been proposed. A brief review of the literature is given at the end of the section.

But before we close it is interesting to consider a special case of (4.4.14) that clarifies what it means for an algorithm to be stable and illustrates how perturbation analysis can structure the search for better methods. In several important applications, $g = 0$, $C$ is diagonal, and the solution subvector $y$ is of primary importance. A manipulation of (4.4.14) shows that this vector is specified by

$$ y = (B^T C^{-1} B)^{-1} B^T C^{-1} f. \quad (4.4.15) $$

Looking at this we are again led to believe that $\kappa(C)$ should have a bearing on the accuracy of the computed $y$. However, it can be shown that

$$ \| (B^T C^{-1} B)^{-1} B^T C^{-1} \| \leq \psi_B \quad (4.4.16) $$

where the upper bound $\psi_B$ is independent of $C$, a result that (correctly) suggests that $y$ is not sensitive to perturbations in $C$. A stable method for computing this vector should respect this, meaning that the accuracy of the computed $y$ should be independent of $C$. Vavasis (1994) has developed a method with this property. It involves the careful assembly of a matrix $V \in \mathbb{R}^{n \times (n-p)}$ whose columns are a basis for the nullspace of $B^T C^{-1}$. The $n$-by-$n$ linear system

$$ \begin{bmatrix} B & V \end{bmatrix} \begin{bmatrix} y \\ q \end{bmatrix} = f $$

is then solved implying $f = By + Vq$. Thus, $B^T C^{-1} f = B^T C^{-1} By$ and (4.4.15) holds.

Problems

P4.4.1 Show that if all the 1-by-1 and 2-by-2 principal submatrices of an $n$-by-$n$ symmetric matrix $A$ are singular, then $A$ is indefinite.

P4.4.2 Show that no 2-by-2 pivots can arise in the Bunch-Kaufman algorithm if $A$ is positive definite.

P4.4.3 Arrange Algorithm 4.4.1 so that only the lower triangular portion of $A$ is referenced and so that $a(j)$ overwrites $A(j, j)$ for $j = 1:n$, $\beta(j)$ overwrites $A(j + 1, j)$ for $j = 1:n - 1$, and $L(i,j)$ overwrites $A(i, j - 1)$ for $j = 2:n - 1$ and $i = j + 1:n$.

P4.4.4 Suppose $A \in \mathbb{R}^{n \times n}$ is nonsingular, symmetric, and strictly diagonally dominant. Give an algorithm that computes the factorization

$$ \Pi A \Pi^T = \begin{bmatrix} R \\ S \\ -M \end{bmatrix} \begin{bmatrix} R^T & S^T \\ 0 & M^T \end{bmatrix} $$

where $R \in \mathbb{R}^{k \times k}$ and $M \in \mathbb{R}^{(n-k) \times (n-k)}$ are lower triangular and nonsingular and $\Pi$ is a permutation.
P4.4.5 Show that if
\[
A = \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & -A_{22} \end{bmatrix}
\]
is symmetric with \(A_{11}\) and \(A_{22}\) positive definite, then it has an \(LDL^T\) factorization with the property that
\[
D = \begin{bmatrix} D_1 & 0 \\ 0 & -D_2 \end{bmatrix}
\]
where \(D_1 \in \mathbb{R}^{n \times n}\) and \(D_2 \in \mathbb{R}^{p \times p}\) have positive diagonal entries.

P4.4.6 Prove (4.4.11) and (4.4.12).

P4.4.7 Show that \(-(B^T C^{-1} B)^{-1}\) is the (2,2) block of \(A^{-1}\) where \(A\) is given by (4.4.13).

P4.4.8 The point of this problem is to consider a special case of (4.4.15). Define the matrix
\[
M(\alpha) = (B^T C^{-1} B)^{-1} B^T C^{-1}
\]
where
\[
C = (I_n + \alpha e_k e_k^T) \quad \alpha > -1.
\]
and \(e_k = I_n(:,k)\). (Note that \(C\) is just the identity with \(\alpha\) added to the \((k,k)\) entry.) Assume that \(B \in \mathbb{R}^{p \times p}\) has rank \(p\) and show that
\[
M(\alpha) = (B^T B)^{-1} B^T \left( I_n - \frac{\alpha}{1 + \alpha w^T e_k w} e_k w^T \right)
\]
where \(w = (I_n - B(B^T B)^{-1} B^T) e_k\). Show that if \(\|w\|_2 = 0\) or \(\|w\|_2 = 1\), then \(\|M(\alpha)\|_2 = 1/\sigma_{\min}(B)\). Show that if \(0 < \|w\|_2 < 1\), then
\[
\|M(\alpha)\|_2 \leq \max \left\{ \frac{1}{1 - \|w\|_2}, 1 + \frac{1}{\|w\|_2} \right\} \bigg/ \sigma_{\min}(B).
\]
Thus, \(\|M(\alpha)\|_2\) has an \(\alpha\)-independent upper bound.

Notes and References for Sec. 4.4

The basic references for computing (4.4.1) are

The diagonal pivoting literature includes

Because "future" columns must be scanned in the pivoting process, it is awkward (but possible) to obtain a gappy-rich diagonal pivoting algorithm. On the other hand, Assen's method is naturally rich in gappy's. Block versions of both procedures are possible. LAPACK uses the diagonal pivoting method. Various performance issues are discussed in

Another idea for a cheap pivoting strategy utilizes error bounds based on more liberal interchange criteria, an idea borrowed from some work done in the area of sparse elimination methods. See

Before using any symmetric $Ax = b$ solver, it may be advisable to equilibrate $A$. An $O(n^2)$ algorithm for accomplishing this task is given in

Analogues of the symmetric indefinite solvers that we have presented exist for skew-symmetric systems. See

The equilibrium system literature is scattered among the several application areas where it has an important role to play. Nice overviews with pointers to this literature include

Other papers include

Some of these papers make use of the QR factorization and other least squares ideas that are discussed in the next chapter and §12.1.

Problems with structure abound in matrix computations and perturbation theory has a key role to play in the search for stable, efficient algorithms. For equilibrium systems, there are several results like (4.4.15) that underpin the most effective algorithms. See

and the included references. A discussion of (4.4.15) may be found in

4.5 Block Systems

In many application areas the matrices that arise have exploitable block structure. As a case study we have chosen to discuss block tridiagonal systems of the form

\[
\begin{bmatrix}
D_1 & F_1 & \cdots & 0 \\
E_1 & D_2 & \cdots & \vdots \\
\vdots & \ddots & \ddots & \ddots \\
0 & \cdots & E_{n-1} & D_n
\end{bmatrix}
\begin{bmatrix}
x_1 \\ x_2 \\ \vdots \\ x_n
\end{bmatrix}
= 
\begin{bmatrix}
b_1 \\ b_2 \\ \vdots \\ b_n
\end{bmatrix}
\]

(4.5.1)

Here we assume that all blocks are \(q\)-by-\(q\) and that the \(x_i\) and \(b_i\) are in \(\mathbb{R}^q\). In this section we discuss both a block LU approach to this problem as well as a divide and conquer scheme known as cyclic reduction. Kronecker product systems are briefly mentioned.

4.5.1 Block Tridiagonal LU Factorization

We begin by considering a block LU factorization for the matrix in (4.5.1). Define the block tridiagonal matrices \(A_k\) by

\[
A_k = \begin{bmatrix}
D_1 & F_1 & \cdots & 0 \\
E_1 & D_2 & \cdots & \vdots \\
\vdots & \ddots & \ddots & \ddots \\
0 & \cdots & E_{k-1} & D_k
\end{bmatrix}
\quad k = 1:n.
\]

(4.5.2)
Comparing blocks in

\[
A_n = \begin{bmatrix}
I & \cdots & 0 \\
L_1 & I & \ \ \\
\vdots & \ddots & \ddots \\
0 & \cdots & L_{n-1} & I
\end{bmatrix}
\begin{bmatrix}
U_1 & F_1 & \cdots & 0 \\
0 & U_2 & \ddots & \vdots \\
\vdots & \ddots & \ddots & \ddots \\
0 & \cdots & 0 & U_n
\end{bmatrix}
\]  

(4.5.3)

we formally obtain the following algorithm for the \(L_i\) and \(U_i\):

\[
U_1 = D_1
\]

for \(i = 2:n\)

Solve \(L_{i-1}U_{i-1} = E_{i-1}\) for \(L_{i-1}\).

\[
U_i = D_i - L_{i-1}F_{i-1}
\]

end

The procedure is defined so long as the \(U_i\) are nonsingular. This is assured, for example, if the matrices \(A_1, \ldots, A_n\) are nonsingular.

Having computed the factorization (4.5.3), the vector \(x\) in (4.5.1) can be obtained via block forward and back substitution:

\[
y_1 = b_1
\]

for \(i = 2:n\)

\[
y_i = b_i - L_{i-1}y_{i-1}
\]

end

Solve \(U_nx_n = y_n\) for \(x_n\).

for \(i = n-1: -1:1\)

Solve \(U_ix_i = y_i - F_iy_{i+1}\) for \(x_i\).

end

To carry out both (4.5.4) and (4.5.5), each \(U_i\) must be factored since linear systems involving these submatrices are solved. This could be done using Gaussian elimination with pivoting. However, this does not guarantee the stability of the overall process. To see this just consider the case when the block size \(q\) is unity.

### 4.5.2 Block Diagonal Dominance

In order to obtain satisfactory bounds on the \(L_i\) and \(U_i\) it is necessary to make additional assumptions about the underlying block matrix. For example, if for \(i = 1:n\) we have the block diagonal dominance relations

\[
\| D_i^{-1} \|_1 \left( \| F_{i-1} \|_1 + \| E_i \|_1 \right) < 1 \quad E_n \equiv F_0 \equiv 0
\]  

(4.5.6)
then the factorization (4.5.3) exists and it is possible to show that the $L_i$ and $U_i$ satisfy the inequalities

$$
\| L_i \|_1 \leq 1 \tag{4.5.7} \\
\| U_i \|_1 \leq \| A_n \|_1 \tag{4.5.8}
$$

\[4.5.3\] Block Versus Band Solving

At this point it is reasonable to ask why we do not simply regard the matrix $A$ in (4.5.1) as a $qn$-by-$qn$ matrix having scalar entries and bandwidth $2q - 1$. Band Gaussian elimination as described in §4.3 could be applied. The effectiveness of this course of action depends on such things as the dimensions of the blocks and the sparsity patterns within each block.

To illustrate this in a very simple setting, suppose that we wish to solve

$$
\begin{bmatrix}
D_1 & F_1 \\
E_1 & D_2
\end{bmatrix}
\begin{bmatrix}
x_1 \\
x_2
\end{bmatrix}
= 
\begin{bmatrix}
b_1 \\
b_2
\end{bmatrix} \tag{4.5.9}
$$

where $D_1$ and $D_2$ are diagonal and $F_1$ and $E_1$ are tridiagonal. Assume that each of these blocks is $n$-by-$n$ and that it is “safe” to solve (4.5.9) via (4.5.3) and (4.5.5). Note that

\[
U_1 = D_1 \quad \text{(diagonal)} \\
L_1 = E_1 U_1^{-1} \quad \text{(tridiagonal)} \\
U_2 = D_2 - L_1 F_1 \quad \text{(pentadiagonal)} \\
y_1 = b_1 \\
y_2 = b_2 - E_1(D_1^{-1}y_1) \\
U_2 x_2 = y_2 \\
D_1 x_1 = y_1 - F_1 x_2.
\]

Consequently, some very simple $n$-by-$n$ calculations with the original banded blocks renders the solution.

On the other hand, the naive application of band Gaussian elimination to the system (4.5.9) would entail a great deal of unnecessary work and storage as the system has bandwidth $n + 1$. However, we mention that by permuting the rows and columns of the system via the permutation

$$
P = [e_1, e_{n+1}, e_2, \ldots, e_n, e_{2n}] \tag{4.5.10}
$$
we find (in the \( n = 5 \) case) that

\[
PAP^T = \begin{bmatrix}
\times & \times & 0 & 0 & 0 \\
\times & \times & \times & 0 & 0 \\
\times & \times & \times & \times & 0 \\
0 & 0 & 0 & \times & \times \\
0 & 0 & 0 & 0 & \times \\
\end{bmatrix}
\]

This matrix has upper and lower bandwidth equal to three and so a very reasonable solution procedure results by applying hand Gaussian elimination to this permuted version of \( A \).

The subject of bandwidth-reducing permutations is important. See George and Liu (1981, Chapter 4). We also refer to the reader to Varah (1972) and George (1974) for further details concerning the solution of block tridiagonal systems.

### 4.5.4 Block Cyclic Reduction

We next describe the method of block cyclic reduction that can be used to solve some important special instances of the block tridiagonal system (4.5.1). For simplicity, we assume that \( A \) has the form

\[
A = \begin{bmatrix}
D & F & \cdots & 0 \\
F & D & \cdots & \vdots \\
\vdots & \vdots & \ddots & F \\
0 & \cdots & F & D \\
\end{bmatrix} \in \mathbb{R}^{nq \times nq}
\]  

(4.5.11)

where \( F \) and \( D \) are \( q \)-by-\( q \) matrices that satisfy \( DF = FD \). We also assume that \( n = 2^k - 1 \). These conditions hold in certain important applications such as the discretization of Poisson’s equation on a rectangle. In that situation,

\[
D = \begin{bmatrix}
4 & -1 & \cdots & 0 \\
-1 & 4 & \cdots & \vdots \\
\vdots & \vdots & \ddots & \vdots \\
0 & \cdots & -1 & 4 \\
\end{bmatrix}
\]  

(4.5.12)
and $F = -I_q$. The integer $n$ is determined by the size of the mesh and can often be chosen to be of the form $n = 2^k - 1$. (Sweet (1977) shows how to proceed when the dimension is not of this form.)

The basic idea behind cyclic reduction is to halve the dimension of the problem on hand repeatedly until we are left with a single $q$-by-$q$ system for the unknown subvector $x_{2^{q-1}}$. This system is then solved by standard means. The previously eliminated $x_i$ are found by a back-substitution process.

The general procedure is adequately motivated by considering the case $n = 7$:

\begin{align*}
  b_1 &= D x_1 + F x_2 \\
  b_2 &= F x_1 + D x_2 + F x_3 \\
  b_3 &= F x_2 + D x_3 + F x_4 \\
  b_4 &= F x_3 + D x_4 + F x_5 \\
  b_5 &= F x_4 + D x_5 + F x_6 \\
  b_6 &= F x_5 + D x_6 + F x_7 \\
  b_7 &= F x_6 + D x_7 
\end{align*}

For $i = 2, 4,$ and $6$ we multiply equations $i - 1$, $i$, and $i + 1$ by $F$, $-D$, and $F$, respectively, and add the resulting equations to obtain

\begin{align*}
  (2F^2 - D^2)x_2 + F^2x_4 &= F(b_1 + b_3) - Db_2 \\
  F^2x_2 + (2F^2 - D^2)x_4 + F^2x_6 &= F(b_3 + b_5) - Db_4 \\
  F^2x_4 + (2F^2 - D^2)x_6 &= F(b_5 + b_7) - Db_6
\end{align*}

Thus, with this tactic we have removed the odd-indexed $x_i$ and are left with a reduced block tridiagonal system of the form

\begin{align*}
  D^{(1)} x_2 + F^{(1)} x_4 &= b_2^{(1)} \\
  F^{(1)} x_2 + D^{(1)} x_4 + F^{(1)} x_6 &= b_4^{(1)} \\
  F^{(1)} x_4 + D^{(1)} x_6 &= b_6^{(1)}
\end{align*}

where $D^{(1)} = 2F^2 - D^2$ and $F^{(1)} = F^2$ commute. Applying the same elimination strategy as above, we multiply these three equations respectively by $F^{(1)}$, $-D^{(1)}$, and $F^{(1)}$. When these transformed equations are added together, we obtain the single equation

\begin{equation}
  \left(2[F^{(1)}]^2 - D^{(1)2}\right)x_4 = F^{(1)} \left(b_2^{(1)} + b_6^{(1)}\right) - D^{(1)} b_4^{(1)}
\end{equation}

which we write as

\begin{equation}
  D^{(2)} x_4 = b^{(2)}.
\end{equation}

This completes the cyclic reduction. We now solve this (small) $q$-by-$q$ system for $x_4$. The vectors $x_2$ and $x_6$ are then found by solving the systems

\begin{align*}
  D^{(1)} x_2 &= b_2^{(1)} - F^{(1)} x_4 \\
  D^{(1)} x_6 &= b_6^{(1)} - F^{(1)} x_4
\end{align*}
Finally, we use the first, third, fifth, and seventh equations in (4.5.13) to compute \(x_1, x_3, x_5,\) and \(x_7,\) respectively.

For general \(n\) of the form \(n = 2^k - 1\) we set \(D^{(0)} = D, F^{(0)} = F, b^{(0)} = b\) and compute:

\[
\begin{align*}
\text{for } p &= 1:k-1 \\
F^{(p)} &= [F^{(p-1)2} \\
D^{(p)} &= 2F^{(p)} - [D^{(p-1)}]^2 \\
r &= 2^p \\
\text{for } j &= 1:2^{k-p} - 1 \\
b^{(p)}_{jr} &= F^{(p-1)} \left( b^{(p-1)}_{jr-r/2} + b^{(p-1)}_{jr+r/2} \right) - D^{(p-1)}b^{(p-1)}_{jr} \\
\end{align*}
(4.5.14)
\]

end

end

The \(x_i\) are then computed as follows:

\[
\begin{align*}
\text{Solve } D^{(k-1)}x_{2^{k-1}-1} &= b^{(k-1)}_1 \text{ for } x_{2^{k-1}-1}. \\
\text{for } p &= k-2:-1:0 \\
r &= 2^p \\
\text{for } j &= 1:2^{k-p} - 1 \\
\text{if } j &= 1 \\
c &= b^{(p)}_{(2j-1)r} - F^{(p)}x_{2jr} \\
\text{elseif } j &= 2^{k-p+1} \\
c &= b^{(p)}_{(2j-1)r} - F^{(p)}x_{(2j-2)r} \\
\text{else} \\
c &= b^{(p)}_{(2j-1)r} - F^{(p)} \left( x_{2jr} + x_{(2j-2)r} \right) \\
\end{align*}
(4.5.15)
\]

end

Solve \(D^{(p)}x_{(2j-1)r} = c \text{ for } x_{(2j-1)r}\)

end

The amount of work required to perform these recursions depends greatly upon the sparsity of the \(D^{(p)}\) and \(F^{(p)}\). In the worse case when these matrices are full, the overall flop count has order \(\log(n)q^3\). Care must be exercised in order to ensure stability during the reduction. For further details, see Buneman (1969).

Example 4.5.1 Suppose \(q = 1, D = (4),\) and \(F = (-1)\) in (4.5.14) and that we wish to solve:

\[
\begin{bmatrix}
4 & -1 & 0 & 0 & 0 & 0 & 0 \\
-1 & 4 & -1 & 0 & 0 & 0 & 0 \\
0 & -1 & 4 & -1 & 0 & 0 & 0 \\
0 & 0 & -1 & 4 & -1 & 0 & 0 \\
0 & 0 & 0 & -1 & 4 & -1 & 0 \\
0 & 0 & 0 & 0 & -1 & 4 & -1 \\
\end{bmatrix}
\begin{bmatrix}
x_1 \\
x_2 \\
x_3 \\
x_4 \\
x_5 \\
x_6 \\
x_7 \\
\end{bmatrix}
= 
\begin{bmatrix}
2 \\
4 \\
6 \\
8 \\
10 \\
12 \\
22 \\
\end{bmatrix}
\]
By executing (4.5.15) we obtain the reduced systems:

\[
\begin{bmatrix}
-14 & 1 & 0 \\
1 & -14 & 1 \\
0 & 1 & -14
\end{bmatrix}
\begin{bmatrix}
x_2 \\
x_4 \\
x_6
\end{bmatrix}
= \begin{bmatrix}
-24 \\
-48 \\
-80
\end{bmatrix}, \quad p = 1
\]

and

\[
\begin{bmatrix}
-194 \\
x_4
\end{bmatrix}
= \begin{bmatrix}
-776
\end{bmatrix}, \quad p = 2
\]

The \( x_i \) are then determined via (4.5.16):

\[
p = 2: \quad x_4 = 4
\]
\[
p = 1: \quad x_2 = 2, \quad x_6 = 6
\]
\[
p = 0: \quad x_1 = 1, \quad x_3 = 3, \quad x_5 = 5, \quad x_7 = 7
\]

Cyclic reduction is an example of a divide and conquer algorithm. Other divide and conquer procedures are discussed in §1.3.8 and §8.6.

### 4.5.5 Kronecker Product Systems

If \( B \in \mathbb{R}^{m \times n} \) and \( C \in \mathbb{R}^{p \times q} \), then their Kronecker product is given by

\[
A = B \otimes C = \begin{bmatrix}
b_{11}C & b_{12}C & \cdots & b_{1n}C \\
b_{21}C & b_{22}C & \cdots & b_{2n}C \\
\vdots & \vdots & \ddots & \vdots \\
b_{m1}C & b_{m2}C & \cdots & b_{mn}C
\end{bmatrix}
\]

Thus, \( A \) is an \( m \times n \) block matrix whose \( (i, j) \) block is \( b_{ij}C \). Kronecker products arise in conjunction with various mesh discretizations and throughout signal processing. Some of the more important properties that the Kronecker product satisfies include

\[
(A \otimes B)(C \otimes D) = AC \otimes BD \tag{4.5.16}
\]
\[
(A \otimes B)^T = A^T \otimes B^T \tag{4.5.17}
\]
\[
(A \otimes B)^{-1} = A^{-1} \otimes B^{-1} \tag{4.5.18}
\]

where it is assumed that all the factor operations are defined.

Related to the Kronecker product is the "vec" operation:

\[
X \in \mathbb{R}^{m \times n} \Leftrightarrow \text{vec}(X) = \begin{bmatrix}
X(:, 1) \\
\vdots \\
X(:, n)
\end{bmatrix} \in \mathbb{R}^{mn}.
\]

Thus, the vec of a matrix amounts to a "stacking" of its columns. It can be shown that

\[
Y = CXB^T \Leftrightarrow \text{vec}(Y) = (B \otimes C)\text{vec}(X). \tag{4.5.19}
\]
It follows that solving a Kronecker product system,

$$(B \otimes C)x = d$$

is equivalent to solving the matrix equation $CXB^T = D$ for $X$ where $x = \text{vec}(X)$ and $d = \text{vec}(D)$. This has efficiency ramifications. To illustrate, suppose $B, C \in \mathbb{R}^{n \times n}$ are symmetric positive definite. If $A = B \otimes C$ is treated as a general matrix and factored in order to solve for $x$, then $O(n^6)$ flops are required since $B \otimes C \in \mathbb{R}^{n^2 \times n^2}$. On the other hand, the solution approach

1. Compute the Cholesky factorizations $B = GG^T$ and $C = HH^T$.
4. $x = \text{vec}(X)$.

involves $O(n^3)$ flops. Note that

$$B \otimes C = GG^T \otimes HH^T = (G \otimes H)(C \otimes H)^T$$

is the Cholesky factorization of $B \otimes C$ because the Kronecker product of a pair of lower triangular matrices is lower triangular. Thus, the above four-step solution approach is a structure-exploiting, Cholesky method applied to $B \otimes C$.

We mention that if $B$ is sparse, then $B \otimes C$ has the same sparsity at the block level. For example, if $B$ is tridiagonal, then $B \otimes C$ is block tridiagonal.

Problems

P4.5.1 Show that a block diagonally dominant matrix is nonsingular.
P4.5.2 Verify that (4.5.6) implies (4.5.7) and (4.5.8).
P4.5.3 Suppose block cyclic reduction is applied with $D$ given by (4.5.12) and $F = -I_q$. What can you say about the band structure of the matrices $F^{(p)}$ and $D^{(p)}$ that arise?
P4.5.4 Suppose $A \in \mathbb{R}^{n \times n}$ is nonsingular and that we have solutions to the linear systems $Ax = b$ and $Ay = g$ where $b, g \in \mathbb{R}^n$ are given. Show how to solve the system

$$\begin{bmatrix} A & g \\ H^T & \alpha \end{bmatrix} \begin{bmatrix} x \\ \mu \end{bmatrix} = \begin{bmatrix} b \\ \beta \end{bmatrix}$$

in $O(n)$ flops where $\alpha, \beta \in \mathbb{R}$ and $h \in \mathbb{R}^n$ are given and the matrix of coefficients $A_+$ is nonsingular. The advisability of going for such a quick solution is a complicated issue that depends upon the condition numbers of $A$ and $A_+$ and other factors.
P4.5.5 Verify (4.5.16)-(4.5.19).
P4.5.7 Show how to construct the SVD of $B \otimes C$ from the SVDs of $B$ and $C$.
P4.5.8 If $A$, $B$, and $C$ are matrices, then it can be shown that $(A \otimes B) \otimes C = A \otimes (B \otimes C)$
and so we just write $A \otimes B \otimes C$ for this matrix. Show how to solve the linear system
\[(A \otimes B \otimes C)x = d\]assuming that $A$, $B$, and $C$ are symmetric positive definite.

Notes and References for Sec. 4.5

The following papers provide insight into the various nuances of block matrix computations:

The property of block diagonal dominance and its various implications is the central theme in

Early methods that involve the idea of cyclic reduction are described in

The accumulation of the right-hand side must be done with great care, for otherwise there would be a significant loss of accuracy. A stable way of doing this is described in

Other literature concerned with cyclic reduction includes

Various generalizations and extensions to cyclic reduction have been proposed:

4.6 Vandermonde Systems and the FFT

Suppose \( x(0:n) \in \mathbb{R}^{n+1} \). A matrix \( V \in \mathbb{R}^{(n+1) \times (n+1)} \) of the form

\[
V = V(x_0, \ldots, x_n) = \begin{bmatrix}
1 & 1 & \cdots & 1 \\
x_0 & x_1 & \cdots & x_n \\
\vdots & \vdots & \ddots & \vdots \\
x_0^n & x_1^n & \cdots & x_n^n
\end{bmatrix}
\]
is said to be a Vandermonde matrix. In this section, we show how the systems $V^T a = f = f(0:n)$ and $V z = b = b(0:n)$ can be solved in $O(n^2)$ flops. The discrete Fourier transform is briefly introduced. This special and extremely important Vandermonde system has a a recursive block structure and can be solved in $O(n \log n)$ flops. In this section, vectors and matrices are subscripted from 0.

### 4.6.1 Polynomial Interpolation: $V^T a = f$

Vandermonde systems arise in many approximation and interpolation problems. Indeed, the key to obtaining a fast Vandermonde solver is to recognize that solving $V^T a = f$ is equivalent to polynomial interpolation. This follows because if $V^T a = f$ and

$$p(x) = \sum_{j=0}^{n} a_j x^j$$

then $p(x_i) = f_i$ for $i = 0:n$.

Recall that if the $x_i$ are distinct then there is a unique polynomial of degree $n$ that interpolates $(x_0, f_0), \ldots, (x_n, f_n)$. Consequently, $V$ is nonsingular as long as the $x_i$ are distinct. We assume this throughout the section.

The first step in computing the $a_j$ of (4.6.1) is to calculate the Newton representation of the interpolating polynomial $p$:

$$p(x) = \sum_{k=0}^{n} c_k \left( \prod_{i=0}^{k-1} (x - x_i) \right).$$

The constants $c_k$ are divided differences and may be determined as follows:

\[
\begin{align*}
c(0:n) &= f(0:n) \\
\text{for } k &= 0:n - 1 \\
\text{for } i &= n: -1:k + 1 \\
c_i &= (c_i - c_{i-1})/(x_i - x_{i-k-1})
\end{align*}
\]

end

See Conte and de Boor (1980, chapter 2).

The next task is to generate $a(0:n)$ from $c(0:n)$. Define the polynomials $p_n(x), \ldots, p_0(x)$ by the iteration

\[
\begin{align*}
p_n(x) &= c_n \\
\text{for } k &= n - 1: -1:0 \\
p_k(x) &= c_k + (x - x_k)p_{k+1}(x)
\end{align*}
\]

e?nd
and observe that \( p_0(x) = p(x) \). Writing
\[
p_k(x) = a_k^{(k)} + a_{k+1}^{(k)} x + \cdots + a_n^{(k)} x^{n-k}
\]
and equating like powers of \( x \) in the equation \( p_k = c_k + (x - x_k)p_{k+1} \) gives the following recursion for the coefficients \( a_i^{(k)} \):
\[
a_n^{(n)} = c_n
\]
for \( k = n - 1; \ldots; 1; 0 \):
\[
a_k^{(k)} = c_k - x_k a_{k+1}^{(k+1)}
\]
for \( i = k + 1; \ldots; n - 1 \):
\[
a_i^{(k)} = a_i^{(k+1)} - x_k a_{i+1}^{(k+1)}
\]
end
\[
a_n^{(k)} = a_n^{(k+1)}
\]
end

Consequently, the coefficients \( a_i = a_i^{(0)} \) can be calculated as follows:
\[
a(0:n) = c(0:n)
\]
for \( k = n - 1; \ldots; 1; 0 \):
\[
\text{for } i = k; \ldots; n - 1
\]
\[
a_i = a_i - x_k a_{i+1}
\]
end
end

Combining this iteration with (4.6.3) renders the following algorithm:

Algorithm 4.6.1 Given \( x(0:n) \in \mathbb{R}^{n+1} \) with distinct entries and \( f = f(0:n) \in \mathbb{R}^{n+1} \), the following algorithm overwrites \( f \) with the solution \( a = a(0:n) \) to the Vandermonde system \( V(x_0, \ldots, x_n)^T a = f \).

\[
\text{for } k = 0; \ldots; n - 1
\]
\[
\text{for } i = n; \ldots; 1; k + 1
\]
\[
f(i) = (f(i) - f(i - 1))/(x(i) - x(i - k - 1))
\]
end
end
\[
\text{for } k = n - 1; \ldots; 1; 0
\]
\[
\text{for } i = k; \ldots; n - 1
\]
\[
f(i) = f(i) - f(i + 1) x(k)
\]
end
end

This algorithm requires \( 5n^2/2 \) flops.

Example 4.6.1 Suppose Algorithm 4.6.1 is used to solve
\[
\begin{bmatrix}
1 & 1 & 1 & 1 \\
1 & 2 & 4 & 8 \\
1 & 3 & 9 & 27 \\
1 & 4 & 16 & 64
\end{bmatrix}^T a = \begin{bmatrix}
a_0 \\
a_1 \\
a_2 \\
a_3
\end{bmatrix} = \begin{bmatrix}
10 \\
26 \\
58 \\
112
\end{bmatrix}.
\]
The first \( k \)-loop computes the Newton representation of \( p(x) \):

\[
p(x) = 10 + 16(x - 1) + 8(x - 1)(x - 2) + (x - 1)(x - 2)(x - 3).
\]

The second \( k \)-loop computes \( a = [4 \ 3 \ 2 \ 1]^T \) from \( [10 \ 16 \ 8 \ 1]^T \).

### 4.6.2 The System \( Vz = b \)

Now consider the system \( Vz = b \). To derive an efficient algorithm for this problem, we describe what Algorithm 4.6.1 does in matrix-vector language. Define the lower bidiagonal matrix \( L_k(\alpha) \in \mathbb{R}^{(n+1) \times (n+1)} \) by

\[
L_k(\alpha) = \begin{bmatrix}
I_k & 0 \\
0 & 1 \\
& -\alpha & 1 \\
& & \ddots & \ddots \\
& & & \ddots & \ddots \\
& & & & \ddots & 1 \\
& & & & & 0 & \ldots & -\alpha & 1
\end{bmatrix}
\]

and the diagonal matrix \( D_k \) by

\[
D_k = \text{diag}(\frac{1}{k+1}, x_{k+1} - x_0, \ldots, x_n - x_{n-k-1}).
\]

With these definitions it is easy to verify from (4.6.3) that if \( f = f(0:n) \) and \( c = c(0:n) \) is the vector of divided differences then \( c = U^T f \) where \( U \) is the upper triangular matrix defined by

\[
U^T = D_{n-1}^{-1}L_{n-1}(1) \cdots D_0^{-1}L_0(1).
\]

Similarly, from (4.6.4) we have

\[
a = L^T c,
\]

where \( L \) is the unit lower triangular matrix defined by:

\[
L^T = L_0(x_0)^T \cdots L_{n-1}(x_{n-1})^T.
\]

Thus, \( a = L^T U^T f \) where \( V^{-T} = U^T U^T \). In other words, Algorithm 4.6.1 solves \( V^T a = f \) by tacitly computing the "UL" factorization of \( V^{-1} \).

Consequently, the solution to the system \( Vz = b \) is given by

\[
z = V^{-1}b = U(\bar{L}b) = (L_0(1)^TD_0^{-1} \cdots L_{n-1}(1)^TD_{n-1}^{-1})(L_{n-1}(x_{n-1}) \cdots L_0(x_0)b)
\]
This observation gives rise to the following algorithm:

Algorithm 4.6.2 Given $x(0:n) \in \mathbb{R}^{n+1}$ with distinct entries and $b = b(0:n) \in \mathbb{R}^{n+1}$, the following algorithm overwrites $b$ with the solution $z = z(0:n)$ to the Vandermonde system $V(x_0, \ldots, x_n)z = b$.

\[
\begin{align*}
&\text{for } k = 0:n-1 \\
&\quad \text{for } i = n: -1: k + 1 \\
&\quad \quad b(i) = b(i) - x(k)b(i - 1) \\
&\quad \text{end} \\
&\text{end} \\
&\text{for } k = n-1: -1: 0 \\
&\quad \text{for } i = k + 1:n \\
&\quad \quad b(i) = b(i)/(x(i) - x(i - k - 1)) \\
&\quad \text{end} \\
&\quad \text{for } i = k:n - 1 \\
&\quad \quad b(i) = b(i) - b(i + 1) \\
&\text{end} \\
\end{align*}
\]

This algorithm requires $5n^2/2$ flops.

Example 4.6.2 Suppose Algorithm 4.6.2 is used to solve

\[
\begin{bmatrix}
1 & 1 & 1 & 1 \\
1 & 2 & 3 & 4 \\
1 & 4 & 9 & 16 \\
1 & 8 & 27 & 64
\end{bmatrix}
\begin{bmatrix}
z_0 \\
z_1 \\
z_2 \\
z_3
\end{bmatrix}
= 
\begin{bmatrix}
0 \\
-1 \\
3 \\
35
\end{bmatrix}
\]

The first $k$-loop computes the vector

\[
\begin{bmatrix}
0 \\
-1 \\
3 \\
35
\end{bmatrix}
=
\begin{bmatrix}
0 \\
-1 \\
3 \\
35
\end{bmatrix}
\]

The second $k$-loop then calculates

\[
\begin{bmatrix}
0 \\
-1 \\
3 \\
35
\end{bmatrix}
= 
\begin{bmatrix}
3 \\
-4 \\
0 \\
1
\end{bmatrix}
\]

4.6.3 Stability

Algorithms 4.6.1 and 4.6.2 are discussed and analyzed in Björck and Pereyra (1970). Their experience is that these algorithms frequently produce surprisingly accurate solutions, even when $V$ is ill-conditioned. They also show how to update the solution when a new coordinate pair $(x_{n+1}, f_{n+1})$
is added to the set of points to be interpolated, and how to solve confluent Vandermonde systems, i.e., systems involving matrices like

\[
V = V(x_0, x_1, x_1, x_3) = \begin{bmatrix}
1 & 1 & 0 & 1 \\
x_0 & x_1 & 1 & x_3 \\
x_0^2 & x_1^2 & 2x_1^2 & x_3^2 \\
x_0^3 & x_1^3 & 3x_1^3 & x_3^3 \\
\end{bmatrix}.
\]

4.6.4 The Fast Fourier Transform

The discrete Fourier transform (DFT) matrix of order \( n \) is defined by

\[
F_n = (f_{jk}) \quad f_{jk} = \omega_n^{jk}
\]

where

\[
\omega_n = \exp(-2\pi i/n) = \cos(2\pi/n) - i \cdot \sin(2\pi/n).
\]

The parameter \( \omega_n \) is an \( n \)th root of unity because \( \omega_n^n = 1 \). In the \( n = 4 \) case, \( \omega_4 = -i \) and

\[
F_4 = \begin{bmatrix}
1 & 1 & 1 & 1 \\
1 & \omega_4 & \omega_4^2 & \omega_4^3 \\
1 & \omega_4^2 & \omega_4^4 & \omega_4^6 \\
1 & \omega_4^3 & \omega_4^6 & \omega_4^9 \\
\end{bmatrix}
= \begin{bmatrix}
1 & 1 & 1 & 1 \\
1 & -i & -1 & i \\
1 & -1 & 1 & -1 \\
1 & i & -1 & -i \\
\end{bmatrix}.
\]

If \( x \in \mathbb{C}^n \), then its DFT is the vector \( F_n x \). The DFT has an extremely important role to play throughout applied mathematics and engineering.

If \( n \) is highly composite, then it is possible to carry out the DFT in many fewer than the \( O(n^2) \) flops required by conventional matrix-vector multiplication. To illustrate this we set \( n = 2^t \) and proceed to develop the radix-2 fast Fourier transform (FFT). The starting point is to look at an even-order DFT matrix when we permute its columns so that the even-indexed columns come first. Consider the case \( n = 8 \). Noting that \( \omega_n^{kj} = \omega_n^{kj \mod 8} \) we have

\[
F_8 = \begin{bmatrix}
1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\
1 & \omega_8 & \omega_8^2 & \omega_8^3 & \omega_8^4 & \omega_8^5 & \omega_8^6 & \omega_8^7 \\
1 & \omega_8^2 & \omega_8^4 & \omega_8^6 & 1 & \omega_8^2 & \omega_8^4 & \omega_8^6 \\
1 & \omega_8^3 & \omega_8^6 & \omega_8 & \omega_8^4 & \omega_8^7 & \omega_8^2 & \omega_8^5 \\
1 & \omega_8^4 & 1 & \omega_8^4 & 1 & \omega_8^4 & 1 & \omega_8^4 \\
1 & \omega_8^5 & \omega_8^2 & \omega_8^7 & \omega_4 & \omega & \omega_8^6 & \omega_3 \\
1 & \omega_8^6 & \omega_4 & \omega_2 & 1 & \omega_8^6 & \omega_4 & \omega_2 \\
1 & \omega_8^7 & \omega_8^5 & \omega_4 & \omega_3 & \omega_2 & \omega & \omega \\
\end{bmatrix}, \quad \omega = \omega_8.
\]
If we define the index vector \( c = [0 \ 2 \ 4 \ 6 \ 1 \ 3 \ 5 \ 7] \), then

\[
F_8(:, c) = \begin{bmatrix}
1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\
1 & \omega^2 & \omega^4 & \omega^6 & \omega & \omega^3 & \omega^5 & \omega^7 \\
1 & \omega^4 & 1 & \omega^4 & \omega^2 & \omega^6 & \omega^2 & \omega^6 \\
1 & \omega^6 & \omega^4 & \omega^2 & \omega^3 & \omega & \omega^7 & \omega^5 \\
1 & 1 & 1 & 1 & -1 & -1 & -1 & -1 \\
1 & \omega^2 & \omega^4 & \omega^6 & -\omega & -\omega^3 & -\omega^5 & -\omega^7 \\
1 & \omega^4 & 1 & \omega^4 & -\omega^2 & -\omega^6 & -\omega^2 & -\omega^6 \\
1 & \omega^6 & \omega^4 & \omega^2 & -\omega^3 & -\omega & -\omega^7 & -\omega^5 \\
\end{bmatrix}.
\]

The lines through the matrix are there to help us think of \( F_n(:, c) \) as a 2-by-2 matrix with 4-by-4 blocks. Noting that \( \omega^2 = \omega_8^2 = \omega_4 \) we see that

\[
F_8(:, c) = \begin{bmatrix}
\frac{F_4}{F_4} & \frac{\Omega_4 F_4}{-\Omega_4 F_4} \\
\end{bmatrix}
\]

where

\[
\Omega_4 = \begin{bmatrix}
1 & 0 & 0 & 0 \\
0 & \omega_8 & 0 & 0 \\
0 & 0 & \omega_8^2 & 0 \\
0 & 0 & 0 & \omega_8^3 \\
\end{bmatrix}.
\]

It follows that if \( x \) in an 8-vector, then

\[
F_8 x = F(:, c) x(c) = \begin{bmatrix}
\frac{F_4}{F_4} & \frac{\Omega_4 F_4}{-\Omega_4 F_4} \\
\end{bmatrix} \begin{bmatrix}
x(0:2:7) \\
x(1:2:7) \\
\end{bmatrix} = \begin{bmatrix}
I & \Omega_4 \\
I & -\Omega_4 \\
\end{bmatrix} \begin{bmatrix}
F_4 x(0:2:7) \\
F_4 x(1:2:7) \\
\end{bmatrix}.
\]

Thus, by simple scalings we can obtain the 8-point DFT \( y = F_8 x \) from the 4-point DFTs \( y_T = F_4 x(0:2:7) \) and \( y_B = F_4 x(1:2:7) \):

\[
y(0:4) = y_T + d \cdot y_B \\
y(4:7) = y_T - d \cdot y_B.
\]

Here,

\[
d = \begin{bmatrix}
1 \\
\omega \\
\omega^2 \\
\omega^3 \\
\end{bmatrix}
\]

and "\(*\)" indicates vector multiplication. In general, if \( n = 2m \), then \( y = F_n x \) is given by

\[
y(0:m-1) = y_T + d \cdot y_B \\
y(m:n-1) = y_B - d \cdot y_B
\]
where
\[
\begin{align*}
    d &= \begin{bmatrix} 1, \omega, \cdots, \omega^{m-1} \end{bmatrix}^T \\
    y_T &= F_m x(0:2:n-1), \\
    y_B &= F_m x(1:2:n-1).
\end{align*}
\]

For \( n = 2^t \) we can recur on this process until \( n = 1 \) for which \( F_1 x = x \):

```
function y = FFT(x, n)
    if n = 1
        y = x
    else
        m = n/2; \omega = e^{-2\pi i/n}
        y_T = FFT(x(0:2:n), m); y_B = FFT(x(1:2:n), m)
        d = \begin{bmatrix} 1, \omega, \cdots, \omega^{m-1} \end{bmatrix}^T ; z = d \ast y_B
        y = \begin{bmatrix} y_T + z \\ y_T - z \end{bmatrix}
    end
```

This is a member of the fast Fourier transform family of algorithms. It has a nonrecursive implementation that is best presented in terms of a factorization of \( F_n \). Indeed, it can be shown that \( F_n = A_1 \cdots A_1 P_n \) where

\[
A_q = I_r \otimes B_L \quad L = 2^q, \quad r = n/L
\]

with

\[
B_L = \begin{bmatrix}
    I_{L/2} & \Omega_{L/2} \\
    I_{L/2} & -\Omega_{L/2}
\end{bmatrix}
\text{ and } \Omega_{L/2} = \text{diag}(1, \omega_L, \ldots, \omega_L^{L/2-1}).
\]

The matrix \( P_n \) is called the bit reversal permutation, the description of which we omit. (Recall the definition of the Kronecker product \( \otimes \) from §4.5.5.) Note that with this factorization, \( y = F_n x \) can be computed as follows:

```
x = P_n x 
for q = 1:t 
    L = 2^q, \quad r = n/L 
    x = (I_r \otimes B_L)x
end
```

The matrices \( A_q = (I_r \otimes B_L) \) have 2 nonzeros per row and it is this sparsity that makes it possible to implement the DFT in \( O(n \log n) \) flops. In fact, a careful implementation involves \( 5n \log_2 n \) flops.

The DFT matrix has the property that

\[
F_n^{-1} = \frac{1}{n} F_n^H = \frac{1}{n} F_n.
\]
That is, the inverse of \( F_n \) is obtained by conjugating its entries and scaling by \( n \). A fast inverse DFT can be obtained from a (forward) FFT merely by replacing all root-of-unity references with their complex conjugate and scaling by \( n \) at the end.

The value of the DFT is that many "hard problems" are made simple by transforming into Fourier space (via \( F_n \)). The sought-after solution is then obtained by transforming the Fourier space solution into original coordinates (via \( F_n^{-1} \)).

Problems

P4.6.1 Show that if \( V = V(x_0, \ldots, x_n) \), then

\[
\det(V) = \prod_{n \geq i > j \geq 0} (x_i - x_j).
\]

P4.6.2 (Gautschi 1975a) Verify the following inequality for the \( n = 1 \) case above:

\[
\| V^{-1} \|_{\infty} \leq \max_{0 \leq k \leq n} \prod_{i=0}^{n} \frac{1 + |x_i|}{|x_k - x_i|}.
\]

Equality results if the \( x_i \) are all on the same ray in the complex plane.

P4.6.3 Suppose \( w = \left[ 1, \omega_n, \omega_n^2, \ldots, \omega_n^{n/2-1} \right] \) where \( n = 2^t \). Using colon notation, express

\[
\left[ 1, \omega_r, \omega_r^2, \ldots, \omega_r^{r/2-1} \right]
\]
as a subvector of \( w \) where \( r = 2^q, q = 1:t \).

P4.6.4 Prove (4.6.6).

P4.6.5 Expand the operation \( x = (I \otimes B_L)x \) in (4.6.5) into a double loop and count the number of flops required by your implementation. (Ignore the details of \( x = P_n x \).)

P4.6.6 Suppose \( n = 3m \) and examine

\[
G = [ F_n(:, 0:3n-1) \ F_n(1:3n-1) \ F_n(:, 2:3n-1) ]
\]
as a 3-by-3 block matrix, looking for scaled copies of \( F_m \). Based on what you find, develop a recursive radix-3 FFT analogous to the radix-2 implementation in the text.

Notes and References for Sec. 4.6

Our discussion of Vandermonde linear systems is drawn from the papers

The divided difference computations we discussed are detailed in chapter 2 of

The latter reference includes an Algol procedure. Error analyses of Vandermonde system solvers include

Interesting theoretical results concerning the condition of Vandermonde systems may be found in

The basic algorithms presented can be extended to cover confluent Vandermonde systems, block Vandermonde systems, and Vandermonde systems that are based on other polynomial bases:

The FFT literature is very extensive and scattered. For an overview of the area couched in Kronecker product notation, see

The point of view in this text is that different FFTs correspond to different factorizations of the DFT matrix. These are sparse factorizations in that the factors have very few nonzeros per row.
4.7 Toeplitz and Related Systems

Matrices whose entries are constant along each diagonal arise in many applications and are called Toeplitz matrices. Formally, $T \in \mathbb{R}^{n \times n}$ is Toeplitz if there exist scalars $r_{-n+1}, \ldots, r_0, \ldots, r_{n-1}$ such that $a_{ij} = r_{j-i}$ for all $i$ and $j$. Thus,

$$
T = \begin{bmatrix}
  r_0 & r_1 & r_2 & r_3 \\
  r_{-1} & r_0 & r_1 & r_2 \\
  r_{-2} & r_{-1} & r_0 & r_1 \\
  r_{-3} & r_{-2} & r_{-1} & r_0 \\
\end{bmatrix}
= \begin{bmatrix}
  3 & 1 & 7 & 6 \\
  4 & 3 & 1 & 7 \\
  0 & 4 & 3 & 1 \\
  9 & 0 & 4 & 3 \\
\end{bmatrix}
$$

is Toeplitz.

Toeplitz matrices belong to the larger class of persymmetric matrices. We say that $B \in \mathbb{R}^{n \times n}$ is persymmetric if it symmetric about its northeast-southwest diagonal, i.e., $b_{ij} = b_{n-j+1,n-i+1}$ for all $i$ and $j$. This is equivalent to requiring $B = EBT^T E$ where $E = [e_n, \ldots, e_1] = I_n(:,n:1:1)$ is the $n$-by-$n$ exchange matrix, i.e.,

$$
E = \begin{bmatrix}
  0 & 0 & 0 & 1 \\
  0 & 0 & 1 & 0 \\
  0 & 1 & 0 & 0 \\
  1 & 0 & 0 & 0 \\
\end{bmatrix}.
$$

It is easy to verify that (a) Toeplitz matrices are persymmetric and (b) the inverse of a nonsingular Toeplitz matrix is persymmetric. In this section we show how the careful exploitation of (b) enables us to solve Toeplitz systems with $O(n^2)$ flops. The discussion focuses on the important case when $T$ is also symmetric and positive definite. Unsymmetric Toeplitz systems and connections with circulant matrices and the discrete Fourier transform are briefly discussed.

4.7.1 Three Problems

Assume that we have scalars $r_1, \ldots, r_n$ such that for $k = 1:n$ the matrices

$$
T_k = \begin{bmatrix}
  1 & r_1 & \cdots & r_{k-2} & r_{k-1} \\
  r_1 & 1 & \cdots & \cdots & \cdots \\
  \vdots & \vdots & \ddots & \ddots & \vdots \\
  r_{k-2} & \cdots & \cdots & r_1 \\
  r_{k-1} & r_{k-2} & \cdots & r_1 & 1 \\
\end{bmatrix}
$$

are positive definite. (There is no loss of generality in normalizing the diagonal.) Three algorithms are described in this section:
• Durbin’s algorithm for the Yule-Walker problem \( T_n y = -[r_1, \ldots, r_n]^T \).
• Levinson’s algorithm for the general righthand side problem \( T_n x = b \).
• Trench’s algorithm for computing \( B = T_n^{-1} \).

In deriving these methods, we denote the \( k \)-by-\( k \) exchange matrix by \( E_k \), i.e., \( E_k = I_k(:, k: -1:1) \).

### 4.7.2 Solving the Yule-Walker Equations

We begin by presenting Durbin’s algorithm for the Yule-Walker equations which arise in conjunction with certain linear prediction problems. Suppose for some \( k \) that satisfies \( 1 \leq k \leq n - 1 \) we have solved the \( k \)-th order Yule-Walker system \( T_k y = -r = -(r_1, \ldots, r_k)^T \). We now show how the \( (k+1) \)-st order Yule-Walker system

\[
\begin{bmatrix}
T_k & E_k r \\
T_k^T E_k & 1
\end{bmatrix}
\begin{bmatrix}
z \\
\alpha
\end{bmatrix}
= \begin{bmatrix}
r \\
r_{k+1}
\end{bmatrix}
\]

can be solved in \( O(k) \) flops. First observe that

\[ z = T_k^{-1}(-r - \alpha E_k r) = y - \alpha T_k^{-1} E_k r \]

and

\[ \alpha = -r_{k+1} - r^T E_k z. \]

Since \( T_k^{-1} \) is persymmetric, \( T_k^{-1} E_k = E_k T_k^{-1} \) and thus,

\[ z = y - \alpha E_k T_k^{-1} r = y + \alpha E_k y. \]

By substituting this into the above expression for \( \alpha \) we find

\[ \alpha = -r_{k+1} - r^T E_k (y + \alpha E_k y) = -(r_{k+1} + r^T E_k y)/(1 + r^T y). \]

The denominator is positive because \( T_{k+1} \) is positive definite and because

\[
\begin{bmatrix}
I & E_k y \\
0 & 1
\end{bmatrix}
^T
\begin{bmatrix}
T_k & E_k r \\
T_k^T E_k & 1
\end{bmatrix}
\begin{bmatrix}
I & E_k y \\
0 & 1
\end{bmatrix}
= \begin{bmatrix}
T_k & 0 \\
0 & 1 + r^T y
\end{bmatrix}
\]

We have illustrated the \( k \)th step of an algorithm proposed by Durbin (1960). It proceeds by solving the Yule-Walker systems

\[ T_k y^{(k)} = -r^{(k)} = -[r_1, \ldots, r_k]^T \]

for \( k = 1:n \) as follows:
\[ y^{(1)} = -r_1 \]
for \( k = 1:n-1 \)
\[
\beta_k = 1 + [r^{(k)}]^T y^{(k)}
\]
\[
\alpha_k = -(r_{k+1} + r^{(k)} E_k y^{(k)}) / \beta_k
\]
\[
z^{(k)} = y^{(k)} + \alpha_k E_k y^{(k)}
\]
\[
y^{(k+1)} = \begin{bmatrix} z^{(k)} \\ \alpha_k \end{bmatrix}
\]
end

As it stands, this algorithm would require \(3n^2\) flops to generate \(y = y^{(n)}\). It is possible, however, to reduce the amount of work even further by exploiting some of the above expressions:

\[
\beta_k = 1 + [r^{(k)}]^T y^{(k)}
\]
\[
= 1 + \begin{bmatrix} r_{k-1}^T \\ r_k \end{bmatrix} \begin{bmatrix} y^{(k-1)} + \alpha_{k-1} E_{k-1} y^{(k-1)} \\ \alpha_{k-1} \end{bmatrix}
\]
\[
= (1 + [r^{(k-1)}]^T y^{(k-1)}) + \alpha_{k-1} \left( [r^{(k-1)}]^T E_{k-1} y^{(k-1)} + r_k \right)
\]
\[
= \beta_{k-1} + \alpha_{k-1} (-\beta_{k-1} \alpha_{k-1})
\]
\[
= (1 - \alpha_{k-1}^2) \beta_{k-1}.
\]

Using this recursion we obtain the following algorithm:

**Algorithm 4.7.1. (Durbin)** Given real numbers \(1 = r_0, r_1, \ldots, r_n\) such that \(T = (r_{i-j}) \in \mathbb{R}^{n \times n}\) is positive definite, the following algorithm computes \(y \in \mathbb{R}^n\) such that \(Ty = -(r_1, \ldots, r_n)^T\).

\[
y(1) = -r(1); \quad \beta = 1; \quad \alpha = -r(1)
\]
for \( k = 1:n-1 \)
\[
\beta = (1 - \alpha^2) \beta
\]
\[
\alpha = -(r(k+1) + r(k-1) E_k y(k)) / \beta
\]
\[
z(1:k) = y(1:k) + \alpha y(k-1:1)
\]
\[
y(1:k+1) = \begin{bmatrix} z(1:k) \\ \alpha \end{bmatrix}
\]
end

This algorithm requires \(2n^2\) flops. We have included an auxiliary vector \(z\) for clarity, but it can be avoided.

**Example 4.7.1** Suppose we wish to solve the Yule-Walker system

\[
\begin{bmatrix} 1 & .5 & .2 \\ .5 & 1 & .5 \\ .2 & .5 & 1 \end{bmatrix} \begin{bmatrix} y_1 \\ y_2 \\ y_3 \end{bmatrix} = -\begin{bmatrix} .5 \\ .2 \\ .1 \end{bmatrix}
\]

using Algorithm 4.7.1. After one pass through the loop we obtain

\[
\alpha = 1/15, \quad \beta = 3/4, \quad v = \begin{bmatrix} -8/15 \\ 1/15 \end{bmatrix}
\]
We then compute
\[ \beta = (1 - \alpha^2)\beta = 56/75 \]
\[ \alpha = -(r_1 + r_2 y_1 + r_1 y_2)/\beta = -1/28 \]
\[ x_1 = y_1 + \alpha y_2 = -225/420 \]
\[ x_2 = y_2 + \alpha y_1 = -36/420, \]
giving the final solution \( y = [-75, 12, -5]^T/140. \)

### 4.7.3 The General Right Hand Side Problem

With a little extra work, it is possible to solve a symmetric positive definite Toeplitz system that has an arbitrary right-hand side. Suppose that we have solved the system
\[ T_k x = b = (b_1, \ldots, b_k)^T \]  \hspace{1cm} (4.7.2)
for some \( k \) satisfying \( 1 \leq k < n \) and that we now wish to solve
\[ \begin{bmatrix} T_k & E_k r \\ r^T E_k & 1 \end{bmatrix} \begin{bmatrix} v \\ \mu \end{bmatrix} = \begin{bmatrix} b \\ b_{k+1} \end{bmatrix}. \]  \hspace{1cm} (4.7.3)

Here, \( r = (r_1, \ldots, r_k)^T \) as above. Assume also that the solution to the \( k \)th order Yule-Walker system \( T_k y = -r \) is also available. From \( T_k v + \mu E_k r = b \) it follows that
\[ v = T_k^{-1}(b - \mu E_k r) = x - \mu T_k^{-1} E_k = x + \mu E_k y \]
and so
\[ \mu = b_{k+1} - r^T E_k v \]
\[ = b_{k+1} - r^T E_k x - \mu r^T y \]
\[ = (b_{k+1} - r^T E_k x) / (1 + r^T y). \]

Consequently, we can effect the transition from (4.7.2) to (4.7.3) in \( O(k) \) flops.

Overall, we can efficiently solve the system \( T_n x = b \) by solving the systems \( T_k x^{(k)} = b^{(k)} = (b_1, \ldots, b_k)^T \) and \( T_k y^{(k)} = -r^{(k)} = (r_1, \ldots, r_k)^T \) "in parallel" for \( k = 1:n \). This is the gist of the following algorithm:

**Algorithm 4.7.2 (Levinson)** Given \( b \in \mathbb{R}^n \) and real numbers \( 1 = r_0, r_1, \ldots, r_n \) such that \( T = (r_{i-j}) \in \mathbb{R}^{n \times n} \) is positive definite, the following algorithm computes \( x \in \mathbb{R}^n \) such that \( Tx = b \).

\[ y(1) = -r(1); \quad x(1) = b(1); \quad \beta = 1; \quad \alpha = -r(1) \]
for \( k = 1:n - 1 \)
\[
\beta = (1 - \alpha^2)\beta; \quad \mu = (b(k + 1) - r(1:k)^T x(k: - 1:1)) / \beta \\
v(1:k) = x(1:k) + \mu y(k: - 1:1) \\
x(1:k + 1) = \begin{bmatrix} v(1:k) \\ \mu \end{bmatrix}
\]

if \( k < n - 1 \)
\[
\alpha = (r(k + 1) + y(1:k)^T y(k: - 1:1)) / \beta \\
z(1:k) = y(1:k) + \alpha y(k: - 1:1) \\
y(1:k + 1) = \begin{bmatrix} z(1:k) \\ \alpha \end{bmatrix}
\]
end

This algorithm requires \( 4n^2 \) flops. The vectors \( z \) and \( v \) are for clarity and can be avoided in a detailed implementation.

Example 4.7.2 Suppose we wish to solve the symmetric positive definite Toeplitz system
\[
\begin{bmatrix}
1 & .5 & .2 \\
.5 & 1 & .5 \\
.2 & .5 & 1 \\
\end{bmatrix}
\begin{bmatrix}
x_1 \\
x_2 \\
x_3 \\
\end{bmatrix}
= \begin{bmatrix}
4 \\
-1 \\
3 \\
\end{bmatrix}
\]

using the above algorithm. After one pass through the loop we obtain
\[
\alpha = 1/15, \quad \beta = 3/4, \quad y = \begin{bmatrix} -8/15 \\ 1/15 \end{bmatrix}, \quad x = \begin{bmatrix} 6 \\ -4 \end{bmatrix}.
\]

We then compute
\[
\begin{align*}
\beta &= (1 - \alpha^2)\beta = 56/75 \\
\mu &= (b_3 - r_1 x_2 - r_2 x_1) / \beta = 285/56 \\
v_1 &= x_1 + \mu y_2 = 355/56 \\
v_2 &= x_2 + \mu y_1 = -376/56
\end{align*}
\]
giving the final solution \( x = [355, -376, 285]^T / 56 \).

4.7.4 Computing the Inverse

One of the most surprising properties of a symmetric positive definite Toeplitz matrix \( T_n \) is that its complete inverse can be calculated in \( O(n^2) \) flops. To derive the algorithm for doing this, partition \( T_n^{-1} \) as follows
\[
T_n^{-1} = \begin{bmatrix} A & E r \\ r^T E & 1 \end{bmatrix}^{-1} = \begin{bmatrix} B & v \\ u^T & \gamma \end{bmatrix}
\]

where \( A = T_{n-1}, E = E_{n-1}, \) and \( r = (r_1, \ldots, r_{n-1})^T \). From the equation
\[
\begin{bmatrix} A & E r \\ r^T E & 1 \end{bmatrix} \begin{bmatrix} v \\ \gamma \end{bmatrix} = \begin{bmatrix} 0 \\ 1 \end{bmatrix}
\]
it follows that \( Av = -\gamma Er = -\gamma E(r_1, \ldots, r_{n-1})^T \) and \( \gamma = 1 - r^T Ev \). If \( y \) solves the \( (n - 1) \)-st order Yule-Walker system \( Ay = -r \), then these
expressions imply that
\[
\gamma = \frac{1}{1 + r^T y}
\]
\[
v = \gamma Ey.
\]
Thus, the last row and column of \(T_n^{-1}\) are readily obtained.

It remains for us to develop working formulae for the entries of the submatrix \(B\) in (4.7.4). Since \(AB + Erv^T = I_{n-1}\), it follows that
\[
B = A^{-1} - (A^{-1}Er)v^T = A^{-1} + \frac{vv^T}{\gamma}.
\]
Now since \(A = T_{n-1}\) is nonsingular and Toeplitz, its inverse is persymmetric. Thus,
\[
b_{ij} = (A^{-1})_{ij} + \frac{v_iv_j}{\gamma}
\]
\[
= (A^{-1})_{n-j,n-i} + \frac{v_iv_j}{\gamma}
\]
\[
= b_{n-j,n-i} - \frac{v_{n-j}v_{n-i}}{\gamma} + \frac{v_iv_j}{\gamma}
\]
\[
= b_{n-j,n-i} + \frac{1}{\gamma}(v_iv_j - v_{n-j}v_{n-i}).
\]  
This indicates that although \(B\) is not persymmetric, we can readily compute an element \(b_{ij}\) from its reflection across the northeast-southwest axis. Coupling this with the fact that \(A^{-1}\) is persymmetric enables us to determine \(B\) from its "edges" to its "interior."

Because the order of operations is rather cumbersome to describe, we preview the formal specification of the algorithm pictorially. To this end, assume that we know the last column and row of \(T_{n-1}^{-1}\):
\[
T_{n-1}^{-1} = \begin{bmatrix}
 u & u & u & u & u & k \\
 u & u & u & u & u & k \\
 u & u & u & u & u & k \\
 u & u & u & u & u & k \\
 u & u & u & u & u & k \\
 k & k & k & k & k & k 
\end{bmatrix}.
\]
Here \(u\) and \(k\) denote the unknown and the known entries respectively, and \(n = 6\). Alternately exploiting the persymmetry of \(T_{n-1}^{-1}\) and the recursion (4.7.5), we can compute \(B\), the leading \((n-1)\)-by-(\(n-1\)) block of \(T_{n-1}^{-1}\), as follows:
\[
\begin{bmatrix}
 k & k & k & k & k \\
 k & u & u & u & k \\
 k & u & u & u & k \\
 k & u & u & u & k \\
 k & k & k & k & k 
\end{bmatrix}
\]  
\[
\begin{bmatrix}
 k & k & k & k & k \\
 k & u & u & u & k \\
 k & u & u & u & k \\
 k & k & k & k & k \\
 k & k & k & k & k 
\end{bmatrix}
\]  
\[
\begin{bmatrix}
 k & k & k & k & k \\
 k & u & u & u & k \\
 k & u & u & u & k \\
 k & k & k & k & k \\
 k & k & k & k & k 
\end{bmatrix}
\]  
\[
\begin{bmatrix}
 k & k & k & k & k \\
 k & u & u & u & k \\
 k & u & u & u & k \\
 k & k & k & k & k \\
 k & k & k & k & k 
\end{bmatrix}
\]  
\[
\begin{bmatrix}
 k & k & k & k & k \\
 k & u & u & u & k \\
 k & u & u & u & k \\
 k & k & k & k & k \\
 k & k & k & k & k 
\end{bmatrix}
\]
Of course, when computing a matrix that is both symmetric and persymmetric, such as $T_n^{-1}$, it is only necessary to compute the "upper wedge" of the matrix—e.g.,

\[ \begin{array}{cccccc}
  \times & \times & \times & \times & \times & \times \\
  \times & \times & \times & \times & \times & \\
 \end{array} \quad (n = 6) \]

With this last observation, we are ready to present the overall algorithm.

**Algorithm 4.7.3 (Trench)** Given real numbers $1 = r_0, r_1, \ldots, r_n$ such that $T = (r_{|i-j|}) \in \mathbb{R}^{n \times n}$ is positive definite, the following algorithm computes $B = T_n^{-1}$. Only those $b_{ij}$ for which $i \leq j$ and $i + j \leq n + 1$ are computed.

Use Algorithm 4.7.1 to solve $T_{n-1}y = -(r_1, \ldots, r_{n-1})^T$.

- $\gamma = 1/(1 + r(1:n-1)^T y(1:n-1))$
- $v(1:n-1) = \gamma y(n-1:1)$
- $B(1,1) = \gamma$
- $B(1,2:n) = v(n-1:1)^T$
- for $i = 2$:floor$((n-1)/2) + 1$
  - for $j = i:n - i + 1$
    - $B(i,j) = B(i-1,j-1) +$
    - $\left( v(n+1-j)v(n+1-i) - v(i-1)v(j-1) \right)/\gamma$
  - end
- end

This algorithm requires $13n^2/4$ flops.

**Example 4.7.3** If the above algorithm is applied to compute the inverse $B$ of the positive definite Toeplitz matrix

\[ \begin{bmatrix}
  1 & .5 & .2 \\
  .5 & 1 & .5 \\
  .2 & .5 & 1 \\
\end{bmatrix} \],

...
then we obtain \( \gamma = 75/56, b_{11} = 75/56, b_{12} = -5/7, b_{13} = 5/56, \) and \( b_{22} = 12/7. \)

4.7.5 Stability Issues

Error analyses for the above algorithms have been performed by Cybenko (1978), and we briefly report on some of his findings.

The key quantities turn out to be the \( \alpha_k \) in (4.7.1). In exact arithmetic these scalars satisfy

\[
|\alpha_k| < 1
\]

and can be used to bound \( \| T^{-1} \|_1 \):

\[
\max \left\{ \frac{1}{\prod_{j=1}^{n-1} (1 - \alpha_j^2)}, \frac{1}{\prod_{j=1}^{n-1} (1 - \alpha_j)} \right\} \leq \| T_n^{-1} \| \leq \prod_{j=1}^{n-1} \frac{1 + |\alpha_j|}{1 - |\alpha_j|} \tag{4.7.6}
\]

Moreover, the solution to the Yule-Walker system \( T_n y = -r(1:n) \) satisfies

\[
\| y \|_1 = \left( \prod_{k=1}^{n} (1 + \alpha_k) \right) - 1 \tag{4.7.7}
\]

provided all the \( \alpha_k \) are non-negative.

Now if \( \hat{x} \) is the computed Durbin solution to the Yule-Walker equations then \( r_D = T_n \hat{x} + r \) can be bounded as follows

\[
\| r_D \| \approx u \prod_{k=1}^{n} (1 + |\hat{\alpha}_k|)
\]

where \( \hat{\alpha}_k \) is the computed version of \( \alpha_k \). By way of comparison, since each \( |r_i| \) is bounded by unity, it follows that \( \| r_C \| \approx u \| y \|_1 \) where \( r_C \) is the residual associated with the computed solution obtained via Cholesky. Note that the two residuals are of comparable magnitude provided (4.7.7) holds. Experimental evidence suggests that this is the case even if some of the \( \alpha_k \) are negative. Similar comments apply to the numerical behavior of the Levinson algorithm.

For the Trench method, the computed inverse \( \hat{B} \) of \( T_n^{-1} \) can be shown to satisfy

\[
\frac{\| T_n^{-1} - \hat{B} \|_1}{\| T_n^{-1} \|_1} \approx u \prod_{k=1}^{n} \frac{1 + |\hat{\alpha}_k|}{1 - |\hat{\alpha}_k|}.
\]

In light of (4.7.7) we see that the right-hand side is an approximate upper bound for \( u \| T_n^{-1} \| \) which is approximately the size of the relative error when \( T_n^{-1} \) is calculated using the Cholesky factorization.
4.7.6 The Unsymmetric Case

Similar recursions can be developed for the unsymmetric case. Suppose we are given scalars \( r_1, \ldots, r_{n-1}, p_1, \ldots, p_{n-1} \), and \( b_1, \ldots, b_n \) and that we want to solve a linear system \( Tx = b \) of the form

\[
\begin{bmatrix}
1 & r_1 & r_2 & r_3 & r_4 \\
p_1 & 1 & r_1 & r_2 & r_3 \\
p_2 & p_1 & 1 & r_1 & r_2 \\
p_3 & p_2 & p_1 & 1 & r_1 \\
p_4 & p_3 & p_2 & p_1 & 1
\end{bmatrix}
\begin{bmatrix}
x_1 \\
x_2 \\
x_3 \\
x_4 \\
x_5
\end{bmatrix} =
\begin{bmatrix}
b_1 \\
b_2 \\
b_3 \\
b_4 \\
b_5
\end{bmatrix}
\quad (n = 5).
\]

In the process that follows we require the leading principle submatrices \( T_k = T(1:k, 1:k) \), \( k = 1:n \) to be nonsingular. Using the same notation as above, it can shown that if we have the solutions to the \( k \)-by-\( k \) systems

\[
T_k^T y = -r = -[r_1 \ r_2 \ \cdots \ r_k]^T
\]

\[
T_kw = -p = -[p_1 \ p_2 \ \cdots \ p_k]^T
\]

\[
T_kx = b = [b_1 \ b_2 \ \cdots \ b_k]^T,
\]

then we can obtain solutions to

\[
\begin{bmatrix}
T_k & E_k r_p \\
p^T E_k & 1
\end{bmatrix}
\begin{bmatrix}
z \\
a
\end{bmatrix} =
\begin{bmatrix}
r \\
r_{k+1}
\end{bmatrix}
\]

\[
\begin{bmatrix}
T_k & E_k r_p \\
p^T E_k & 1
\end{bmatrix}
\begin{bmatrix}
u \\
v
\end{bmatrix} =
\begin{bmatrix}
p \\
p_{k+1}
\end{bmatrix}
\quad (4.7.9)
\]

\[
\begin{bmatrix}
T_k & E_k r_p \\
p^T E_k & 1
\end{bmatrix}
\begin{bmatrix}
u \\
\mu
\end{bmatrix} =
\begin{bmatrix}
b \\
b_{k+1}
\end{bmatrix}
\]

in \( O(k) \) flops. This means that in principle it is possible to solve an unsymmetric Toeplitz system in \( O(n^2) \) flops. However, the stability of the process cannot be assured unless the matrices \( T_k = T(1:k, 1:k) \) are sufficiently well conditioned.

4.7.7 Circulant Systems

A very important class of Toeplitz matrices are the circulant matrices. Here is an example:

\[
C(v) =
\begin{bmatrix}
v_0 & v_4 & v_3 & v_2 & v_1 \\
v_1 & v_0 & v_4 & v_3 & v_2 \\
v_2 & v_1 & v_0 & v_4 & v_3 \\
v_3 & v_2 & v_1 & v_0 & v_4 \\
v_4 & v_3 & v_2 & v_1 & v_0
\end{bmatrix}.
\]
Notice that each column of a circulant is a "downshifted" version of its predecessor. In particular, if we define the downshift permutation $S_n$ by

$$S_n = \begin{bmatrix}
0 & 0 & 0 & 0 & 1 \\
1 & 0 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 0 \\
0 & 0 & 0 & 1 & 0 \\
\end{bmatrix} \quad (n = 5)$$

and $v = \begin{bmatrix} v_0 & v_1 & \cdots & v_{n-1} \end{bmatrix}^T$, then $C(v) = \begin{bmatrix} v, S_n v, S_n^2 v, \ldots, S_n^{n-1} v \end{bmatrix}$.

There are important connections between circulant matrices, Toeplitz matrices, and the DFT. First of all, it can be shown that

$$C(v) = F_n^{-1} \text{diag}(F_n v) F_n. \quad (4.7.10)$$

This means that a product of the form $y = C(v)x$ can be solved at "FFT speed":

$$\begin{align*}
\tilde{x} &= F_n x \\
\tilde{v} &= F_n v \\
x &= \tilde{v} \ast \tilde{x} \\
y &= F_n^{-1} x
\end{align*}$$

In other words, three DFTs and a vector multiply suffice to carry out the product of a circulant matrix and a vector. Products of this form are called convolutions and they are ubiquitous in signal processing and other areas.

Toeplitz-vector products can also be computed fast. The key idea is that any Toeplitz matrix can be "embedded" in a circulant. For example,

$$T = \begin{bmatrix} 5 & 2 & 7 \\
4 & 5 & 2 \\
9 & 4 & 5 \end{bmatrix}$$

is the leading 3-by-3 submatrix of

$$C = \begin{bmatrix} 5 & 2 & 7 & 9 & 4 \\
4 & 5 & 2 & 7 & 9 \\
9 & 4 & 5 & 2 & 7 \\
7 & 9 & 4 & 5 & 2 \\
2 & 7 & 9 & 4 & 5 \end{bmatrix}.$$ 

In general, if $T = (t_{ij})$ is an $n$-by-$n$ Toeplitz matrix, then $T = C(1:n, 1:n)$ where $C \in \mathbb{R}^{(2n-1) \times (2n-1)}$ is a circulant with

$$C(:, 1) = \begin{bmatrix} T(1:n, 1) \\
T(1:n, -1:2)^T \end{bmatrix}.$$ 

Note that if $y = Cx$ and $x(n+1:2n-1) = 0$, then $y(1:n) = T x(1:n)$ showing that Toeplitz vector products can also be computed at "FFT speed."
Problems

P4.7.1 For any \( v \in \mathbb{R}^n \) define the vectors \( v_+ = (v + E_n v)/2 \) and \( v_- = (v - E_n v)/2 \). Suppose \( A \in \mathbb{R}^{n \times n} \) is symmetric and persymmetric. Show that if \( Az = \delta \) then \( Ax_+ = \delta_+ \) and \( Ax_- = \delta_- \).

P4.7.2 Let \( U \in \mathbb{R}^{n \times n} \) be the unit upper triangular matrix with the property that:
\[
U(1,k-1,k) = E_{k-1} \psi^{(k-1)} \text{ where } \psi^{(k)} \text{ is defined by (4.7.1).}
\]
Show that
\[
U^T T_n U = \text{diag}(1, \beta_1, \ldots, \beta_{n-1}).
\]

P4.7.3 Suppose \( z \in \mathbb{R}^n \) and that \( S \in \mathbb{R}^{n \times n} \) is orthogonal. Show that if
\[
X = [z, S z, \ldots, S^{n-1} z]
\]
then \( X^T X \) is Toeplitz.

P4.7.4 Consider the LDL\(^T\) factorization of an \( n \times n \) symmetric, tridiagonal, positive definite Toeplitz matrix. Show that \( d_n \) and \( t_{n,n-1} \) converge as \( n \to \infty \).

P4.7.5 Show that the product of two lower triangular Toeplitz matrices is Toeplitz.

P4.7.6 Give an algorithm for determining \( \mu \in \mathbb{R} \) such that
\[
T_n + \mu (e_n e_n^T + e_1 e_1^T)
\]
is singular. Assume \( T_n = (r_{i,j}) \) is positive definite, with \( r_{0,0} = 1 \).

P4.7.7 Rewrite Algorithm 4.7.2 so that it does not require the vectors \( z \) and \( v \).

P4.7.8 Give an algorithm for computing \( \kappa_{\infty}(T_k) \) for \( k = 1:n \).

P4.7.9 Suppose \( A_1, A_2, A_3 \) and \( A_4 \) are \( m \times m \) matrices and that
\[
A = \begin{bmatrix}
A_0 & A_1 & A_2 & A_3 \\
A_3 & A_0 & A_1 & A_2 \\
A_2 & A_3 & A_0 & A_1 \\
A_1 & A_2 & A_3 & A_0
\end{bmatrix}.
\]
Show that there is a permutation matrix \( \Pi \) such that \( \Pi^T A \Pi = C = (C_{ij}) \) where each \( C_{ij} \) is a 4-by-4 circulant matrix.

P4.7.10 A \( p \times p \) block matrix \( A = (A_{ij}) \) with \( m \times m \) blocks is block Toeplitz if there exist \( A_{-p+1}, \ldots, A_{-1}, A_0, A_1, \ldots, A_{p-1} \in \mathbb{R}^{m \times m} \) so that \( A_{ij} = A_{i-j} \), e.g.,
\[
A = \begin{bmatrix}
A_0 & A_1 & A_2 & A_3 \\
A_{-1} & A_0 & A_1 & A_2 \\
A_{-2} & A_{-1} & A_0 & A_1 \\
A_{-3} & A_{-2} & A_{-1} & A_0
\end{bmatrix}.
\]
(a) Show that there is a permutation \( \Pi \) such that
\[
\Pi^T A \Pi = \begin{bmatrix}
T_{11} & T_{12} & \cdots & T_{1m} \\
T_{21} & T_{22} & \cdots & \\
& & \ddots & \vdots \\
T_{m1} & \cdots & & T_{mm}
\end{bmatrix}
\]
where each \( T_{ij} \) is \( p \times p \) and Toeplitz. Each \( T_{ij} \) should be "made up" of \( (i,j) \) entries selected from the \( A_k \) matrices. (b) What can you say about the \( T_{ij} \) if \( A_k = A_{-k} \), \( k = 1:p-1 \)?

P4.7.11 Show how to compute the solutions to the systems in (4.7.9) given that the
solutions to the systems in (4.7.8) are available. Assume that all the matrices involved are nonsingular. Proceed to develop a fast unsymmetric Toeplitz solver for $Tx = b$ assuming that $T$'s leading principle submatrices are all nonsingular.

P4.7.12 A matrix $H \in \mathbb{R}^{n \times n}$ is Hankel if $H(n: -1:1, :) = $ Toeplitz. Show that if $A \in \mathbb{R}^{n \times n}$ is defined by

$$a_{ij} = \int_{a}^{b} \cos(k\theta) \cos(j\theta) d\theta$$

then $A$ is the sum of a Hankel matrix and Toeplitz matrix. Hint. Make use of the identity $\cos(u + v) = \cos(u) \cos(v) - \sin(u) \sin(v)$.

P4.7.13 Verify that $F_{n}C(v) = \text{diag}(F_{n}v)F_{n}$.

P4.7.14 Show that it is possible to embed a symmetric Toeplitz matrix into a symmetric circulant matrix.

P4.7.15 Consider the $k$th order Yule-Walker system $T_{k}y^{(k)} = -r^{(k)}$ that arises in (4.7.1):

$$T_{k} \begin{bmatrix} y_{1} \\ \vdots \\ y_{k} \end{bmatrix} = \begin{bmatrix} r_{1} \\ \vdots \\ r_{k} \end{bmatrix}.$$  

Show that if

$$L = \begin{bmatrix}
1 & 0 & 0 & 0 & \cdots & 0 \\
y_{11} & 1 & 0 & 0 & \cdots & 0 \\
y_{22} & y_{21} & 1 & 0 & \cdots & 0 \\
y_{33} & y_{32} & y_{31} & 1 & \cdots & 0 \\
\vdots & \vdots & \vdots & \vdots & \ddots & \vdots \\
y_{n-1,n-1} & y_{n-1,n-2} & y_{n-1,n-3} & \cdots & y_{n-1,1} & 1
\end{bmatrix},$$

then $LT_{n}L^{T} = \text{diag}(1, \beta_{1}, \ldots, \beta_{n-1})$ where $\beta_{k} = 1 + r^{(k)}T_{k}$. Thus, the Durbin algorithm can be thought of as a fast method for computing the $LDL^{T}$ factorization of $T_{n}^{-1}$.

Notes and References for Sec. 4.7

Anyone who ventures into the vast Toeplitz method literature should first read

for a clarification of stability issues. As is true with the "fast algorithms" area in general, unstable Toeplitz techniques abound and caution must be exercised. See also

Chapter 5

Orthogonalization and Least Squares

§5.1 Householder and Givens Matrices
§5.2 The QR Factorization
§5.3 The Full Rank LS Problem
§5.4 Other Orthogonal Factorizations
§5.5 The Rank Deficient LS Problem
§5.6 Weighting and Iterative Improvement
§5.7 Square and Underdetermined Systems

This chapter is primarily concerned with the least squares solution of overdetermined systems of equations, i.e., the minimization of \( \| Ax - b \|_2 \) where \( A \in \mathbb{R}^{m \times n} \) with \( m \geq n \) and \( b \in \mathbb{R}^m \). The most reliable solution procedures for this problem involve the reduction of \( A \) to various canonical forms via orthogonal transformations. Householder reflections and Givens rotations are central to this process and we begin the chapter with a discussion of these important transformations. In §5.2 we discuss the computation of the factorization \( A = QR \) where \( Q \) is orthogonal and \( R \) is upper triangular. This amounts to finding an orthonormal basis for \( \text{ran}(A) \). The QR factorization can be used to solve the full rank least squares problem as we show in §5.3. The technique is compared with the method of normal equations after a perturbation theory is developed. In §5.4 and §5.5 we consider methods for handling the difficult situation when \( A \) is rank deficient (or nearly so). QR with column pivoting and the SVD are featured. In §5.6 we discuss several steps that can be taken to improve the quality of a computed
least squares solution. Some remarks about square and underdetermined systems are offered in §5.7.

Before You Begin

Chapters 1, 2, and 3 and §§4.1-4.3 are assumed. Within this chapter there are the following dependencies:

5.1 Householder and Givens Matrices

Recall that $Q \in \mathbb{R}^{n \times n}$ is orthogonal if $Q^TQ = QQ^T = I_n$. Orthogonal matrices have an important role to play in least squares and eigenvalue computations. In this section we introduce the key players in this game: Householder reflections and Givens rotations.

5.1.1 A 2-by-2 Preview

It is instructive to examine the geometry associated with rotations and reflections at the $n = 2$ level. A 2-by-2 orthogonal matrix $Q$ is a rotation if it has the form

$$Q = \begin{bmatrix} \cos(\theta) & \sin(\theta) \\ -\sin(\theta) & \cos(\theta) \end{bmatrix}.$$

If $y = Q^Tx$, then $y$ is obtained by rotating $x$ counterclockwise through an angle $\theta$.

A 2-by-2 orthogonal matrix $Q$ is a reflection if it has the form

$$Q = \begin{bmatrix} \cos(\theta) & \sin(\theta) \\ \sin(\theta) & -\cos(\theta) \end{bmatrix}.$$

If $y = Q^Tx = Qx$, then $y$ is obtained by reflecting the vector $x$ across the line defined by

$$S = \text{span} \left\{ \begin{bmatrix} \cos(\theta/2) \\ \sin(\theta/2) \end{bmatrix} \right\}.$$

Reflections and rotations are computationally attractive because they are easily constructed and because they can be used to introduce zeros in a vector by properly choosing the rotation angle or the reflection plane.

**Example 5.1.1** Suppose $x = [1, \sqrt{3}]^T$. If we set

$$Q = \begin{bmatrix} \cos(-60^\circ) & \sin(-60^\circ) \\ -\sin(-60^\circ) & \cos(-60^\circ) \end{bmatrix} = \begin{bmatrix} 1/2 & -\sqrt{3}/2 \\ \sqrt{3}/2 & 1/2 \end{bmatrix}$$

then $Q^Tx = [2, 0]^T$. Thus, a rotation of $-60^\circ$ zeros the second component of $x$. If

$$Q = \begin{bmatrix} \cos(30^\circ) & \sin(30^\circ) \\ \sin(30^\circ) & -\cos(30^\circ) \end{bmatrix} = \begin{bmatrix} \sqrt{3}/2 & 1/2 \\ 1/2 & -\sqrt{3}/2 \end{bmatrix}$$

then $Q^Tx = [2, 0]^T$. Thus, by reflecting $x$ across the $30^\circ$ line we can zero its second component.
5.1.2 Householder Reflections

Let \( v \in \mathbb{R}^n \) be nonzero. An \( n \times n \) matrix \( P \) of the form

\[
P = I - \frac{2}{v^Tv}vv^T
\]

(5.1.1)

is called a Householder reflection. (Synonyms: Householder matrix, Householder transformation.) The vector \( v \) is called a Householder vector. If a vector \( x \) is multiplied by \( P \), then it is reflected in the hyperplane \( \text{span}\{v\}^\perp \). It is easy to verify that Householder matrices are symmetric and orthogonal.

Householder reflections are similar in two ways to Gauss transformations, which we introduced in §3.2.1. They are rank-1 modifications of the identity and they can be used to zero selected components of a vector. In particular, suppose we are given \( 0 \neq x \in \mathbb{R}^n \) and want \( Px \) to be a multiple of \( e_1 = I_n(1,1) \). Note that

\[
P x = \left( I - \frac{2vv^T}{v^Tv} \right) x = x - \frac{2v^Tx}{v^Tv} v
\]

and \( Px \in \text{span}\{e_1\} \) imply \( v \in \text{span}\{x,e_1\} \). Setting \( v = x + \alpha e_1 \) gives

\[
v^T x = x^T x + \alpha x_1
\]

and

\[
v^T v = x^T x + 2\alpha x_1 + \alpha^2,
\]

and therefore

\[
P x = \left( 1 - 2 \frac{x^T x + \alpha x_1}{x^T x + 2\alpha x_1 + \alpha^2} \right) x - 2\alpha \frac{v^T x}{v^Tv} e_1.
\]

In order for the coefficient of \( x \) to be zero, we set \( \alpha = \pm \|x\|_2 \) for then

\[
v = x \pm \|x\|_2 e_1 \Rightarrow Px = \left( I - \frac{vv^T}{v^Tv} \right) x = \mp \|x\|_2 e_1.
\]

(5.1.2)

It is this simple determination of \( v \) that makes the Householder reflection so useful.

Example 5.1.2 If \( x = [3,1,5,1]^T \) and \( v = [9,1,5,1]^T \), then

\[
P = I - 2\frac{vv^T}{v^Tv} = \frac{1}{54} \begin{bmatrix} -27 & -9 & -45 & -9 \\ -9 & 53 & -5 & -1 \\ -45 & -5 & 29 & -5 \\ -9 & -1 & -5 & 53 \end{bmatrix}
\]

has the property that \( Px = [-6, 0, 0, 0]^T \).
5.1.3 Computing the Householder Vector

There are a number of important practical details associated with the determination of a Householder matrix, i.e., the determination of a Householder vector. One concerns the choice of sign in the definition of $v$ in (5.1.2). Setting

$$v_1 = x_1 - \| x \|_2$$

has the nice property that $Px$ is a positive multiple of $e_1$. But this recipe is dangerous if $x$ is close to a positive multiple of $e_1$ because severe cancellation would occur. However, the formula

$$v_1 = x_1 - \| x \|_2 = \frac{x_1^2 - \| x \|^2}{x_1 + \| x \|_2} = \frac{-x_2^2 + \cdots + x_n^2}{x_1 + \| x \|_2}$$

suggested by Parlett (1971) does not suffer from this defect in the $x_1 > 0$ case.

In practice, it is handy to normalize the Householder vector so that $v(1) = 1$. This permits the storage of $v(2:n)$ where the zeros have been introduced in $x$, i.e., $x(2:n)$. We refer to $v(2:n)$ as the essential part of the Householder vector. Recalling that $\beta = 2/v^Tv$ and letting $\text{length}(x)$ specify vector dimension, we obtain the following encapsulation:

Algorithm 5.1.1 (Householder Vector) Given $x \in \mathbb{R}^n$, this function computes $v \in \mathbb{R}^n$ with $v(1) = 1$ and $\beta \in \mathbb{R}$ such that $P = I_n - \beta vv^T$ is orthogonal and $Px = \| x \|_2 e_1$.

function: $[v, \beta] = \text{house}(x)$

$n = \text{length}(x)$

$\sigma = x(2:n)^T x(2:n)$

$v = \begin{bmatrix} 1 \\ x(2:n) \end{bmatrix}$

if $\sigma = 0$

$\beta = 0$

else

$\mu = \sqrt{x(1)^2 + \sigma}$

if $x(1) \leq 0$

$v(1) = x(1) - \mu$

else

$v(1) = -\sigma/(x(1) + \mu)$

end

$\beta = 2v(1)^2/(\sigma + v(1)^2)$

$v = v/v(1)$

end

This algorithm involves about $3n$ flops and renders a computed Householder matrix that is orthogonal to machine precision, a concept discussed below.
A production version of Algorithm 5.1.1 may involve a preliminary scaling of the $x$ vector ($x \leftarrow x/\|x\|$) to avoid overflow.

5.1.4 Applying Householder Matrices

It is critical to exploit structure when applying a Householder reflection to a matrix. If $A \in \mathbb{R}^{m \times n}$ and $P = I - \beta vv^T \in \mathbb{R}^{m \times m}$, then

$$PA = (I - \beta vv^T)A = A - vv^T$$

where $w = \beta A^Tv$. Likewise, if $P = I - \beta vv^T \in \mathbb{R}^{n \times n}$, then

$$AP = A(I - \beta vv^T) = A - vv^T$$

where $w = \beta Av$. Thus, an $m$-by-$n$ Householder update involves a matrix-vector multiplication and an outer product update. It requires $4mn$ flops. Failure to recognize this and to treat $P$ as a general matrix increases work by an order of magnitude. Householder updates never entail the explicit formation of the Householder matrix.

Both of the above Householder updates can be implemented in a way that exploits the fact that $v(1) = 1$. This feature can be important in the computation of $PA$ when $m$ is small and in the computation of $AP$ when $n$ is small.

As an example of a Householder matrix update, suppose we want to overwrite $A \in \mathbb{R}^{m \times n}$ ($m \geq n$) with $B = Q^TA$ where $Q$ is an orthogonal matrix chosen so that $B(j+1:m, j) = 0$ for some $j$ that satisfies $1 \leq j \leq n$. In addition, suppose $A(j:m, 1:j - 1) = 0$ and that we want to store the essential part of the Householder vector in $A(j + 1:m, j)$. The following instructions accomplish this task:

$$[v, \beta] = \text{house}(A(j:m, j))$$
$$A(j:m, j:n) = (I_{m-j+1} - \beta vv^T)A(j:m, j:n)$$
$$A(j + 1:m, j) = v(2:m - j + 1)$$

From the computational point of view, we have applied an order $m - j + 1$ Householder matrix to the bottom $m - j + 1$ rows of $A$. However, mathematically we have also applied the $m$-by-$m$ Householder matrix

$$\tilde{P} = \begin{bmatrix} I_{j-1} & 0 \\ 0 & P \end{bmatrix} = I_m - \beta \tilde{v}\tilde{v}^T \quad \tilde{v} = \begin{bmatrix} 0 \\ v \end{bmatrix}$$

to $A$ in its entirety. Regardless, the "essential" part of the Householder vector can be recorded in the zeroed portion of $A$. 
5.1.5 Roundoff Properties

The roundoff properties associated with Householder matrices are very favorable. Wilkinson (1965, pp. 152-62) shows that house produces a Householder vector \( \hat{v} \) very near the exact \( v \). If \( \hat{P} = I - 2\hat{v}\hat{v}^T / \hat{v}^T \hat{v} \) then

\[
\| \hat{P} - P \|_2 = O(u)
\]

meaning that \( \hat{P} \) is orthogonal to machine precision. Moreover, the computed updates with \( \hat{P} \) are close to the exact updates with \( P \):

\[
f(I(\hat{P}A) = P(A + E) \quad \| E \|_2 = O(u\| A \|_2)
\]

\[
f(I(A\hat{P}) = (A + E)P \quad \| E \|_2 = O(u\| A \|_2)
\]

5.1.6 Factored Form Representation

Many Householder based factorization algorithms that are presented in the following sections compute products of Householder matrices

\[
Q = Q_1Q_2 \cdots Q_r \quad Q_j = I - \beta_jv^{(j)}v^{(j)^T}
\]  

(5.1.3)

where \( r \leq n \) and each \( v^{(j)} \) has the form

\[
v^{(j)} = (0, 0, \ldots, 1, v_{j+1}^{(j)}, \ldots, v_n^{(j)})^T.
\]

It is usually not necessary to compute \( Q \) explicitly even if it is involved in subsequent calculations. For example, if \( C \in \mathbb{R}^{n \times q} \) and we wish to compute \( Q^TC \), then we merely execute the loop

\[
\text{for } j = 1:r \\
C = Q_jC
\]

end

The storage of the Householder vectors \( v^{(1)} \ldots v^{(r)} \) and the corresponding \( \beta_j \) (if convenient) amounts to a factored form representation of \( Q \). To illustrate the economies of the factored form representation, suppose that we have an array \( A \) and that \( A(j+1:n,j) \) houses \( v^{(j)}(j+1:n) \), the essential part of the \( j \)th Householder vector. The overwriting of \( C \in \mathbb{R}^{n \times q} \) with \( Q^TC \) can then be implemented as follows:

\[
\text{for } j = 1:r \\
v(j:n) = \left[ \begin{array}{c} 1 \\ A(j+1:n,j) \end{array} \right]
\]  

(5.1.4)

\[
C(j:n,:) = (I - \beta_jv(j:n)v(j:n)^T)C(j:n,:)
\]

end
This involves about \(2qr(2n - r)\) flops. If \(Q\) is explicitly represented as an \(n\)-by-\(n\) matrix, \(Q^T C\) would involve \(2n^2q\) flops.

Of course, in some applications, it is necessary to explicitly form \(Q\) (or parts of it). Two possible algorithms for computing the Householder product matrix \(Q\) in (5.1.3) are forward accumulation,

\[
Q = I_n \\
\text{for } j = 1:r \\
\quad Q = QQ_j \\
\text{end}
\]

and backward accumulation,

\[
Q = I_n \\
\text{for } j = r: -1:1 \\
\quad Q = Q_jQ \\
\text{end}
\]

Recall that the leading \((j-1)\)-by-\((j-1)\) portion of \(Q_j\) is the identity. Thus, at the beginning of backward accumulation, \(Q\) is "mostly the identity" and it gradually becomes full as the iteration progresses. This pattern can be exploited to reduce the number of required flops. In contrast, \(Q\) is full in forward accumulation after the first step. For this reason, backward accumulation is cheaper and the strategy of choice:

\[
Q = I_n \\
\text{for } j = r: -1:1 \\
\quad v(j:n) = \begin{bmatrix} 1 \\ A(j + 1:n, j) \end{bmatrix} \\
\quad Q(j:n, j:n) = (I - \beta_j v(j:n) v(j:n)^T)Q(j:n, j:n) \\
\text{end}
\]  

(5.1.5)

This involves about \(4(n^2r - nr^2 + r^3/3)\) flops.

5.1.7 A Block Representation

Suppose \(Q = Q_1 \cdots Q_r\) is a product of \(n\)-by-\(n\) Householder matrices as in (5.1.3). Since each \(Q_j\) is a rank-one modification of the identity, it follows from the structure of the Householder vectors that \(Q\) is a rank-\(r\) modification of the identity and can be written in the form

\[
Q = I + WY^T
\]  

(5.1.6)

where \(W\) and \(Y\) are \(n\)-by-\(r\) matrices. The key to computing the block representation (5.1.6) is the following lemma.
Lemma 5.1.1 Suppose \( Q = I + WY^T \) is an \( n \times n \) orthogonal matrix with \( W, Y \in \mathbb{R}^{n \times j} \). If \( P = I - \beta vv^T \) with \( v \in \mathbb{R}^n \) and \( z = -\beta Qu \), then

\[
Q_+ = PQ = I + W_+ Y_+^T
\]

where \( W_+ = [W \ z] \) and \( Y_+ = [Y \ v] \) are each \( n \times (j + 1) \).

Proof.

\[
QP = (I + WY^T)(I - \beta vv^T) = I + WY^T - \beta Qvv^T
\]

\[
= I + WY^T + zz^T = I + [W \ z][Y \ v]^T \quad \square
\]

By repeatedly applying the lemma, we can generate the block representation of \( Q \) in (5.1.3) from the factored form representation as follows:

Algorithm 5.1.2 Suppose \( Q = Q_1 \cdots Q_r \) is a product of \( n \times n \) Householder matrices as described in (5.1.3). This algorithm computes matrices \( W, Y \in \mathbb{R}^{n \times r} \) such that \( Q = I + WY^T \).

\[
Y = v^{(1)}
\]

\[
W = -\beta_1 v^{(1)}
\]

for \( j = 2:r \)

\[
z = -\beta_j (I + WY^T)v^{(j)}
\]

\[
W = [W \ z]
\]

\[
Y = [Y \ v^{(j)}]
\]

end

This algorithm involves about \( 2r^2n - 2r^3/3 \) flops if the zeros in the \( v^{(j)} \) are exploited. Note that \( Y \) is merely the matrix of Householder vectors and is therefore unit lower triangular. Clearly, the central task in the generation of the \( WY \) representation (5.1.6) is the computation of the \( W \) matrix.

The block representation for products of Householder matrices is attractive in situations where \( Q \) must be applied to a matrix. Suppose \( C \in \mathbb{R}^{n \times q} \). It follows that the operation

\[
C \leftarrow Q^TC = (I + WY^T)^TC = C + Y(WTC)
\]

is rich in level-3 operations. On the other hand, if \( Q \) is in factored form, \( Q^TC \) is just rich in the level-2 operations of matrix-vector multiplication and outer product updates. Of course, in this context the distinction between level-2 and level-3 diminishes as \( C \) gets narrower.

We mention that the "\( WY \)" representation is not a generalized Householder transformation from the geometric point of view. True block reflectors have the form \( Q = I - 2VV^T \) where \( V \in \mathbb{R}^{n \times r} \) satisfies \( V^TV = I_r \). See Schreiber and Parlett (1987) and also Schreiber and Van Loan (1989).

Example 5.1.3 If \( n = 4, r = 2 \), and \( [1, .6, 0, .8]^T \) and \( [0, 1, .8, .6]^T \) are the
Householder vectors associated with $Q_1$ and $Q_2$ respectively, then

$$Q_1 Q_2 = I_4 + W Y^T = I_4 + \begin{bmatrix} -1 & 1.080 \\ -0.6 & -0.352 \\ -0.0 & -0.800 \\ -0.8 & 0.264 \end{bmatrix} \begin{bmatrix} 1 & 0.6 & 0.8 \\ 0 & 1.8 & 0.6 \end{bmatrix}.$$ 

### 5.1.8 Givens Rotations

Householder reflections are exceedingly useful for introducing zeros on a grand scale, e.g., the annihilation of all but the first component of a vector. However, in calculations where it is necessary to zero elements more selectively, Givens rotations are the transformation of choice. These are rank-two corrections to the identity of the form

$$G(i, k, \theta) = \begin{bmatrix} 1 & \cdots & 0 & \cdots & 0 \\ \vdots & \ddots & \vdots & \ddots & \vdots \\ 0 & \cdots & c & \cdots & s \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & \cdots & 0 & \cdots & 0 \end{bmatrix}$$

where $c = \cos(\theta)$ and $s = \sin(\theta)$ for some $\theta$. Givens rotations are clearly orthogonal.

Premultiplication by $G(i, k, \theta)^T$ amounts to a counterclockwise rotation of $\theta$ radians in the $(i, k)$ coordinate plane. Indeed, if $x \in \mathbb{R}^n$ and $y = G(i, k, \theta)^T x$, then

$$y_j = \begin{cases} \frac{c x_i - s x_k}{\sqrt{x_i^2 + x_k^2}} & j = i \\ \frac{s x_i + c x_k}{\sqrt{x_i^2 + x_k^2}} & j = k \\ x_j & j \neq i, k \end{cases}$$

From these formulae it is clear that we can force $y_k$ to be zero by setting

$$c = \frac{x_i}{\sqrt{x_i^2 + x_k^2}} \quad s = \frac{-x_k}{\sqrt{x_i^2 + x_k^2}} \quad (5.1.8)$$

Thus, it is a simple matter to zero a specified entry in a vector by using a Givens rotation. In practice, there are better ways to compute $c$ and $s$ than (5.1.8). The following algorithm, for example, guards against overflow.
Algorithm 5.1.3 Given scalars \( a \) and \( b \), this function computes \( c = \cos(\theta) \)
and \( s = \sin(\theta) \) so
\[
\begin{bmatrix}
c & s \\
-s & c
\end{bmatrix}
\begin{bmatrix}
a \\
b
\end{bmatrix}
= \begin{bmatrix}
r \\
0
\end{bmatrix}.
\]

function: \([c, s] = \text{givens}(a, b)\)

if \( b = 0 \)
\( c = 1; \ s = 0 \)

else
if \( |b| > |a| \)
\( \tau = -a/b; \ s = 1/\sqrt{1 + \tau^2}; \ c = s\tau \)
else
\( \tau = -b/a; \ c = 1/\sqrt{1 + \tau^2}; \ s = c\tau \)
end
end

This algorithm requires 5 flops and a single square root. Note that it does not compute \( \theta \) and so it does not involve inverse trigonometric functions.

Example 5.1.4 If \( x = [1, \ 2, \ 3, \ 4]^T \), \( \cos(\theta) = 1/\sqrt{5} \), and \( \sin(\theta) = -2/\sqrt{5} \), then \( G(2, 4, \theta)x = [1, \ \sqrt{20}, \ 3, \ 0]^T \).

5.1.9 Applying Givens Rotations

It is critical that the simple structure of a Givens rotation matrix be exploited when it is involved in a matrix multiplication. Suppose \( A \in \mathbb{R}^{m \times n} \), 
\( c = \cos(\theta) \), and \( s = \sin(\theta) \). If \( G(i, k, \theta) \in \mathbb{R}^{m \times m} \), then the update \( A \leftarrow G(i, k, \theta)^T A \) affects just two rows of \( A \),
\[
A([i, k], :) = \begin{bmatrix}
c & s \\
-s & c
\end{bmatrix}^T A([i, k], :)
\]
and requires just 6n flops:

for \( j = 1:n \)
\( \tau_1 = A(i, j) \)
\( \tau_2 = A(k, j) \)
\( A(1, j) = c\tau_1 - s\tau_2 \)
\( A(2, j) = s\tau_1 + c\tau_2 \)
end

Likewise, if \( G(i, k, \theta) \in \mathbb{R}^{n \times n} \), then the update \( A \leftarrow AG(i, k, \theta) \) affects just two columns of \( A \),
\[
A(:, [i, k]) = A(:, [i, k]) \begin{bmatrix}
c & s \\
-s & c
\end{bmatrix}
\]
and requires just 6m flops:
for $j = 1:m$
\begin{align*}
    &\tau_1 = A(j, i) \\
    &\tau_2 = A(j, k) \\
    &A(j, i) = c\tau_1 - s\tau_2 \\
    &A(j, k) = s\tau_1 + c\tau_2
\end{align*}
end

5.1.10 Roundoff Properties

The numerical properties of Givens rotations are as favorable as those for Householder reflections. In particular, it can be shown that the computed $\hat{c}$ and $\hat{s}$ in `givens` satisfy
\begin{align*}
    \hat{c} &= c(1 + \epsilon_c) & \epsilon_c &= O(u) \\
    \hat{s} &= s(1 + \epsilon_s) & \epsilon_s &= O(u).
\end{align*}

If $\hat{c}$ and $\hat{s}$ are subsequently used in a Givens update, then the computed update is the exact update of a nearby matrix:
\begin{align*}
    \|fI[\hat{G}(i, k, \theta)^T A]\| &= \|G(i, k, \theta)^T(A + E)\|_2 \\
    &\approx u\|A\|_2 \\
    \|fI[A\hat{G}(i, k, \theta)]\| &= \|(A + E)G(i, k, \theta)\|_2 \\
    &\approx u\|A\|_2.
\end{align*}

A detailed error analysis of Givens rotations may be found in Wilkinson (1965, pp. 131-39).

5.1.11 Representing Products of Givens Rotations

Suppose $Q = G_1 \cdots G_k$ is a product of Givens rotations. As we have seen in connection with Householder reflections, it is more economical to keep the orthogonal matrix $Q$ in factored form than to compute explicitly the product of the rotations. Using a technique demonstrated by Stewart (1976), it is possible to do this in a very compact way. The idea is to associate a single floating point number $\rho$ with each rotation. Specifically, if
\[
    Z = \begin{bmatrix} c & s \\ -s & c \end{bmatrix}, \quad c^2 + s^2 = 1
\]

then we define the scalar $\rho$ by
\begin{align*}
    \text{if } c = 0 & \quad \rho = 1 \\
    \text{elseif } |s| < |c| & \quad \rho = \text{sign}(c)s/2 \\
    \text{else} & \quad \rho = 2\text{sign}(s)/c
\end{align*} \quad (5.1.9)

end
Essentially, this amounts to storing $s/2$ if the sine is smaller and $2/c$ if the cosine is smaller. With this encoding, it is possible to reconstruct $\pm Z$ as follows:

\[
\begin{align*}
    \text{if } \rho &= 1 \\
    c &= 0; \ s = 1 \\
    \text{elseif } |\rho| &< 1 \\
    s &= 2\rho; \ c = \sqrt{1-s^2} \\
    \text{else} \\
    c &= 2/\rho; \ s = \sqrt{1-c^2}
\end{align*}
\] (5.1.10)

That $-Z$ may be generated is usually of no consequence for if $Z$ zeros a particular matrix entry, so does $-Z$. The reason for essentially storing the smaller of $c$ and $s$ is that the formula $\sqrt{1-x^2}$ renders poor results if $x$ is near unity. More details may be found in Stewart (1976). Of course, to "reconstruct" $G(i,k,\theta)$ we need $i$ and $k$ in addition to the associated $\rho$. This usually poses no difficulty as we discuss in §5.2.3.

5.1.12 Error Propagation

We offer some remarks about the propagation of roundoff error in algorithms that involve sequences of Householder/Givens updates. To be precise, suppose $A = A_0 \in \mathbb{R}^{m \times n}$ is given and that matrices $A_1, \ldots, A_p = B$ are generated via the formula

\[ A_k = fl(\hat{Q}_k A_{k-1} \hat{Z}_k) \quad k = 1:p. \]

Assume that the above Householder and Givens algorithms are used for both the generation and application of the $\hat{Q}_k$ and $\hat{Z}_k$. Let $Q_k$ and $Z_k$ be the orthogonal matrices that would be produced in the absence of roundoff. It can be shown that

\[ B = (Q_p \cdots Q_1)(A + E)(Z_1 \cdots Z_p), \] (5.1.11)

where $\|E\|_2 \leq c\|A\|_2$ and $c$ is a constant that depends mildly on $n$, $m$, and $p$. In plain English, $B$ is an exact orthogonal update of a matrix near to $A$.

5.1.13 Fast Givens Transformations

The ability to introduce zeros in a selective fashion makes Givens rotations an important zeroing tool in certain structured problems. This has led to the development of "fast Givens" procedures. The fast Givens idea amounts to a clever representation of $Q$ when $Q$ is the product of Givens rotations.
In particular, $Q$ is represented by a matrix pair $(M, D)$ where $M^T M = D = \text{diag}(d_i)$ and each $d_i$ is positive. The matrices $Q$, $M$, and $D$ are connected through the formula

$$Q = MD^{-1/2} = M\text{diag}(1/\sqrt{d_i}).$$

Note that $(MD^{-1/2})^T(MD^{-1/2}) = D^{-1/2}DD^{-1/2} = I$ and so the matrix $MD^{-1/2}$ is orthogonal. Moreover, if $F$ is an $n$-by-$n$ matrix with $F^T D F = D_{\text{new}}$ diagonal, then $M_{\text{new}}^T M_{\text{new}} = D_{\text{new}}$ where $M_{\text{new}} = MF$. Thus, it is possible to update the fast Givens representation $(M, D)$ to obtain $(M_{\text{new}}, D_{\text{new}})$. For this idea to be of practical interest, we must show how to give $F$ zeroing capabilities subject to the constraint that it "keeps" $D$ diagonal.

The details are best explained at the 2-by-2 level. Let $x = [x_1 \ x_2]^T$ and $D = \text{diag}(d_1, d_2)$ be given and assume that $d_1$ and $d_2$ are positive. Define

$$M_1 = \begin{bmatrix} \beta_1 & 1 \\ 1 & \alpha_1 \end{bmatrix} \quad (5.1.12)$$

and observe that

$$M_1^T x = \begin{bmatrix} \beta_1 x_1 + x_2 \\ x_1 + \alpha_1 x_2 \end{bmatrix}$$

and

$$M_1^T D M_1 = \begin{bmatrix} d_2 + \beta_1^2 d_1 & \beta_1 \beta_1 + d_2 \alpha_1 \\ \beta_1 \beta_1 + d_2 \alpha_1 & d_1 + \alpha_1^2 d_2 \end{bmatrix} = D_1.$$ 

If $x_2 \neq 0$, $\alpha_1 = -x_1/x_2$, and $\beta_1 = -\alpha_1 d_2/d_1$, then

$$M_1^T x = \begin{bmatrix} x_2(1 + \gamma_1) \\ 0 \end{bmatrix}$$

and

$$M_1^T D M_1 = \begin{bmatrix} d_2(1 + \gamma_1) & 0 \\ 0 & d_1(1 + \gamma_1) \end{bmatrix}$$

where $\gamma_1 = -\alpha_1 \beta_1 = (d_2/d_1)(x_1/x_2)^2$.

Analogously, if we assume $x_1 \neq 0$ and define $M_2$ by

$$M_2 = \begin{bmatrix} 1 & \alpha_2 \\ \beta_2 & 1 \end{bmatrix} \quad (5.1.13)$$

where $\alpha_2 = -x_2/x_1$ and $\beta_2 = -(d_1/d_2)\alpha_2$, then

$$M_2^T x = \begin{bmatrix} x_1(1 + \gamma_2) \\ 0 \end{bmatrix}$$

and

$$M_2^T D M_2 = \begin{bmatrix} d_1(1 + \gamma_2) & 0 \\ 0 & d_2(1 + \gamma_2) \end{bmatrix} = D_2,$$
where $\gamma_2 = -\alpha_2 \beta_2 = (d_1/d_2)(x_2/x_1)^2$.

It is easy to show that for either $i = 1$ or 2, the matrix $J = D^{1/2} M_i D_i^{-1/2}$ is orthogonal and that it is designed so that the second component of $J^T (D^{-1/2} x)$ is zero. ($J$ may actually be a reflection and thus it is half-correct to use the popular term “fast Givens.”)

Notice that the $\gamma_i$ satisfy $\gamma_1 \gamma_2 = 1$. Thus, we can always select $M_i$ in the above so that the “growth factor” $(1 + \gamma_i)$ is bounded by 2. Matrices of the form

\[
M_1 = \begin{bmatrix} \beta_1 & 1 \\ 1 & \alpha_1 \end{bmatrix} \quad M_2 = \begin{bmatrix} 1 & \alpha_2 \\ \beta_2 & 1 \end{bmatrix}
\]

that satisfy $-1 \leq \alpha_i \beta_i \leq 0$ are 2-by-2 fast Givens transformations. Notice that premultiplication by a fast Givens transformation involves half the number of multiplies as premultiplication by an “ordinary” Givens transformation. Also, the zeroing is carried out without an explicit square root.

In the $n$-by-$n$ case, everything “scales up” as with ordinary Givens rotations. The “type 1” transformations have the form

\[
F(i, k, \alpha, \beta) = \begin{bmatrix}
1 & \ldots & 0 & \ldots & 0 & \ldots & 0 \\
\vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots \\
0 & \ldots & \beta & \ldots & 1 & \ldots & 0 \\
\vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots \\
0 & \ldots & 1 & \ldots & \alpha & \ldots & 0 \\
\vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots \\
0 & \ldots & 0 & \ldots & 0 & \ldots & 1
\end{bmatrix}
\]

\[(5.1.14)\]

while the “type 2” transformations are structured as follows:

\[
F(i, k, \alpha, \beta) = \begin{bmatrix}
1 & \ldots & 0 & \ldots & 0 & \ldots & 0 \\
\vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots \\
0 & \ldots & 1 & \ldots & \alpha & \ldots & 0 \\
\vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots \\
0 & \ldots & \beta & \ldots & 1 & \ldots & 0 \\
\vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots \\
0 & \ldots & 0 & \ldots & 0 & \ldots & 1
\end{bmatrix}
\]

\[(5.1.15)\]

Encapsulating all this we obtain

**Algorithm 5.1.4** Given $x \in \mathbb{R}^2$ and positive $d \in \mathbb{R}^2$, the following algorithm computes a 2-by-2 fast Givens transformation $M$ such that the
second component of $M^T z$ is zero and $M^T D M = D_1$ is diagonal where $D = \text{diag}(d_1, d_2)$. If type $= 1$ then $M$ has the form (5.1.12) while if type $= 2$ then $M$ has the form (5.1.13). The diagonal elements of $D_1$ overwrite $d$.

function: $[\alpha, \beta, \text{type}] = \text{fast.givens}(x, d)$
if $x(2) \neq 0$
  $\alpha = -x(1)/x(2); \beta = -\alpha d(2)/d(1); \gamma = -\alpha \beta$
if $\gamma \leq 1$ 
  type $= 1$
  $\tau = d(1); d(1) = (1 + \gamma)d(2); d(2) = (1 + \gamma)\tau$
else 
  type $= 2$
  $\alpha = 1/\alpha; \beta = 1/\beta; \gamma = 1/\gamma$
  $d(1) = (1 + \gamma)d(1); d(2) = (1 + \gamma)d(2)$
end 
else 
  type $= 2$
  $\alpha = 0; \beta = 0$
end 

The application of fast Givens transformations is analogous to that for ordinary Givens transformations. Even with the appropriate type of transformation used, the growth factor $1 + \gamma$ may still be as large as two. Thus, $2^s$ growth can occur in the entries of $D$ and $M$ after $s$ updates. This means that the diagonal $D$ must be monitored during a fast Givens procedure to avoid overflow. See Anda and Park (1994) for how to do this efficiently.

Nevertheless, element growth in $M$ and $D$ is controlled because at all times we have $M D^{-1/2}$ orthogonal. The roundoff properties of a fast Givens procedure are what we would expect of a Givens matrix technique. For example, if we computed $\hat{Q} = fl(M \hat{D}^{-1/2})$ where $\hat{M}$ and $\hat{D}$ are the computed $M$ and $D$, then $\hat{Q}$ is orthogonal to working precision: $\| \hat{Q}^T \hat{Q} - I \|_2 \approx u$.

Problems

P5.1.1 Execute house with $x = [1, 7, 2, 3, -1]^T$.

P5.1.2 Let $x$ and $y$ be nonzero vectors in $\mathbb{R}^n$. Give an algorithm for determining a Householder matrix $P$ such that $Px$ is a multiple of $y$.

P5.1.3 Suppose $x \in \mathbb{C}^n$ and that $x_1 = |x_1|e^{i\theta}$ with $\theta \in \mathbb{R}$. Assume $x \neq 0$ and define $u = x + e^{i\theta}\|x\|_2 e_1$. Show that $P = I - 2uu^H/uu^Hu$ is unitary and that $Px = -e^{i\theta}\|x\|_2 e_1$.

P5.1.4 Use Householder matrices to show that $\det(I + xy^T) = 1 + x^Ty$ where $x$ and $y$ are given $n$-vectors.

P5.1.5 Suppose $x \in \mathbb{C}^2$. Give an algorithm for determining a unitary matrix of the form

$$Q = \begin{bmatrix} c & s \\ -s & c \end{bmatrix}, \quad c \in \mathbb{R}, \quad c^2 + |s|^2 = 1$$

such that the second component of $Q^H x$ is zero.
P5.1.6 Suppose $x$ and $y$ are unit vectors in $\mathbb{R}^n$. Give an algorithm using Givens transformations which computes an orthogonal $Q$ such that $Q^T x = y$.

P5.1.7 Determine $c = \cos(\theta)$ and $s = \sin(\theta)$ such that
\[
\begin{bmatrix}
  c & s \\
  -s & c
\end{bmatrix}
\begin{bmatrix}
  5 \\
  12
\end{bmatrix}
= \begin{bmatrix}
  13 \\
  0
\end{bmatrix}.
\]

P5.1.8 Suppose that $Q = I + YTY^T$ is orthogonal where $Y \in \mathbb{R}^{n \times j}$ and $T \in \mathbb{R}^{j \times j}$ is upper triangular. Show that if $Q_+ = QP$ where $P = I - 2uu^T/u^Tv$ is a Householder matrix, then $Q_+$ can be expressed in the form $Q_+ = I + Y_+T_+Y_+^T$ where $Y_+ \in \mathbb{R}^{n \times (j+1)}$ and $T_+ \in \mathbb{R}^{(j+1) \times (j+1)}$ is upper triangular.

P5.1.9 Give a detailed implementation of Algorithm 5.1.2 with the assumption that $v^{(j+1)}(j+1:n)$, the essential part of the the $j$th Householder vector, is stored in $A(j+1:n,j)$. Since $Y$ is effectively represented in $A$, your procedure need only set up the $W$ matrix.

P5.1.10 Show that if $S$ is skew-symmetric ($S^T = -S$), then $Q = (I + S)(I - S)^{-1}$ is orthogonal. ($Q$ is called the Cayley transform of $S$.) Construct a rank-2 $S$ so that if $z$ is a vector then $Qz$ is zero except in the first component.

P5.1.11 Suppose $P \in \mathbb{R}^{m \times n}$ satisfies $\|P^TP - I_n\|_2 = \epsilon < 1$. Show that all the singular values of $P$ are in the interval $[1-\epsilon, 1+\epsilon]$ and that $\|P - U\Sigma V^T\|_2 \leq \epsilon$ where $P = U\Sigma V^T$ is the SVD of $P$.

P5.1.12 Suppose $A \in \mathbb{R}^{2 \times 2}$. Under what conditions is the closest rotation to $A$ closer than the closest reflection to $A$?

Notes and References for Sec. 5.1

Householder matrices are named after A.S. Householder, who popularized their use in numerical analysis. However, the properties of these matrices have been known for quite some time. See

Other references concerned with Householder transformations include

A detailed error analysis of Householder transformations is given in Lawson and Hanson (1974, 83-89).

The basic references for block Householder representations and the associated computations include

Givens rotations, named after W. Givens, are also referred to as Jacobi rotations. Jacobi devised a symmetric eigenvalue algorithm based on these transformations in 1846. See §8.4. The Givens rotation storage scheme discussed in the text is detailed in

Fast Givens transformations are also referred to as "square-root-free" Givens transformations. (Recall that a square root must ordinarily be computed during the formation of Givens transformation.) There are several ways fast Givens calculations can be arranged. See

### 5.2 The QR Factorization

We now show how Householder and Givens transformations can be used to compute various factorizations, beginning with the QR factorization. The QR factorization of an $m$-by-$n$ matrix $A$ is given by

$$A = QR$$

where $Q \in \mathbb{R}^{m \times m}$ is orthogonal and $R \in \mathbb{R}^{m \times n}$ is upper triangular. In this section we assume $m \geq n$. We will see that if $A$ has full column rank, then the first $n$ columns of $Q$ form an orthonormal basis for $\text{ran}(A)$. Thus, calculation of the QR factorization is one way to compute an orthonormal basis for a set of vectors. This computation can be arranged in several ways. We give methods based on Householder, block Householder, Givens, and fast Givens transformations. The Gram-Schmidt orthogonalization process and a numerically more stable variant called modified Gram-Schmidt are also discussed.
5.2.1 Householder QR

We begin with a QR factorization method that utilizes Householder transformations. The essence of the algorithm can be conveyed by a small example. Suppose \( m = 6, n = 5 \), and assume that Householder matrices \( H_1 \) and \( H_2 \) have been computed so that

\[
H_2 H_1 A = \begin{bmatrix}
  x & x & x & x & x \\
  0 & x & x & x & x \\
  0 & 0 & x & x & x \\
  0 & 0 & x & x & x \\
  0 & 0 & x & x & x \\
  0 & 0 & x & x & x \\
\end{bmatrix}.
\]

Concentrating on the highlighted entries, we determine a Householder matrix \( \bar{H}_3 \in \mathbb{R}^{4 \times 4} \) such that

\[
\bar{H}_3 \begin{bmatrix}
  x \\
  0 \\
  0 \\
  0 \\
\end{bmatrix} = \begin{bmatrix}
  x \\
  0 \\
  0 \\
\end{bmatrix}.
\]

If \( H_3 = \text{diag}(I_2, \bar{H}_3) \), then

\[
H_3 H_2 H_1 A = \begin{bmatrix}
  x & x & x & x & x \\
  0 & x & x & x & x \\
  0 & 0 & x & x & x \\
  0 & 0 & x & x & x \\
  0 & 0 & x & x & x \\
\end{bmatrix}.
\]

After \( n \) such steps we obtain an upper triangular \( H_n H_{n-1} \cdots H_1 A = R \) and so by setting \( Q = H_1 \cdots H_n \) we obtain \( A = QR \).

Algorithm 5.2.1 (Householder QR) Given \( A \in \mathbb{R}^{m \times n} \) with \( m \geq n \), the following algorithm finds Householder matrices \( H_1, \ldots, H_n \) such that if \( Q = H_1 \cdots H_n \), then \( Q^T A = R \) is upper triangular. The upper triangular part of \( A \) is overwritten by the upper triangular part of \( R \) and components \( j + 1:m \) of the \( j \)th Householder vector are stored in \( A(j + 1:m, j), j < m \).

\[
\text{for } j = 1:n \\
\quad [v, \beta] = \text{house}(A(j:m, j)) \\
\quad A(j:m, j:n) = (I_{m-j+1} - \beta vv^T)A(j:m, j:n) \\
\quad \text{if } j < m \\
\quad\quad A(j + 1:m, j) = v(2:m - j + 1)
\text{end}
\text{end}
This algorithm requires \(2n^2(m - n/3)\) flops.

To clarify how \(A\) is overwritten, if

\[
v^{(j)} = [0, \ldots, 0, 1, v_{j+1}^{(j)}, \ldots, v_m^{(j)}]^T
\]

is the \(j\)th Householder vector, then upon completion

\[
A = \begin{bmatrix}
    r_{11} & r_{12} & r_{13} & r_{14} & r_{15} \\
    v_2^{(1)} & r_{22} & r_{23} & r_{24} & r_{25} \\
    v_3^{(1)} & v_3^{(2)} & r_{33} & r_{34} & r_{35} \\
    v_4^{(1)} & v_4^{(2)} & v_4^{(3)} & r_{44} & r_{45} \\
    v_5^{(1)} & v_5^{(2)} & v_5^{(3)} & v_5^{(4)} & r_{55} \\
    v_6^{(1)} & v_6^{(2)} & v_6^{(3)} & v_6^{(4)} & v_6^{(5)}
\end{bmatrix}
\]

If the matrix \(Q = H_1 \cdots H_n\) is required, then it can be accumulated using (5.1.5). This accumulation requires \(4(m^2n - mn^2 + n^3/3)\) flops.

The computed upper triangular matrix \(\hat{R}\) is the exact \(R\) for a nearby \(A\) in the sense that \(Z^T(A + E) = \hat{R}\) where \(Z\) is some exact orthogonal matrix and \(\| E \|_2 \approx u\| A \|_2\).

### 5.2.2 Block Householder QR Factorization

Algorithm 5.2.1 is rich in the level-2 operations of matrix-vector multiplication and outer product updates. By reorganizing the computation and using the block Householder representation discussed in §5.1.7 we can obtain a level-3 procedure. The idea is to apply clusters of Householder transformations that are represented in the WY form of §5.1.7.

A small example illustrates the main idea. Suppose \(n = 12\) and that the "blocking parameter" \(r\) has the value \(r = 3\). The first step is to generate Householders \(H_1, H_2,\) and \(H_3\) as in Algorithm 5.2.1. However, unlike Algorithm 5.2.1 where the \(H_i\) are applied to all of \(A\), we only apply \(H_1, H_2,\) and \(H_3\) to \(A(:, 1:3)\). After this is accomplished we generate the block representation \(H_1H_2H_3 = I + W_1Y_1^T\) and then perform the level-3 update

\[
A(:, 4:12) = (I + WY^T)A(:, 4:12).
\]

Next, we generate \(H_4, H_5,\) and \(H_6\) as in Algorithm 5.2.1. However, these transformations are not applied to \(A(:, 7:12)\) until their block representation \(H_4H_5H_6 = I + W_2Y_2^T\) is found. This illustrates the general pattern.
\( \lambda = 1; \ k = 0 \)

while \( \lambda \leq n \)

\( \tau = \min(\lambda + \tau - 1, n); \ k = k + 1 \)

Using Algorithm 5.2.1, upper triangularize \( A(\lambda:m, \lambda:n) \)

- generating Householder matrices \( H_\lambda, \ldots, H_\tau \) \hspace{1cm} (5.2.1)

Use Algorithm 5.1.2 to get the block representation

\[ I + W_k Y_k = H_\lambda, \ldots, H_\tau. \]

\[ A(\lambda:m, \tau + 1:n) = (I + W_k Y_k^T)^T A(\lambda:m, \tau + 1:n) \]

\( \lambda = \tau + 1 \)

end

The zero-nonzero structure of the Householder vectors that define the matrices \( H_\lambda, \ldots, H_\tau \) implies that the first \( \lambda - 1 \) rows of \( W_k \) and \( Y_k \) are zero. This fact would be exploited in a practical implementation.

The proper way to regard (5.2.1) is through the partitioning

\[ A = [A_1, \ldots, A_N] \quad N = \lceil n/r \rceil \]

where block column \( A_k \) is processed during the \( k \)th step. In the \( k \)th step of (5.2.1), a block Householder is formed that zeros the subdiagonal portion of \( A_k \). The remaining block columns are then updated.

The roundoff properties of (5.2.1) are essentially the same as those for Algorithm 5.2.1. There is a slight increase in the number of flops required because of the \( W \)-matrix computations. However, as a result of the blocking, all but a small fraction of the flops occur in the context of matrix multiplication. In particular, the level-3 fraction of (5.2.1) is approximately \( 1 - 2/N \). See Bischof and Van Loan (1987) for further details.

### 5.2.3 Givens QR Methods

Givens rotations can also be used to compute the QR factorization. The 4-by-3 case illustrates the general idea:

\[
\begin{bmatrix}
  x & x & x \\
  x & x & x \\
  x & x & x \\
  0 & x & x \\
\end{bmatrix}
\begin{bmatrix}
  x & x & x \\
  x & x & x \\
  x & x & x \\
  0 & x & x \\
\end{bmatrix}
\begin{bmatrix}
  x & x & x \\
  0 & x & x \\
  0 & x & x \\
  0 & 0 & x \\
\end{bmatrix}
\begin{bmatrix}
  x & x & x \\
  0 & x & x \\
  0 & 0 & x \\
  0 & 0 & x \\
\end{bmatrix}
\]

\((3,4)\)

\((2,3)\)

\((1,2)\)

Here we have highlighted the 2-vectors that define the underlying Givens rotations. Clearly, if \( G_j \) denotes the \( j \)th Givens rotation in the reduction, then \( Q^T A = R \) is upper triangular where \( Q = G_1 \cdots G_t \) and \( t \) is the total
number of rotations. For general $m$ and $n$ we have:

Algorithm 5.2.2 (Givens QR) Given $A \in \mathbb{R}^{m \times n}$ with $m \geq n$, the following algorithm overwrites $A$ with $Q^T A = R$, where $R$ is upper triangular and $Q$ is orthogonal.

for $j = 1:n$
  for $i = m: -1:j + 1$
    $[c, s] = \text{givens}(A(i - 1, j), A(i, j))$
    $A(i - 1:i, j:n) = \begin{bmatrix} c & s \\ -s & c \end{bmatrix}^T A(i - 1:i, j:n)$
  end
end

This algorithm requires $3n^2(m - n/3)$ flops. Note that we could use (5.1.9) to encode $(c, s)$ in a single number $\rho$ which could then be stored in the zeroed entry $A(i, j)$. An operation such as $x \leftarrow Q^T x$ could then be implemented by using (5.1.10), taking care to reconstruct the rotations in the proper order.

Other sequences of rotations can be used to upper triangularize $A$. For example, if we replace the for statements in Algorithm 5.2.2 with

for $i = m: -1:2$
  for $j = 1:\text{min}\{i - 1, n\}$
then the zeros in $A$ are introduced row-by-row.

Another parameter in a Givens QR procedure concerns the planes of rotation that are involved in the zeroing of each $a_{ij}$. For example, instead of rotating rows $i - 1$ and $i$ to zero $a_{ij}$ as in Algorithm 5.2.2, we could use rows $j$ and $i$:

for $j = 1:n$
  for $i = m: -1:j + 1$
    $[c, s] = \text{givens}(A(j, j), A(i, j))$
    $A([j \ i], j:n) = \begin{bmatrix} c & s \\ -s & c \end{bmatrix}^T A([j \ i], j:n)$
  end
end

5.2.4 Hessenberg QR via Givens

As an example of how Givens rotations can be used in structured problems, we show how they can be employed to compute the QR factorization of an upper Hessenberg matrix. A small example illustrates the general idea.
Suppose \( n = 6 \) and that after two steps we have computed

\[
G(2, 3, \theta_2)^T G(1, 2, \theta_1)^T A = \begin{bmatrix}
\times & \times & \times & \times & \times & \times \\
0 & \times & \times & \times & \times & \times \\
0 & 0 & \times & \times & \times & \times \\
0 & 0 & 0 & \times & \times & \times \\
0 & 0 & 0 & 0 & \times & \times \\
0 & 0 & 0 & 0 & 0 & \times 
\end{bmatrix}.
\]

We then compute \( G(3, 4, \theta_3) \) to zero the current \((4,3)\) entry thereby obtaining

\[
G(3, 4, \theta_3)^T G(2, 3, \theta_2)^T G(1, 2, \theta_1)^T A = \begin{bmatrix}
\times & \times & \times & \times & \times & \times \\
0 & \times & \times & \times & \times & \times \\
0 & 0 & \times & \times & \times & \times \\
0 & 0 & 0 & \times & \times & \times \\
0 & 0 & 0 & 0 & \times & \times \\
0 & 0 & 0 & 0 & 0 & \times 
\end{bmatrix}.
\]

Overall we have

**Algorithm 5.2.3 (Hessenberg QR)** If \( A \in \mathbb{R}^{n \times n} \) is upper Hessenberg, then the following algorithm overwrites \( A \) with \( Q^T A = R \) where \( Q \) is orthogonal and \( R \) is upper triangular. \( Q = G_1 \cdots G_{n-1} \) is a product of Givens rotations where \( G_j \) has the form \( G_j = G(j, j + 1, \theta_j) \).

for \( j = 1 : n - 1 \)

\[
[A(j,j), A(j+1,j)] = \text{givens}(A(j,j), \ldots, A(j+1,j))
\]

\[
A(j,j+1,j:n) = \begin{bmatrix}
c & s \\
-s & c
\end{bmatrix}^T A(j,j+1,j:n)
\]

end

This algorithm requires about \( 3n^2 \) flops.

### 5.2.5 Fast Givens QR

We can use the fast Givens transformations described in §5.1.13 to compute an \((M, D)\) representation of \( Q \). In particular, if \( M \) is nonsingular and \( D \) is diagonal such that \( M^T A = T \) is upper triangular and \( M^T M = D \) is diagonal, then \( Q = M D^{-1/2} \) is orthogonal and \( Q^T A = D^{-1/2} T \equiv R \) is upper triangular. Analogous to the Givens QR procedure we have:

**Algorithm 5.2.4 (Fast Givens QR)** Given \( A \in \mathbb{R}^{m \times n} \) with \( m \geq n \), the following algorithm computes nonsingular \( M \in \mathbb{R}^{m \times m} \) and positive \( d(1:m) \) such that \( M^T A = T \) is upper triangular, and \( M^T M = \text{diag}(d_1, \ldots, d_m) \). \( A \) is overwritten by \( T \). Note: \( A = (M D^{-1/2})(D^{1/2} T) \) is a QR factorization of \( A \).
for \( i = 1:m \)
\[
d(i) = 1
\]
end
for \( j = 1:n \)
for \( i = m:-1:j+1 \)
    \[
    [\alpha, \beta, \text{type}] = \text{fast.givens}(A(i-1:i,j), d(i-1:i))
    \]
    if \( \text{type} = 1 \)
        \[
        A(i-1:i,j:n) = \begin{bmatrix} \beta & 1 \\ 1 & \alpha \end{bmatrix}^T A(i-1:i,j:n)
        \]
    else
        \[
        A(i-1:i,j:n) = \begin{bmatrix} 1 & \alpha \\ \beta & 1 \end{bmatrix}^T A(i-1:i,j:n)
        \]
    end
end
This algorithm requires \( 2n^2(m - n/3) \) flops. As we mentioned in the previous section, it is necessary to guard against overflow in fast Givens algorithms such as the above. This means that \( M, D, \) and \( A \) must be periodically scaled if their entries become large.

If the QR factorization of a narrow band matrix is required, then the fast Givens approach is attractive because it involves no square roots. (We found \( LDL^T \) preferable to Cholesky in the narrow band case for the same reason; see §4.3.6.) In particular, if \( A \in \mathbb{R}^{m \times n} \) has upper bandwidth \( q \) and lower bandwidth \( p \), then \( Q^T A = R \) has upper bandwidth \( p + q \). In this case Givens QR requires about \( O(np(p + q)) \) flops and \( O(np) \) square roots. Thus, the square roots are a significant portion of the overall computation if \( p, q \ll n \).

### 5.2.6 Properties of the QR Factorization

The above algorithms “prove” that the QR factorization exists. Now we relate the columns of \( Q \) to \( \text{ran}(A) \) and \( \text{ran}(A)^\perp \) and examine the uniqueness question.

**Theorem 5.2.1** If \( A = QR \) is a QR factorization of a full column rank \( A \in \mathbb{R}^{m \times n} \) and \( A = [a_1, \ldots, a_n] \) and \( Q = [q_1, \ldots, q_m] \) are column partitionings, then

\[
\text{span}\{a_1, \ldots, a_k\} = \text{span}\{q_1, \ldots, q_k\} \quad k = 1:n.
\]

In particular, if \( Q_1 = Q(1:m, 1:n) \) and \( Q_2 = Q(1:m, n+1:m) \) then

\[
\text{ran}(A) = \text{ran}(Q_1)
\]
\[
\text{ran}(A)^\perp = \text{ran}(Q_2)
\]

and \( A = Q_1 R_1 \) with \( R_1 = R(1:n, 1:n) \).
Proof. Comparing $k$th columns in $A = QR$ we conclude that

$$a_k = \sum_{i=1}^{k} r_{ik} q_i \in \text{span}\{q_1, \ldots, q_k\} .$$

(5.2.2)

Thus, $\text{span}\{a_1, \ldots, a_k\} \subseteq \text{span}\{q_1, \ldots, q_k\}$. However, since $\text{rank}(A) = n$ it follows that $\text{span}\{a_1, \ldots, a_k\}$ has dimension $k$ and so must equal $\text{span}\{q_1, \ldots, q_k\}$. The rest of the theorem follows trivially. $\square$

The matrices $Q_1 = Q(1:m, 1:n)$ and $Q_2 = Q(1:m, n+1:m)$ can be easily computed from a factored form representation of $Q$.

If $A = QR$ is a QR factorization of $A \in \mathbb{R}^{m \times n}$ and $m \geq n$, then we refer to $A = Q(:, 1:n)R(1:n, 1:n)$ as the thin QR factorization. The next result addresses the uniqueness issue for the thin QR factorization.

**Theorem 5.2.2** Suppose $A \in \mathbb{R}^{m \times n}$ has full column rank. The thin QR factorization

$$A = Q_1 R_1$$

is unique where $Q_1 \in \mathbb{R}^{m \times n}$ has orthonormal columns and $R_1$ is upper triangular with positive diagonal entries. Moreover, $R_1 = G^T$ where $G$ is the lower triangular Cholesky factor of $A^T A$.

Proof. Since $A^T A = (Q_1 R_1)^T (Q_1 R_1) = R_1^T R_1$ we see that $G = R_1^T$ is the Cholesky factor of $A^T A$. This factor is unique by Theorem 4.2.5. Since $Q_1 = AR_1^{-1}$ it follows that $Q_1$ is also unique. $\square$

How are $Q_1$ and $R_1$ affected by perturbations in $A$? To answer this question we need to extend the notion of condition to rectangular matrices. Recall from §2.7.3 that the 2-norm condition of a square nonsingular matrix is the ratio of the largest and smallest singular values. For rectangular matrices with full column rank we continue with this definition:

$$A \in \mathbb{R}^{m \times n}, \text{rank}(A) = n \implies \kappa_2(A) = \frac{\sigma_{\text{max}}(A)}{\sigma_{\text{min}}(A)} .$$

If the columns of $A$ are nearly dependent, then $\kappa_2(A)$ is large. Stewart (1993) has shown that $O(\epsilon)$ relative error in $A$ induces $O(\epsilon \kappa_2(A))$ relative error in $R$ and $Q_1$.

### 5.2.7 Classical Gram-Schmidt

We now discuss two alternative methods that can be used to compute the thin QR factorization $A = Q_1 R_1$ directly. If $\text{rank}(A) = n$, then equation (5.2.2) can be solved for $q_k$:

$$q_k = \left( a_k - \sum_{i=1}^{k-1} r_{ik} q_i \right) / r_{kk} .$$
Thus, we can think of \( q_k \) as a unit 2-norm vector in the direction of

\[
x_k = a_k - \sum_{i=1}^{k-1} r_{ik} q_i
\]

where to ensure \( x_k \in \text{span}\{q_1, \ldots, q_{k-1}\}^\perp \) we choose

\[
r_{ik} = q_i^T a_k \quad i = 1:k-1.
\]

This leads to the classical Gram-Schmidt (CGS) algorithm for computing \( A = Q_1 R_1 \).

\[
R(1, 1) = \| A(:, 1) \|_2 \\
Q(:, 1) = A(:, 1)/R(1, 1)
\]

for \( k = 2:n \)

\[
R(1:k-1, k) = Q(1:m, 1:k-1)^T A(1:m, k) \\
z = A(1:m, k) - Q(1:m, 1:k-1) R(1:k-1, k)
\]

\[
R(k, k) = \| z \|_2 \\
Q(1:m, k) = z/R(k, k)
\]

end

In the \( k \)th step of CGS, the \( k \)th columns of both \( Q \) and \( R \) are generated.

### 5.2.8 Modified Gram-Schmidt

Unfortunately, the CGS method has very poor numerical properties in that there is typically a severe loss of orthogonality among the computed \( q_i \). Interestingly, a rearrangement of the calculation, known as modified Gram-Schmidt (MGS), yields a much sounder computational procedure. In the \( k \)th step of MGS, the \( k \)th column of \( Q \) (denoted by \( q_k \)) and the \( k \)th row of \( R \) (denoted by \( r_k^T \)) are determined. To derive the MGS method, define the matrix \( A^{(k)} \in \mathbb{R}^{m \times (n-k+1)} \) by

\[
A - \sum_{i=1}^{k-1} q_i r_i^T = \sum_{i=k}^{n} q_i r_i^T = \begin{bmatrix} 0 & A^{(k)} \end{bmatrix}.
\]

It follows that if

\[
A^{(k)} = \begin{bmatrix} z & B \\ 1 & n-k \end{bmatrix}
\]

then \( r_{kk} = \| z \|_2 \), \( q_k = z/r_{kk} \) and \( (r_{k,k+1} \cdots r_{kn}) = q_k^T B \). We then compute the outer product \( A^{(k+1)} = B - q_k (r_{k,k+1} \cdots r_{kn}) \) and proceed to the next step. This completely describes the \( k \)th step of MGS.

**Algorithm 5.2.5 (Modified Gram-Schmidt)** Given \( A \in \mathbb{R}^{m \times n} \) with \( \text{rank}(A) = n \), the following algorithm computes the factorization \( A = Q_1 R_1 \) where \( Q_1 \in \mathbb{R}^{m \times n} \) has orthonormal columns and \( R_1 \in \mathbb{R}^{n \times n} \) is upper triangular.
for $k = 1:n$
\[
R(k,k) = \| A(1:m,k) \|_2 \\
Q(1:m,k) = A(1:m,k)/R(k,k)
\]
for $j = k + 1:n$
\[
R(k,j) = Q(1:m,k)^T A(1:m,j) \\
A(1:m,j) = A(1:m,j) - Q(1:m,k)R(k,j)
\]
end

This algorithm requires $2mn^2$ flops. It is not possible to overwrite $A$ with both $Q_1$ and $R_1$. Typically, the MGS computation is arranged so that $A$ is overwritten by $Q_1$ and the matrix $R_1$ is stored in a separate array.

5.2.9 Work and Accuracy

If one is interested in computing an orthonormal basis for $\text{ran}(A)$, then the Householder approach requires $2mn^2 - 2n^3/3$ flops to get $Q$ in factored form and another $2mn^2 - 2n^3/3$ flops to get the first $n$ columns of $Q$. (This requires "paying attention" to just the first $n$ columns of $Q$ in (5.1.5).) Therefore, for the problem of finding an orthonormal basis for $\text{ran}(A)$, MGS is about twice as efficient as Householder orthogonalization. However, Björck (1967) has shown that MGS produces a computed $\hat{Q}_1 = \{ \hat{q}_1, \ldots, \hat{q}_n \}$ that satisfies
\[
\hat{Q}_1^T \hat{Q}_1 = I + E_{\text{MGS}} \quad \| E_{\text{MGS}} \|_2 \approx u \kappa_2(A)
\]
whereas the corresponding result for the Householder approach is of the form
\[
\hat{Q}_1^T \hat{Q}_1 = I + E_H \quad \| E_H \|_2 \approx u.
\]
Thus, if orthonormality is critical, then MGS should be used to compute orthonormal bases only when the vectors to be orthogonalized are fairly independent.

We also mention that the computed triangular factor $\hat{R}$ produced by MGS satisfies $\| A - \hat{Q} \hat{R} \| \approx u \| A \|$ and that there exists a $Q$ with perfectly orthonormal columns such that $\| A - Q \hat{R} \| \approx u \| A \|$. See Higham (1996, p.379).

Example 5.2.1 If modified Gram-Schmidt is applied to
\[
A = \begin{bmatrix}
1 & 1 \\
10^{-3} & 0 \\
0 & 10^{-3}
\end{bmatrix} \quad \kappa_2(A) \approx 1.4 \cdot 10^3
\]
with 6-digit decimal arithmetic, then
\[
[\hat{q}_1 \hat{q}_2] = \begin{bmatrix}
1.00000 \\
.001 \\
0
\end{bmatrix} \quad \begin{bmatrix}
0 \\
-.707107 \\
.707107
\end{bmatrix}.
\]
5.2.10  A Note on Complex QR

Most of the algorithms that we present in this book have complex versions that are fairly straightforward to derive from their real counterparts. (This is not to say that everything is easy and obvious at the implementation level.) As an illustration we outline what a complex Householder QR factorization algorithm looks like.

Starting at the level of an individual Householder transformation, suppose $0 \neq x \in \mathbb{C}^n$ and that $x_1 = re^{i\theta}$ where $r, \theta \in \mathbb{R}$. If $v = x \pm e^{i\theta} \| x \| e_1$ and $P = I_n - \beta vv^H$, $\beta = 2/v^H v$, then $Px = \mp e^{i\theta} \| x \| e_1$. (See P5.1.3.) The sign can be determined to maximize $\| v \|_2$ for the sake of stability.

The upper triangularization of $A \in \mathbb{R}^{m \times n}$, $m \geq n$, proceeds as in Algorithm 5.2.1. In step $j$ we zero the subdiagonal portion of $A(j:m,j)$:

\[
\text{for } j = 1:n \\
x = A(j:m,j) \\
v = x \pm e^{i\theta} \| x \| e_1 \text{ where } x_1 = re^{i\theta} \\
\beta = 2/v^H v \\
A(j:m,j:n) = (I_{m-j+1} - \beta vv^H)A(j:m,j:n)
\]

end

The reduction involves $8n^2(m - n/3)$ real flops, four times the number required to execute Algorithm 5.2.1. If $Q = P_1 \cdots P_n$ is the product of the Householder transformations, then $Q$ is unitary and $Q^TA = R \in \mathbb{R}^{m \times n}$ is complex and upper triangular.

Problems

P5.2.1  Adapt the Householder QR algorithm so that it can efficiently handle the case when $A \in \mathbb{R}^{m \times n}$ has lower bandwidth $p$ and upper bandwidth $q$.

P5.2.2  Adapt the Householder QR algorithm so that it computes the factorization $A = QL$ where $L$ is lower triangular and $Q$ is orthogonal. Assume that $A$ is square. This involves rewriting the Householder vector function $v = \text{house}(x)$ so that $(I - 2vv^T/v^Tv)x$ is zero everywhere but its bottom component.

P5.2.3  Adapt the Givens QR factorization algorithm so that the zeros are introduced by diagonal. That is, the entries are zeroed in the order $(m,1)$, $(m-1,1)$, $(m,2)$, $(m-2,1)$, $(m-1,2)$, $(m,3)$, etc.

P5.2.4  Adapt the fast Givens QR factorization algorithm so that it efficiently handles the case when $A$ is $n$-by-$n$ and tridiagonal. Assume that the subdiagonal, diagonal, and superdiagonal of $A$ are stored in $e(1:n-1)$, $a(1:n)$, $f(1:n-1)$ respectively. Design your algorithm so that these vectors are overwritten by the nonzero portion of $T$.

P5.2.5  Suppose $L \in \mathbb{R}^{m \times n}$ with $m \geq n$ is lower triangular. Show how Householder matrices $H_1 \cdots H_n$ can be used to determine a lower triangular $L_1 \in \mathbb{R}^{n \times n}$ so that

\[
H_n \cdots H_1 L = \begin{bmatrix} L_1 \\ 0 \end{bmatrix}
\]
Hint: The second step in the 6-by-3 case involves finding $H_2$ so that

$$H_2 \begin{bmatrix} x & 0 & 0 \\ x & x & 0 \\ x & x & x \\ x & x & 0 \\ x & x & 0 \\ x & x & 0 \end{bmatrix} = \begin{bmatrix} x & 0 & 0 \\ x & x & 0 \\ x & x & x \\ x & x & 0 \\ x & x & 0 \\ x & x & 0 \end{bmatrix}$$

with the property that rows 1 and 3 are left alone.

P5.2.6 Show that if

$$A = \begin{bmatrix} R & w \\ 0 & v \end{bmatrix} \quad \begin{array}{c} k \\ m-k \end{array} \quad \begin{array}{c} \hat{a} \\ \hat{b} \end{array} = \begin{bmatrix} c \\ d \end{bmatrix} \quad \begin{array}{c} k \\ m-k \end{array}$$

and $A$ has full column rank, then $\min \|Ax - b\|_2^2 = \|d\|_2^2 - (v^T d/\|v\|_2)^2$.

P5.2.7 Suppose $A \in \mathbb{R}^{n \times n}$ and $D = \text{diag}(d_1, \ldots, d_n) \in \mathbb{R}^{n \times n}$. Show how to construct an orthogonal $Q$ such that $Q^T A - DQ^T = R$ is upper triangular. Do not worry about efficiency—this is just an exercise in QR manipulation.

P5.2.8 Show how to compute the QR factorization of the product $A = A_p \cdots A_2 A_1$ without explicitly multiplying the matrices $A_1, \ldots, A_p$ together. Hint: In the $p = 3$ case, write $Q^T A = Q^T_A A_3 Q_2^T A_2 Q_1^T A_1$ and determine orthogonal $Q_i$ so that $Q_i^T (A_i Q_{i-1})$ is upper triangular. ($Q_0 = I$).

P5.2.9 Suppose $A \in \mathbb{R}^{n \times n}$ and let $E$ be the permutation obtained by reversing the order of the rows in $I_n$. (This is just the exchange matrix of §4.7.) (a) Show that if $R \in \mathbb{R}^{n \times n}$ is upper triangular, then $L = ERE$ is lower triangular. (b) Show how to compute an orthogonal $Q \in \mathbb{R}^{n \times n}$ and a lower triangular $L \in \mathbb{R}^{n \times n}$ so that $A = QL$ assuming the availability of a procedure for computing the QR factorization.

P5.2.10 MGS applied to $A \in \mathbb{R}^{n \times n}$ is numerically equivalent to the first step in Householder QR applied to

$$\hat{A} = \begin{bmatrix} O_n \\ A \end{bmatrix}$$

where $O_n$ is the $n$-by-$n$ zero matrix. Verify that this statement is true after the first step of each method is completed.

P5.2.11 Reverse the loop orders in Algorithm 5.2.5 (MGS QR) so that $R$ is computed column-by-column.

P5.2.12 Develop a complex version of the Givens QR factorization. Refer to P5.1.5, where complex Givens rotations are the theme. Is it possible to organize the calculations so that the diagonal elements of $R$ are nonnegative?

Notes and References for Sec. 5.3

### 5.3 The Full Rank LS Problem

Consider the problem of finding a vector \( x \in \mathbb{R}^n \) such that \( Ax = b \) where the data matrix \( A \in \mathbb{R}^{m \times n} \) and the observation vector \( b \in \mathbb{R}^m \) are given and \( m \geq n \). When there are more equations than unknowns, we say that the system \( Ax = b \) is overdetermined. Usually an overdetermined system has no exact solution since \( b \) must be an element of \( \text{ran}(A) \), a proper subspace of \( \mathbb{R}^m \).

This suggests that we strive to minimize \( \| Ax - b \|_p \) for some suitable choice of \( p \). Different norms render different optimum solutions. For example, if \( A = [1, 1, 1]^T \) and \( b = [b_1, b_2, b_3]^T \) with \( b_1 \geq b_2 \geq b_3 \geq 0 \), then it can be verified that

\[
\begin{align*}
  p &= 1 \quad \Rightarrow \quad x_{\text{opt}} = b_2 \\
  p &= 2 \quad \Rightarrow \quad x_{\text{opt}} = (b_1 + b_2 + b_3)/3 \\
  p &= \infty \quad \Rightarrow \quad x_{\text{opt}} = (b_1 + b_3)/2.
\end{align*}
\]

Minimization in the 1-norm and \( \infty \)-norm is complicated by the fact that the function \( f(x) = \| Ax - b \|_p \) is not differentiable for these values of \( p \). However, much progress has been made in this area, and there are several good techniques available for 1-norm and \( \infty \)-norm minimization. See Coleman and Li (1992), Li (1993), and Zhang (1993).

In contrast to general \( p \)-norm minimization, the *least squares* (LS) problem

\[
\min_{x \in \mathbb{R}^n} \| Ax - b \|_2
\]

(5.3.1)

is more tractable for two reasons:

- \( \phi(x) = \frac{1}{2} \| Ax - b \|_2^2 \) is a differentiable function of \( x \) and so the minimizers of \( \phi \) satisfy the gradient equation \( \nabla \phi(x) = 0 \). This turns out to be an easily constructed symmetric linear system which is positive definite if \( A \) has full column rank.
• The 2-norm is preserved under orthogonal transformation. This means that we can seek an orthogonal $Q$ such that the equivalent problem of minimizing $\| (Q^T A)x - (Q^T b) \|_2$ is "easy" to solve.

In this section we pursue these two solution approaches for the case when $A$ has full column rank. Methods based on normal equations and the QR factorization are detailed and compared.

### 5.3.1 Implications of Full Rank

Suppose $x \in \mathbb{R}^n$, $z \in \mathbb{R}^n$, and $\alpha \in \mathbb{R}$ and consider the equality

$$\| A(x + \alpha z) - b \|_2^2 = \| Ax - b \|_2^2 + 2\alpha z^T A^T (Ax - b) + \alpha^2 \| Ax \|_2^2$$

where $A \in \mathbb{R}^{m \times n}$ and $b \in \mathbb{R}^m$. If $x$ solves the LS problem (5.3.1) then we must have $A^T (Ax - b) = 0$. Otherwise, if $z = -A^T (Ax - b)$ and we make $\alpha$ small enough, then we obtain the contradictory inequality $\| A(x + \alpha z) - b \|_2 < \| Ax - b \|_2$. We may also conclude that if $x$ and $x + \alpha z$ are LS minimizers, then $z \in \operatorname{null}(A)$.

Thus, if $A$ has full column rank, then there is a unique LS solution $x_{LS}$ and it solves the symmetric positive definite linear system

$$A^T A x_{LS} = A^T b.$$ 

These are called the normal equations. Since $\nabla \phi(x) = A^T (Ax - b)$ where $\phi(x) = \frac{1}{2} \| Ax - b \|_2^2$, we see that solving the normal equations is tantamount to solving the gradient equation $\nabla \phi = 0$. We call

$$r_{LS} = b - A x_{LS}$$

the minimum residual and we use the notation

$$\rho_{LS} = \| A x_{LS} - b \|_2$$

to denote its size. Note that if $\rho_{LS}$ is small, then we can "predict" $b$ with the columns of $A$.

So far we have been assuming that $A \in \mathbb{R}^{m \times n}$ has full column rank. This assumption is dropped in §5.5. However, even if rank($A$) = $n$, then we can expect trouble in the above procedures if $A$ is nearly rank deficient.

When assessing the quality of a computed LS solution $\hat{x}_{LS}$, there are two important issues to bear in mind:

• How close is $\hat{x}_{LS}$ to $x_{LS}$?

• How small is $r_{LS} = b - A \hat{x}_{LS}$ compared to $r_{LS} = b - A x_{LS}$?
The relative importance of these two criteria varies from application to application. In any case it is important to understand how \( x_{LS} \) and \( r_{LS} \) are affected by perturbations in \( A \) and \( b \). Our intuition tells us that if the columns of \( A \) are nearly dependent, then these quantities may be quite sensitive.

**Example 5.3.1** Suppose

\[
A = \begin{bmatrix}
1 & 0 \\
0 & 10^{-6} \\
0 & 0
\end{bmatrix}, \quad \delta A = \begin{bmatrix}
0 & 0 \\
0 & 0 \\
0 & 10^{-8}
\end{bmatrix}, \quad b = \begin{bmatrix}
1 \\
0 \\
1
\end{bmatrix}, \quad \delta b = \begin{bmatrix}
0 \\
0 \\
0
\end{bmatrix},
\]

and that \( x_{LS} \) and \( \tilde{x}_{LS} \) minimize \( \| Ax - b \|_2 \) and \( \| (A + \delta A)x - (b + \delta b) \|_2 \) respectively. Let \( r_{LS} \) and \( \tilde{r}_{LS} \) be the corresponding minimum residuals. Then

\[
x_{LS} = \begin{bmatrix}
1 \\
0
\end{bmatrix}, \quad \tilde{x}_{LS} = \begin{bmatrix}
1 \\
.9999 \cdot 10^4
\end{bmatrix}, \quad r_{LS} = \begin{bmatrix}
0 \\
0 \\
1
\end{bmatrix}, \quad \tilde{r}_{LS} = \begin{bmatrix}
0 \\
-.9999 \cdot 10^{-2} \\
.9999 \cdot 10^9
\end{bmatrix}.
\]

Since \( \kappa_2(A) = 10^8 \) we have

\[
\frac{\| \tilde{x}_{LS} - x_{LS} \|_2}{\| x_{LS} \|_2} \approx .9999 \cdot 10^4 \leq \kappa_2(A)^2 \frac{\| \delta A \|_2}{\| A \|_2} = 10^{12} \cdot 10^{-8}
\]

and

\[
\frac{\| \tilde{r}_{LS} - r_{LS} \|_2}{\| b \|_2} \approx .7070 \cdot 10^{-2} \leq \kappa_2(A) \frac{\| \delta A \|_2}{\| A \|_2} = 10^8 \cdot 10^{-8}.
\]

The example suggests that the sensitivity of \( x_{LS} \) depends upon \( \kappa_2(A)^2 \). At the end of this section we develop a perturbation theory for the LS problem and the \( \kappa_2(A)^2 \) factor will return.

**5.3.2 The Method of Normal Equations**

The most widely used method for solving the full rank LS problem is the method of normal equations.

**Algorithm 5.3.1 (Normal Equations)** Given \( A \in \mathbb{R}^{m \times n} \) with the property that \( \text{rank}(A) = n \) and \( b \in \mathbb{R}^m \), this algorithm computes the solution \( x_{LS} \) to the LS problem \( \min \| Ax - b \|_2 \) where \( b \in \mathbb{R}^m \).

1. Compute the lower triangular portion of \( C = A^T A \).
2. \( d = A^T b \)
3. Compute the Cholesky factorization \( C = GG^T \).
4. Solve \( Gy = d \) and \( G^T x_{LS} = y \).

This algorithm requires \((m + n/3)n^2 \) flops. The normal equation approach is convenient because it relies on standard algorithms: Cholesky factorization, matrix-matrix multiplication, and matrix-vector multiplication. The compression of the \( m \)-by-\( n \) data matrix \( A \) into the (typically) much smaller \( n \)-by-\( n \) cross-product matrix \( C \) is attractive.
Let us consider the accuracy of the computed normal equations solution \( \hat{x}_{LS} \). For clarity, assume that no roundoff errors occur during the formation of \( C = A^T A \) and \( d = A^T b \). (On many computers inner products are accumulated in double precision and so this is not a terribly unfair assumption.) It follows from what we know about the roundoff properties of the Cholesky factorization (cf. \S 4.2.7) that

\[
(A^T A + E) \hat{x}_{LS} = A^T b,
\]

where \( \| E \|_2 \approx u \| A^T \|_2 \| A \|_2 \approx u \| A^T A \|_2 \) and thus we can expect

\[
\frac{\| \hat{x}_{LS} - x_{LS} \|_2}{\| x_{LS} \|_2} \approx u \kappa_2(A^T A) = u \kappa_2(A)^2.
\]

(5.3.2)

In other words, the accuracy of the computed normal equations solution depends on the square of the condition. This seems to be consistent with Example 5.3.1 but more refined comments follow in \S 5.3.9.

Example 5.3.2 It should be noted that the formation of \( A^T A \) can result in a severe loss of information.

\[
A = \begin{bmatrix} 1 & 1 \\ 10^{-3} & 0 \\ 0 & 10^{-3} \end{bmatrix} \quad \text{and} \quad b = \begin{bmatrix} 2 \\ 10^{-3} \\ 10^{-3} \end{bmatrix}
\]

then \( \kappa_2(A) \approx 1.4 \cdot 10^3 \), \( x_{LS} = [1 \ 1]^T \), and \( \rho_{LS} = 0 \). If the normal equations method is executed with base 10, \( \tau = 6 \) arithmetic, then a divide-by-zero occurs during the solution process, since

\[
f_l(A^T A) = \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}
\]

is exactly singular. On the other hand, if \( 7 \)-digit arithmetic is used, then \( \hat{x}_{LS} = [2.000001 \ 0]^T \) and \( \| \hat{x}_{LS} - x_{LS} \|_2 / \| x_{LS} \|_2 \approx u \kappa_2(A)^2 \).

5.3.3 LS Solution Via QR Factorization

Let \( A \in \mathbb{R}^{m \times n} \) with \( m \geq n \) and \( b \in \mathbb{R}^m \) be given and suppose that an orthogonal matrix \( Q \in \mathbb{R}^{m \times m} \) has been computed such that

\[
Q^T A = R = \begin{bmatrix} R_1 \\ 0 \end{bmatrix} \quad \begin{array}{c} n \\ m-n \end{array}
\]

(5.3.3)

is upper triangular. If

\[
Q^T b = \begin{bmatrix} c \\ d \end{bmatrix} \quad \begin{array}{c} n \\ m-n \end{array}
\]

then

\[
\| Ax - b \|_2^2 = \| Q^T Ax - Q^T b \|_2^2 = \| R_1 x - c \|_2^2 + \| d \|_2^2
\]
for any $x \in \mathbb{R}^n$. Clearly, if $\text{rank}(A) = \text{rank}(R_1) = n$, then $x_{LS}$ is defined by the upper triangular system $R_1 x_{LS} = c$. Note that

$$\rho_{LS} = \| d \|_2.$$ 

We conclude that the full rank LS problem can be readily solved once we have computed the QR factorization of $A$. Details depend on the exact QR procedure. If Householder matrices are used and $Q^T$ is applied in factored form to $b$, then we obtain

**Algorithm 5.3.2 (Householder LS Solution)** If $A \in \mathbb{R}^{m \times n}$ has full column rank and $b \in \mathbb{R}^m$, then the following algorithm computes a vector $x_{LS} \in \mathbb{R}^n$ such that $\| Ax_{LS} - b \|_2$ is minimum.

- Use Algorithm 5.2.1 to overwrite $A$ with its QR factorization.
  - for $j = 1:n$
    - $v(j) = 1$; $v(j + 1:m) = A(j + 1:m, j)$
    - $b(j:m) = (I_{m-j+1} - \beta_j v v^T) b(j:m)$
  - end
- Solve $R(1:n, 1:n) x_{LS} = b(1:n)$ using back substitution.

This method for solving the full rank LS problem requires $2n^2(m - n/3)$ flops. The $O(mn)$ flops associated with the updating of $b$ and the $O(n^2)$ flops associated with the back substitution are not significant compared to the work required to factor $A$.

It can be shown that the computed $\hat{x}_{LS}$ solves

$$\min \| (A + \delta A)x - (b + \delta b) \|_2$$

where

$$\| \delta A \|_F \leq (6m - 3n + 41)nu\| A \|_F + O(u^2)$$

and

$$\| \delta b \|_2 \leq (6m - 3n + 40)nu\| b \|_2 + O(u^2).$$

These inequalities are established in Lawson and Hanson (1974, p.90ff) and show that $\hat{x}_{LS}$ satisfies a "nearby" LS problem. (We cannot address the relative error in $\hat{x}_{LS}$ without an LS perturbation theory, to be discussed shortly.) We mention that similar results hold if Givens QR is used.

### 5.3.4 Breakdown in Near-Rank Deficient Case

Like the method of normal equations, the Householder method for solving the LS problem breaks down in the back substitution phase if $\text{rank}(A) < n$. Numerically, trouble can be expected whenever $\kappa_2(A) = \kappa_2(R) \approx 1/u$. This is in contrast to the normal equations approach, where completion of the Cholesky factorization becomes problematical once $\kappa_2(A)$ is in the
neighborhood of $1/\sqrt{n}$. (See Example 5.3.2.) Hence the claim in Lawson and Hanson (1974, 126–127) that for a fixed machine precision, a wider class of LS problems can be solved using Householder orthogonalization.

### 5.3.5 A Note on the MGS Approach

In principle, MGS computes the thin QR factorization $A = Q_1 R_1$. This is enough to solve the full rank LS problem because it transforms the normal equations $(A^T A)x = A^T b$ to the upper triangular system $R_1 x = Q_1^T b$. But an analysis of this approach when $Q_1^T b$ is explicitly formed introduces a $\kappa_2(A)^2$ term. This is because the computed factor $\hat{Q}_1$ satisfies $\| \hat{Q}_1^T \hat{Q}_1 - I_n \|_2 \approx \varepsilon \kappa_2(A)$ as we mentioned in §5.2.9.

However, if MGS is applied to the augmented matrix

$$A_+ = [A \ b] = [Q_1 q_{n+1}] \begin{bmatrix} R_1 & z \\ 0 & \rho \end{bmatrix},$$

then $z = Q_1^T b$. Computing $Q_1^T b$ in this fashion and solving $R_1 x_{LS} = z$ produces an LS solution $\hat{x}_{LS}$ that is "just as good" as the Householder QR method. That is to say, a result of the form (5.3.4)-(5.3.6) applies. See Björck and Paige (1992).

It should be noted that the MGS method is slightly more expensive than Householder QR because it always manipulates $m$-vectors whereas the latter procedure deals with ever shorter vectors.

### 5.3.6 Fast Givens LS Solver

The LS problem can also be solved using fast Givens transformations. Suppose $M^T M = D$ is diagonal and

$$M^T A = \begin{bmatrix} S_1 \\ 0 \end{bmatrix}^{n \times n}$$

is upper triangular. If

$$M^T b = \begin{bmatrix} c \\ d \end{bmatrix}^{n \times n}$$

then

$$\| Ax - b \|_2^2 = \| D^{-1/2} M^T (Ax - b) \|_2^2 = \| D^{-1/2} \begin{bmatrix} S_1 \\ 0 \end{bmatrix} x - \begin{bmatrix} c \\ d \end{bmatrix} \|_2^2$$

for any $x \in \mathbb{R}^n$. Clearly, $x_{LS}$ is obtained by solving the nonsingular upper triangular system $S_1 x = c$.

The computed solution $\hat{x}_{LS}$ obtained in this fashion can be shown to solve a nearby LS problem in the sense of (5.3.4)-(5.3.6). This may seem
surprising since large numbers can arise during the calculation. An entry in the scaling matrix $D$ can double in magnitude after a single fast Givens update. However, largeness in $D$ must be exactly compensated for by largeness in $M$, since $D^{-1/2}M$ is orthogonal at all stages of the computation. It is this phenomenon that enables one to push through a favorable error analysis.

5.3.7 The Sensitivity of the LS Problem

We now develop a perturbation theory that assists in the comparison of the normal equations and QR approaches to the LS problem. The theorem below examines how the LS solution and its residual are affected by changes in $A$ and $b$. In so doing, the condition of the LS problem is identified.

Two easily established facts are required in the analysis:

$$
\| A \|_2 \| (A^T A)^{-1} A^T \|_2 = \kappa_2(A)
$$

$$
\| A \|_2^2 \| (A^T A)^{-1} \|_2 = \kappa_2(A)^2
$$

(5.3.7)

These equations can be verified using the SVD.

**Theorem 5.3.1** Suppose $x$, $r$, $\hat{x}$, and $\hat{r}$ satisfy

$$
\| Ax - b \|_2 = \min \quad r = b - Ax
$$

$$
\| (A + \delta A)\hat{x} - (b + \delta b) \|_2 = \min \quad \hat{r} = (b + \delta b) - (A + \delta A)\hat{x}
$$

where $A$ and $\delta A$ are in $\mathbb{R}^{m \times n}$ with $m \geq n$ and $0 \neq b$ and $\delta b$ are in $\mathbb{R}^m$. If

$$
\epsilon = \max \left\{ \frac{\| \delta A \|_2}{\| A \|_2}, \frac{\| \delta b \|_2}{\| b \|_2} \right\} < \frac{\sigma_n(A)}{\sigma_1(A)}
$$

and

$$
\sin(\theta) = \frac{\rho_{LS}}{\| b \|_2} \neq 1
$$

where $\rho_{LS} = \| Ax_{LS} - b \|_2$, then

$$
\frac{\| \hat{x} - x \|_2}{\| x \|_2} \leq \epsilon \left\{ \frac{2\kappa_2(A)}{\cos(\theta)} + \tan(\theta)\kappa_2(A)^2 \right\} + O(\epsilon^2)
$$

(5.3.8)

$$
\frac{\| \hat{r} - r \|_2}{\| b \|_2} \leq \epsilon (1 + 2\kappa_2(A)) \min(1, m - n) + O(\epsilon^2).
$$

(5.3.9)
5.3. The Full Rank LS Problem

Proof. Let $E$ and $f$ be defined by $E = \delta A/\varepsilon$ and $f = \delta b/\varepsilon$. By hypothesis $\| \delta A \|_2 < \sigma_n(A)$ and so by Theorem 2.5.2 we have $\text{rank}(A + tE) = n$ for all $t \in [0, \varepsilon]$. It follows that the solution $x(t)$ to

$$(A + tE)^T(A + tE)x(t) = (A + tE)^T(b + tf)$$

(5.3.10)

is continuously differentiable for all $t \in [0, \varepsilon]$. Since $x = x(0)$ and $\dot{x} = x'(0)$, we have

$$\dot{x} = x + \varepsilon \dot{x}(0) + O(\varepsilon^2).$$

The assumptions $b \neq 0$ and $\sin(\theta) \neq 1$ ensure that $x$ is nonzero and so

$$\frac{\| \dot{x} - x \|_2}{\| x \|_2} = \varepsilon \frac{\| \dot{x}(0) \|_2}{\| x \|_2} + O(\varepsilon^2).$$

(5.3.11)

In order to bound $\| \dot{x}(0) \|_2$, we differentiate (5.3.10) and set $t = 0$ in the result. This gives

$$E^T Ax + A^T Ex + A^T A \dot{x}(0) = A^T f + E^T b$$

i.e.,

$$\dot{x}(0) = (A^T A)^{-1} A^T (f - Ex) + (A^T A)^{-1} E^T r.$$  

(5.3.12)

By substituting this result into (5.3.11), taking norms, and using the easily verified inequalities $\| f \|_2 \leq \| b \|_2$ and $\| E \|_2 \leq \| A \|_2$ we obtain

$$\frac{\| \dot{x} - x \|_2}{\| x \|_2} \leq \varepsilon \left\{ \frac{\| A \|_2}{\| x \|_2} (A^T A)^{-1} A^T \left( \frac{\| b \|_2}{\| A \|_2 \| x \|_2} + 1 \right) + \frac{\rho_{LS}}{\| A \|_2 \| x \|_2} \| A \|_2^2 \| (A^T A)^{-1} \|_2 \right\} + O(\varepsilon^2).$$

Since $A^T (Ax - b) = 0$, $Ax$ is orthogonal to $Ax - b$ and so

$$\| b - Ax \|_2^2 + \| Ax \|_2^2 = \| b \|_2^2.$$

Thus,

$$\| A \|_2^2 \| x \|_2^2 \geq \| b \|_2^2 - \rho_{LS}^2$$

and so by using (5.3.7)

$$\frac{\| \dot{x} - x \|_2}{\| x \|_2} \leq \varepsilon \left\{ \kappa_2(A) \left( \frac{1}{\cos(\theta)} + 1 \right) + \kappa_2(A)^2 \frac{\sin(\theta)}{\cos(\theta)} \right\} + O(\varepsilon^2)$$

thereby establishing (5.3.8).

To prove (5.3.9), we define the differentiable vector function $r(t)$ by

$$r(t) = (b + tf) - (A + tE)x(t)$$
and observe that $r = r(0)$ and $r = r(\epsilon)$. Using (5.3.12) it can be shown that

$$
\hat{r}(0) = (I - A(A^T A)^{-1} A^T) (f - E x) - A(A^T A)^{-1} E^T r.
$$

Since $\| \hat{r} - r \|_2 = \epsilon \| \hat{r}(0) \|_2 + O(\epsilon^2)$ we have

$$
\frac{\| \hat{r} - r \|_2}{\| b \|_2} = \epsilon \frac{\| \hat{r}(0) \|_2}{\| b \|_2} + O(\epsilon^2)
\leq \epsilon \left\{ \| I - A(A^T A)^{-1} A^T \|_2 \left( 1 + \frac{\| A \|_2 \| x \|_2}{\| b \|_2} \right) 
+ \| A(A^T A)^{-1} \|_2 \| A \|_2 \frac{\rho_{LS}}{\| b \|_2} \right\} + O(\epsilon^2).
$$

Inequality (5.3.9) now follows because

$$
\| A \|_2 \| x \|_2 = \| A \|_2 \| A^+ b \|_2 \leq \kappa_2(A) \| b \|_2,
$$

$$
\rho_{LS} = \| (I - A(A^T A)^{-1} A^T)b \|_2 \leq \| I - A(A^T A)^{-1} A^T \|_2 \| b \|_2,
$$

and

$$
\| (I - A(A^T A)^{-1} A^T \|_2 = \min(m - n, 1). \square
$$

An interesting feature of the upper bound in (5.3.8) is the factor

$$
\tan(\theta) \kappa_2(A)^2 = \frac{\rho_{LS}}{\sqrt{\| b \|_2^2 - \rho_{LS}^2}} \kappa_2(A)^2.
$$

Thus, in nonzero residual problems it is the square of the condition that measures the sensitivity of $x_{LS}$. In contrast, residual sensitivity depends just linearly on $\kappa_2(A)$. These dependencies are confirmed by Example 5.3.1.

### 5.3.8 Normal Equations Versus QR

It is instructive to compare the normal equation and QR approaches to the LS problem. Recall the following main points from our discussion:

- The sensitivity of the LS solution is roughly proportional to the quantity $\kappa_2(A) + \rho_{LS} \kappa_2(A)^2$.

- The method of normal equations produces an $\hat{x}_{LS}$ whose relative error depends on the square of the condition.

- The QR approach (Householder, Givens, careful MGS) solves a nearby LS problem and therefore produces a solution that has a relative error approximately given by $u(\kappa_2(A) + \rho_{LS} \kappa_2(A)^2)$.
Thus, we may conclude that if $\rho_{LS}$ is small and $\kappa_2(A)$ is large, then the method of normal equations does not solve a nearby problem and will usually render an LS solution that is less accurate than a stable QR approach. Conversely, the two methods produce comparably inaccurate results when applied to large residual, ill-conditioned problems.

Finally, we mention two other factors that figure in the debate about QR versus normal equations:

- The normal equations approach involves about half of the arithmetic when $m \gg n$ and does not require as much storage.

- QR approaches are applicable to a wider class of matrices because the Cholesky process applied to $A^T A$ breaks down "before" the back substitution process on $Q^T A = R$.

At the very minimum, this discussion should convince you how difficult it can be to choose the "right" algorithm!

Problems

P5.3.1 Assume $A^T Ax = A^T b$, $(A^T A + F) \hat{x} = A^T b$, and $2\| F \|_2 \leq \sigma_n(A)^2$. Show that if $r = b - Ax$ and $\hat{r} = b - A\hat{x}$, then $\hat{r} - r = A(A^T A + F)^{-1} F x$ and

$$\| \hat{r} - r \|_2 \leq 2\kappa_2(A) \frac{\| F \|_2}{\| A \|_2} \| x \|_2.$$  

P5.3.2 Assume that $A^T Ax = A^T b$ and that $A^T A \hat{x} = A^T b + f$ where $\| f \|_2 \leq c \| A^T \|_2 \| b \|_2$ and $A$ has full column rank. Show that

$$\frac{\| x - \hat{x} \|_2}{\| x \|_2} \leq c \kappa_2(A) \frac{\| A^T \|_2 \| b \|_2}{\| A^T b \|}.$$  

P5.3.3 Let $A \in \mathbb{R}^{m \times n}$ with $m > n$ and $y \in \mathbb{R}^m$ and define $\tilde{A} = [A \ y] \in \mathbb{R}^{m \times (n+1)}$. Show that $\sigma_1(\tilde{A}) \geq \sigma_1(A)$ and $\sigma_{n+1}(\tilde{A}) \leq \sigma_n(A)$. Thus, the condition grows if a column is added to a matrix.

P5.3.4 Let $A \in \mathbb{R}^{m \times n}$ ($m \geq n$), $w \in \mathbb{R}^n$, and define

$$B = \begin{bmatrix} A \\ w^T \end{bmatrix}.$$  

Show that $\sigma_n(B) \geq \sigma_n(A)$ and $\sigma_1(B) \leq \sqrt{\| A \|_2^2 + \| w \|_2^2}$. Thus, the condition of a matrix may increase or decrease if a row is added.

P5.3.5 (Cline 1973) Suppose that $A \in \mathbb{R}^{m \times n}$ has rank $n$ and that Gaussian elimination with partial pivoting is used to compute the factorization $PA = LU$, where $L \in \mathbb{R}^{m \times n}$ is unit lower triangular, $U \in \mathbb{R}^{n \times n}$ is upper triangular, and $P \in \mathbb{R}^{m \times m}$ is a permutation. Explain how the decomposition in P5.2.5 can be used to find a vector $z \in \mathbb{R}^n$ such that $\| L z - P b \|_2$ is minimized. Show that if $U z = z$, then $\| A z - b \|_2$ is minimum. Show that this method of solving the LS problem is more efficient than Householder QR from the flop point of view whenever $m \leq 5n/3$.

P5.3.6 The matrix $C = (A^T A)^{-1}$, where rank$(A) = n$, arises in many statistical applications and is known as the variance-covariance matrix. Assume that the factorization
A = QR is available. (a) Show \( C = (R^T R)^{-1} \). (b) Give an algorithm for computing the diagonal of \( C \) that requires \( n^3/3 \) flops. (c) Show that

\[
R = \begin{bmatrix} \alpha & v^T \\ 0 & S \end{bmatrix} \quad \Rightarrow \quad C = (R^T R)^{-1} = \begin{bmatrix} (1 + v^T C_1 v) / \alpha^2 & -v^T C_1 / \alpha \\ -C_1 v / \alpha & C_1 \end{bmatrix}
\]

where \( C_1 = (S^T S)^{-1} \). (d) Using (c), give an algorithm that overwrites the upper triangular portion of \( R \) with the upper triangular portion of \( C \). Your algorithm should require \( 2n^3/3 \) flops.

P5.3.7 Suppose \( A \in \mathbb{R}^{n \times n} \) is symmetric and that \( r = b - Ax \) where \( r, b, x \in \mathbb{R}^n \) and \( x \) is nonzero. Show how to compute a symmetric \( E \in \mathbb{R}^{n \times n} \) with minimal Frobenius norm so that \( (A + E)x = b \). Hint. Use the QR factorization of \( [x, r] \) and note that \( Ex = r \Rightarrow (Q^T EQ)(Q^T x) = Q^T r \).

P5.3.8 Show how to compute the nearest circulant matrix to a given Toeplitz matrix. Measure distance with the Frobenius norm.

Notes and References for Sec. 5.3

Our restriction to least squares approximation is not a vote against minimization in other norms. There are occasions when it is advisable to minimize \( \| Ax - b \|_p \) for \( p = 1 \) and \( \infty \). Some algorithms for doing this are described in

The use of Gauss transformations to solve the LS problem has attracted some attention because they are cheaper to use than Householder or Givens matrices. See

Important analyses of the LS problem and various solution approaches include

5.3. THE FULL RANK LS PROBLEM

The "seminormal" equations are given by $RTRx = ATb$ where $A = QR$. In the above paper it is shown that by solving the seminormal equations an acceptable LS solution is obtained if one step of fixed precision iterative improvement is performed.

An Algol implementation of the MGS method for solving the LS problem appears in

Least squares problems often have special structure which, of course, should be exploited.

The use of Householder matrices to solve sparse LS problems requires careful attention to avoid excessive fill-in.

Although the computation of the QR factorization is more efficient with Householder reflections, there are some settings where the Givens approach is advantageous. For example, if $A$ is sparse, then the careful application of Givens rotations can minimize fill-in.

5.4 Other Orthogonal Factorizations

If \( A \) is rank deficient, then the QR factorization need not give a basis for \( \text{ran}(A) \). This problem can be corrected by computing the QR factorization of a column-permuted version of \( A \), i.e., \( A\Pi = QR \) where \( \Pi \) is a permutation.

The "data" in \( A \) can be compressed further if we permit right multiplication by a general orthogonal matrix \( Z \):

\[
Q^T A Z = T.
\]

There are interesting choices for \( Q \) and \( Z \) and these, together with the column pivoted QR factorization, are discussed in this section.

5.4.1 Rank Deficiency: QR with Column Pivoting

If \( A \in \mathbb{R}^{m \times n} \) and \( \text{rank}(A) < n \), then the QR factorization does not necessarily produce an orthonormal basis for \( \text{ran}(A) \). For example, if \( A \) has three columns and

\[
A = [a_1, a_2, a_3] = [q_1, q_2, q_3] \begin{bmatrix} 1 & 1 & 1 \\ 0 & 0 & 1 \\ 0 & 0 & 1 \end{bmatrix}
\]

is its QR factorization, then \( \text{rank}(A) = 2 \) but \( \text{ran}(A) \) does not equal any of the subspaces \( \text{span}\{q_1, q_2\} \), \( \text{span}\{q_1, q_3\} \), or \( \text{span}\{q_2, q_3\} \).

Fortunately, the Householder QR factorization procedure (Algorithm 5.2.1) can be modified in a simple way to produce an orthonormal basis for \( \text{ran}(A) \). The modified algorithm computes the factorization

\[
Q^T A \Pi = \begin{bmatrix} R_{11} & R_{12} \\ 0 & 0 \end{bmatrix} \tau_{m-r} = \begin{bmatrix} \tau \\ n-r \end{bmatrix}
\]

(5.4.1)

where \( r = \text{rank}(A) \), \( Q \) is orthogonal, \( R_{11} \) is upper triangular and nonsingular, and \( \Pi \) is a permutation. If we have the column partitionings \( A\Pi = [a_{c_1}, \ldots, a_{c_n}] \) and \( Q = [q_1, \ldots, q_m] \), then for \( k = 1:n \) we have

\[
a_{c_k} = \sum_{i=1}^{\min\{r,k\}} r_{ik} q_i \in \text{span}\{q_1, \ldots, q_r\}
\]

implying

\[\text{ran}(A) = \text{span}\{q_1, \ldots, q_r\}.\]

The matrices \( Q \) and \( \Pi \) are products of Householder matrices and interchange matrices respectively. Assume for some \( k \) that we have computed
Householder matrices $H_1, \ldots, H_{k-1}$ and permutations $\Pi_1, \ldots, \Pi_{k-1}$ such that
\[
(H_{k-1} \cdots H_1)A(\Pi_1 \cdots \Pi_{k-1}) = R^{(k-1)}
\]
where $R^{(k-1)}$ is a nonsingular and upper triangular matrix. Now suppose that
\[
R^{(k-1)}_{22} = \begin{bmatrix} z^{(k-1)}_1, \ldots, z^{(k-1)}_n \end{bmatrix}
\]
is a column partitioning and let $p \geq k$ be the smallest index such that
\[
\| z^{(k-1)}_p \|_2 = \max \left\{ \| z^{(k-1)}_k \|_2, \ldots, \| z^{(k-1)}_n \|_2 \right\} .
\]
Note that if $k - 1 = \text{rank}(A)$, then this maximum is zero and we are finished. Otherwise, let $\Pi_k$ be the $n$-by-$n$ identity with columns $p$ and $k$ interchanged and determine a Householder matrix $H_k$ such that if $R^{(k)} = H_k R^{(k-1)} \Pi_k$, then $R^{(k)}(k+1:m, k) = 0$. In other words, $\Pi_k$ moves the largest column in $R^{(k-1)}_{22}$ to the lead position and $H$ zeroes all of its subdiagonal components.

The column norms do not have to be recomputed at each stage if we exploit the property
\[
Q^T z = \begin{bmatrix} \alpha \\ w \end{bmatrix} \implies \| w \|_2^2 = \| z \|_2^2 - \alpha^2,
\]
which holds for any orthogonal matrix $Q \in \mathbb{R}^{s \times s}$. This reduces the overhead associated with column pivoting from $O(mn^2)$ flops to $O(mn)$ flops because we can get the new column norms by updating the old column norms, e.g.,
\[
\| z^{(j)} \|_2^2 = \| z^{(j-1)} \|_2^2 - r_{kj}^2.
\]
Combining all of the above we obtain the following algorithm established by Businger and Golub (1965):

Algorithm 5.4.1 (Householder QR With Column Pivoting) Given $A \in \mathbb{R}^{m \times n}$ with $m \geq n$, the following algorithm computes $r = \text{rank}(A)$ and the factorization (5.4.1) with $Q = H_1 \cdots H_r$ and $\Pi = \Pi_1 \cdots \Pi_r$. The upper triangular part of $A$ is overwritten by the upper triangular part of $R$ and components $j + 1:m$ of the $j$th Householder vector are stored in $A(j + 1:m, j)$. The permutation $\Pi$ is encoded in an integer vector $piv$. In particular, $\Pi_j$ is the identity with rows $j$ and $piv(j)$ interchanged.
for } j = 1:n \n\nonumber \c(j) = A(1:m, j)^T A(1:m, j) \end{align*}
end
$r = 0; \; \tau = \max\{c(1), \ldots, c(n)\}$
Find smallest } k \text{ with } 1 \leq k \leq n \text{ so } c(k) = \tau
while } \tau > 0
\begin{align*}
\tau &= r + 1 \\
piv(r) &= k; \; A(1:m, r) \leftrightarrow A(1:m, k); \; c(r) \leftrightarrow c(k) \\
[v, \beta] &= \text{house}(A(r:m, r)) \\
A(r:m, r:n) &= (I_{m-r+1} - \beta vv^T) A(r:m, r:n) \\
A(r + 1:m, r) &= v(2:m - r + 1)
for } i = r + 1:n
\begin{align*}
c(i) &= c(i) - A(r, i)^2 \\
\end{align*}
end
if } \tau < n
\begin{align*}
\tau &= \max\{c(r + 1), \ldots, c(n)\} \\
\text{Find smallest } k \text{ with } r + 1 \leq k \leq n \text{ so } c(k) = \tau.
\end{align*}
else
\begin{align*}
\tau &= 0
\end{align*}
end
This algorithm requires } 4mn^2 - 2r^2(m + n) + 4r^3/3 \text{ flops where } r = \text{rank}(A).
As with the nonpivoting procedure, Algorithm 5.2.1, the orthogonal matrix } Q \text{ is stored in factored form in the subdiagonal portion of } A.
Example 5.4.1 If Algorithm 5.4.1 is applied to
\begin{align*}
A &= \begin{bmatrix}
1 & 2 & 3 \\
1 & 5 & 6 \\
1 & 8 & 9 \\
1 & 11 & 12
\end{bmatrix},
\end{align*}
then } \Pi = [e_3 \; e_2 \; e_1] \text{ and to three significant digits we obtain }
\begin{align*}
\Pi \Pi^T &= QR = \\
&= \begin{bmatrix}
-0.182 & -0.816 & 0.514 & 0.191 \\
-0.365 & 0.408 & -0.827 & 0.129 \\
0.548 & 0.000 & 0.113 & -0.829 \\
-0.730 & 0.408 & 0.200 & 0.510
\end{bmatrix} \begin{bmatrix}
-16.4 & -14.600 & -1.820 \\
0.0 & 0.816 & -0.816 \\
0.0 & 0.000 & 0.000
\end{bmatrix}.
\end{align*}

5.4.2 Complete Orthogonal Decompositions
The matrix } R \text{ produced by Algorithm 5.4.1 can be further reduced if it is post-multiplied by an appropriate sequence of Householder matrices. In particular, we can use Algorithm 5.2.1 to compute
\begin{align*}
Z_r \cdots Z_1 \begin{bmatrix}
R_{11}^T \\
R_{12}^T
\end{bmatrix} &= \begin{bmatrix}
T_{11}^T \\
0
\end{bmatrix}^{r} \begin{bmatrix}
\end{bmatrix}^{n-r} \quad (5.4.4)
\end{align*}
where the $Z_i$ are Householder transformations and $T_{11}^T$ is upper triangular. It then follows that

$$Q^T AZ = T = \begin{bmatrix} T_{11} & 0 & \cdots & 0 \\ 0 & 0 & \cdots & \cdots \\ \vdots & \vdots & \ddots & \vdots \\ 0 & \cdots & 0 & 0 \end{bmatrix}^{r \rightarrow m-r} \begin{bmatrix} r \\ n-r \end{bmatrix}$$

(5.4.5)

where $Z = \Pi Z_1 \cdots Z_r$. We refer to any decomposition of this form as a complete orthogonal decomposition. Note that $\text{null}(A) = \text{ran}(Z(1:n, r + 1:n))$. See P5.2.5 for details about the exploitation of structure in (5.4.4).

### 5.4.3 Bidiagonalization

Suppose $A \in \mathbb{R}^{m \times n}$ and $m \geq n$. We next show how to compute orthogonal $U_B$ ($m$-by-$m$) and $V_B$ ($n$-by-$n$) such that

$$U_B^T AV_B = \begin{bmatrix} d_1 & f_1 & 0 & \cdots & 0 \\ 0 & d_2 & f_2 & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & \cdots & d_{n-1} & f_{n-1} & 0 \\ 0 & \cdots & 0 & d_n & 0 \end{bmatrix}$$

(5.4.6)

$U_B = U_1 \cdots U_n$ and $V_B = V_1 \cdots V_{n-2}$ can each be determined as a product of Householder matrices:

$$\begin{bmatrix} x & x & x & x \\ x & x & x & x \\ x & x & x & x \\ x & x & x & x \\ x & x & x & x \end{bmatrix} \overset{U_1}{\longrightarrow} \begin{bmatrix} x & x & x & x \\ x & x & x & x \\ x & x & x & x \\ x & x & x & x \\ 0 & 0 & 0 & 0 \end{bmatrix} \overset{U_2}{\longrightarrow} \begin{bmatrix} x & x & 0 & 0 \\ x & x & 0 & 0 \\ x & x & 0 & 0 \\ x & x & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix} \overset{U_3}{\longrightarrow} \begin{bmatrix} x & x & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}$$

$U_B = U_1 \cdots U_n$ and $V_B = V_1 \cdots V_{n-2}$ can each be determined as a product of Householder matrices:
In general, $U_k$ introduces zeros into the $k$th column, while $V_k$ zeros the appropriate entries in row $k$. Overall we have:

Algorithm 5.4.2 (Householder Bidiagonalization) Given $A \in \mathbb{R}^{m \times n}$ with $m \geq n$, the following algorithm overwrites $A$ with $U_B^T A V_B = B$ where $B$ is upper bidiagonal and $U_B = U_1 \cdots U_n$ and $V_B = V_1 \cdots V_{n-2}$. The essential part of $U_j$'s Householder vector is stored in $A(j+1:m,j)$ and the essential part of $V_j$'s Householder vector is stored in $A(j,j+2:n)$.

for $j = 1:n$

\[ [v, \beta] = \text{house}(A(j:m,j)) \]
\[ A(j:m,j;n) = (I_{m-j+1} - \beta vv^T)A(j:m,j;n) \]
\[ A(j+1:m,j) = v(2m - j + 1) \]

if $j \leq n - 2$

\[ [v, \beta] = \text{house}(A(j,j+1:n)^T) \]
\[ A(j:m,j+1:n) = A(j:m,j+1:n)(I_{n-j} - \beta vv^T) \]
\[ A(j,j+2:n) = v(2n - j)^T \]

end

end

This algorithm requires $4m n^2 - 4n^3/3$ flops. Such a technique is used in Golub and Kahan (1965), where bidiagonalization is first described. If the matrices $U_B$ and $V_B$ are explicitly desired, then they can be accumulated in $4m^2 n - 4n^3/3$ and $4n^3/3$ flops, respectively. The bidiagonalization of $A$ is related to the tridiagonalization of $A^T A$. See §8.2.1.

Example 5.4.2 If Algorithm 5.4.2 is applied to

\[ A = \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \\ 7 & 8 & 9 \\ 10 & 11 & 12 \end{bmatrix} \]

then to three significant digits we obtain

\[ \hat{\beta} = \begin{bmatrix} 12.8 & 21.8 & 0 \\ 0 & 2.24 & -0.613 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \quad \hat{V}_B = \begin{bmatrix} 1.00 & 0.00 & 0.00 \\ 0.00 & -0.667 & -0.745 \\ 0.00 & -0.745 & 0.667 \end{bmatrix} \]

\[ \hat{U}_B = \begin{bmatrix} -0.0776 & -0.833 & 0.392 & -0.383 \\ -0.3110 & -0.451 & -0.238 & 0.802 \\ -0.5430 & -0.089 & 0.701 & -0.457 \\ -0.7760 & 0.312 & -0.547 & 0.037 \end{bmatrix} \]

5.4.4 R-Bidiagonalization

A faster method of bidiagonalizing when $m \gg n$ results if we upper triangularize $A$ first before applying Algorithm 5.4.2. In particular, suppose we
compute an orthogonal \( Q \in \mathbb{R}^{n \times m} \) such that

\[
Q^T A = \begin{bmatrix} R_1 \\ 0 \end{bmatrix}
\]

is upper triangular. We then bidiagonalize the square matrix \( R_1 \),

\[
U_R^T R_1 V_B = B_1.
\]

Here \( U_R \) and \( V_B \) are \( n \times n \) orthogonal and \( B_1 \) is \( n \times n \) upper bidiagonal. If \( U_B = Q \text{ diag} (U_R, I_{m-n}) \) then

\[
U^T A V = \begin{bmatrix} B_1 \\ 0 \end{bmatrix} \equiv B
\]

is a bidiagonalization of \( A \).

The idea of computing the bidiagonalization in this manner is mentioned in Lawson and Hanson (1974, p.119) and more fully analyzed in Chan (1982a). We refer to this method as \( R \)-bidiagonalization. By comparing its flop count \( (2mn^2 + 2n^3) \) with that for Algorithm 5.4.2 \((4mn^2 - 4n^3 / 3)\) we see that it involves fewer computations (approximately) whenever \( m \geq 5n/3 \).

### 5.4.5 The SVD and its Computation

Once the bidiagonalization of \( A \) has been achieved, the next step in the Golub-Reinsch SVD algorithm is to zero the superdiagonal elements in \( B \). This is an iterative process and is accomplished by an algorithm due to Golub and Kahan (1965). Unfortunately, we must defer our discussion of this iteration until §8.6 as it requires an understanding of the symmetric eigenvalue problem. Suffice it to say here that it computes orthogonal matrices \( U_\Sigma \) and \( V_\Sigma \) such that

\[
U_\Sigma^T B V_\Sigma = \Sigma = \text{diag}(\sigma_1, \ldots, \sigma_n) \in \mathbb{R}^{m \times n}.
\]

By defining \( U = U_B U_\Sigma \) and \( V = V_B V_\Sigma \) we see that \( U^T A V = \Sigma \) is the SVD of \( A \). The flop counts associated with this portion of the algorithm depend upon "how much" the SVD is required. For example, when solving the LS problem, \( U^T \) need never be explicitly formed but merely applied to \( b \) as it is developed. In other applications, only the matrix \( U_1 = U(:, 1:n) \) is required. Altogether there are six possibilities and the total amount of work required by the SVD algorithm in each case is summarized in the table below. Because of the two possible bidiagonalization schemes, there are two columns of flop counts. If the bidiagonalization is achieved via Algorithm 5.4.2, the Golub-Reinsch (1970) SVD algorithm results, while if \( R \)-bidiagonalization is invoked we obtain the \( R \)-SVD algorithm detailed in Chan (1982a). By comparing the entries in this table (which are meant only as approximate estimates of work), we conclude that the \( R \)-SVD approach is more efficient unless \( m \approx n \).
## Problems

P5.4.1 Suppose $A \in \mathbb{R}^{m \times n}$ with $m < n$. Give an algorithm for computing the factorization

$$U^TAV = [B \ O]$$

where $B$ is an $m$-by-$m$ upper bidiagonal matrix. (Hint: Obtain the form

$$
\begin{bmatrix}
    x & x & 0 & 0 & 0 & 0 \\
    0 & x & x & 0 & 0 & 0 \\
    0 & 0 & x & x & 0 & 0 \\
    0 & 0 & 0 & x & x & 0
\end{bmatrix}
$$

using Householder matrices and then "chase" the $(m, m+1)$ entry up the $(m+1)^{st}$ column by applying Givens rotations from the right.)

P5.4.2 Show how to efficiently bidiagonalize an $n$-by-$n$ upper triangular matrix using Givens rotations.

P5.4.3 Show how to upper bidiagonalize a tridiagonal matrix $T \in \mathbb{R}^{n \times n}$ using Givens rotations.

P5.4.4 Let $A \in \mathbb{R}^{m \times n}$ and assume that $0 \neq v$ satisfies $\| Av \|_2 = \sigma_n(A) \| v \|_2$ Let $\Pi$ be a permutation such that if $\Pi T v = w$, then $|w_n| = \| w \|_\infty$. Show that if $\Pi T = QR$ is the QR factorization of $\Pi A$, then $|r_{nm}| \leq \sqrt{n} \sigma_n(A)$. Thus, there always exists a permutation $\Pi$ such that the QR factorization of $A\Pi$ "displays" near rank deficiency.

P5.4.5 Let $x, y \in \mathbb{R}^m$ and $Q \in \mathbb{R}^{m \times m}$ be given with $Q$ orthogonal. Show that if

$$Q^T x = \begin{bmatrix} \alpha \\ u \end{bmatrix} \begin{bmatrix} 1 \\ m-1 \end{bmatrix}, \quad Q^T y = \begin{bmatrix} \beta \\ v \end{bmatrix} \begin{bmatrix} 1 \\ m-1 \end{bmatrix}$$

then $u^T v = x^T y - \alpha \beta$.

P5.4.6 Let $A = [a_1, \ldots, a_m] \in \mathbb{R}^{m \times n}$ and $b \in \mathbb{R}^m$ be given. For any subset of $A$'s columns $\{a_{c_1}, \ldots, a_{c_k}\}$ define

$$\text{res}[a_{c_1}, \ldots, a_{c_k}] = \min_{x \in \mathbb{R}^k} \| [a_{c_1}, \ldots, a_{c_k}] x - b \|_2$$

Describe an alternative pivot selection procedure for Algorithm 5.4.1 such that if $QR = A\Pi = [a_{c_1}, \ldots, a_{c_k}]$ in the final factorization, then for $k = 1:n$:

$$\text{res}[a_{c_1}, \ldots, a_{c_k}] = \min_{i \geq k} \text{res}[a_{c_1}, \ldots, a_{c_{k-1}}, a_{c_i}]$$

## Notes and References for Sec. 5.4

Aspects of the complete orthogonal decomposition are discussed in
5.4. Other Orthogonal Factorizations

The computation of the SVD is detailed in §8.6. But here are some of the standard references concerned with its calculation:

QR with column pivoting was first discussed in

Knowing when to stop in the algorithm is difficult. In questions of rank deficiency, it is helpful to obtain information about the smallest singular value of the upper triangular matrix $R$. This can be done using the techniques of §3.5.4 or those that are discussed in

Other aspects of rank estimation with QR are discussed in

5.5 The Rank Deficient LS Problem

If \( A \) is rank deficient, then there are an infinite number of solutions to the LS problem and we must resort to special techniques. These techniques must address the difficult problem of numerical rank determination.

After some SVD preliminaries, we show how QR with column pivoting can be used to determine a minimizer \( x_B \) with the property that \( Ax_B \) is a linear combination of \( r = \text{rank}(A) \) columns. We then discuss the minimum 2-norm solution that can be obtained from the SVD.

5.5.1 The Minimum Norm Solution

Suppose \( A \in \mathbb{R}^{m \times n} \) and \( \text{rank}(A) = r < n \). The rank deficient LS problem has an infinite number of solutions, for if \( x \) is a minimizer and \( z \in \text{null}(A) \) then \( x + z \) is also a minimizer. The set of all minimizers

\[
\mathcal{X} = \{ x \in \mathbb{R}^n : \| Ax - b \|_2 = \text{min} \}
\]

is convex, for if \( x_1, x_2 \in \mathcal{X} \) and \( \lambda \in [0, 1] \), then

\[
\| A(\lambda x_1 + (1 - \lambda)x_2) - b \|_2 \leq \lambda\| Ax_1 - b \|_2 + (1 - \lambda)\| Ax_2 - b \|_2
\]

\[
= \text{min} \| Ax - b \|_2.
\]

Thus, \( \lambda x_1 + (1 - \lambda)x_2 \in \mathcal{X} \). It follows that \( \mathcal{X} \) has a unique element having minimum 2-norm and we denote this solution by \( x_{LS} \). (Note that in the full rank case, there is only one LS solution and so it must have minimal 2-norm. Thus, we are consistent with the notation in §5.3.)

5.5.2 Complete Orthogonal Factorization and \( x_{LS} \)

Any complete orthogonal factorization can be used to compute \( x_{LS} \). In particular, if \( Q \) and \( Z \) are orthogonal matrices such that

\[
Q^T A Z = T = \begin{bmatrix} T_{11} & 0 \\ 0 & 0 \end{bmatrix}^r m - r \\
\begin{array}{cc}
11 & 0 \\
r & n - r
\end{array}
\]

then

\[
\| Ax - b \|_2^2 = \| (Q^T AZ) Z^T x - Q^T b \|_2^2 = \| T_{11} w - c \|_2^2 + \| d \|_2^2
\]

where

\[
Z^T x = \begin{bmatrix} w \\ y \end{bmatrix}^r n - r,
\quad Q^T b = \begin{bmatrix} c \\ d \end{bmatrix}^r m - r
\]

Clearly, if \( x \) is to minimize the sum of squares, then we must have \( w = T_{11}^{-1} c \).

For \( x \) to have minimal 2-norm, \( y \) must be zero, and thus,

\[
x_{LS} = Z \begin{bmatrix} T_{11}^{-1} c \\ 0 \end{bmatrix}.
\]
5.5.3 The SVD and the LS Problem

Of course, the SVD is a particularly revealing complete orthogonal decomposition. It provides a neat expression for $x_{LS}$ and the norm of the minimum residual $\rho_{LS} = \| Ax_{LS} - b \|_2$.

Theorem 5.5.1 Suppose $U^TAV = \Sigma$ is the SVD of $A \in \mathbb{R}^{m \times n}$ with $r = \text{rank}(A)$. If $U = [u_1, \ldots, u_m]$ and $V = [v_1, \ldots, v_n]$ are column partitionings and $b \in \mathbb{R}^m$, then

$$x_{LS} = \sum_{i=1}^{r} \frac{u_i^T b}{\sigma_i} u_i$$

(5.5.1)

minimizes $\| Ax - b \|_2$ and has the smallest 2-norm of all minimizers. Moreover

$$\rho_{LS}^2 = \| Ax_{LS} - b \|_2^2 = \sum_{i=r+1}^{m} (u_i^T b)^2.$$  

(5.5.2)

Proof. For any $x \in \mathbb{R}^n$ we have:

$$\| Ax - b \|_2^2 = \| (U^TAV)(V^T x) - U^Tb \|_2^2 = \| \Sigma \alpha - U^Tb \|_2^2 = \sum_{i=1}^{r} (\sigma_i \alpha_i - u_i^T b)^2 + \sum_{i=r+1}^{m} (u_i^T b)^2$$

where $\alpha = V^T x$. Clearly, if $x$ solves the LS problem, then $\alpha_i = (u_i^T b / \sigma_i)$ for $i = 1:r$. If we set $\alpha(r+1:n) = 0$, then the resulting $x$ clearly has minimal 2-norm. □

5.5.4 The Pseudo-Inverse

Note that if we define the matrix $A^+ \in \mathbb{R}^{n \times m}$ by $A^+ = V \Sigma^+ U^T$ where

$$\Sigma^+ = \text{diag} \left( \frac{1}{\sigma_1}, \ldots, \frac{1}{\sigma_r}, 0, \ldots, 0 \right) \in \mathbb{R}^{n \times m} \quad r = \text{rank}(A)$$

then $x_{LS} = A^+ b$ and $\rho_{LS} = \| (I - A A^+) b \|_2$. $A^+$ is referred to as the **pseudo-inverse** of $A$. It is the unique minimal Frobenius norm solution to the problem

$$\min_{X \in \mathbb{R}^{n \times m}} \| AX - I_m \|_F.$$  

(5.5.3)

If $\text{rank}(A) = n$, then $A^+ = (A^T A)^{-1} A^T$, while if $m = n = \text{rank}(A)$, then $A^+ = A^{-1}$. Typically, $A^+$ is defined to be the unique matrix $X \in \mathbb{R}^{n \times m}$ that satisfies the four Moore-Penrose conditions:

(i) $A X A = A$  \quad (iii) $(AX)^T = AX$

(ii) $X A X = X$  \quad (iv) $(XA)^T = XA$.  

These conditions amount to the requirement that $AA^+$ and $A^+A$ be orthogonal projections onto $\text{ran}(A)$ and $\text{ran}(A^T)$, respectively. Indeed, $AA^+ = U_1U_1^T$ where $U_1 = U(1:m, 1:r)$ and $A^+A = V_1V_1^T$ where $V_1 = V(1:n, 1:r)$.

### 5.5.5 Some Sensitivity Issues

In §5.3 we examined the sensitivity of the full rank LS problem. The behavior of $x_{LS}$ in this situation is summarized in Theorem 5.3.1. If we drop the full rank assumptions then $x_{LS}$ is not even a continuous function of the data and small changes in $A$ and $b$ can induce arbitrarily large changes in $x_{LS} = A^+b$. The easiest way to see this is to consider the behavior of the pseudo inverse. If $A$ and $\delta A$ are in $\mathbb{R}^{m \times n}$, then Wedin (1973) and Stewart (1975) show that

$$\| (A + \delta A)^+ - A^+ \|_F \leq 2\| \delta A \|_F \max \left\{ \| A^+ \|_2^2, \| (A + \delta A)^+ \|_2^2 \right\}.$$ 

This inequality is a generalization of Theorem 2.3.4 in which perturbations in the matrix inverse are bounded. However, unlike the square nonsingular case, the upper bound does not necessarily tend to zero as $\delta A$ tends to zero. If

$$A = \begin{bmatrix} 1 & 0 \\ 0 & 0 \\ 0 & 0 \end{bmatrix} \quad \text{and} \quad \delta A = \begin{bmatrix} 0 & 0 \\ 0 & \epsilon \\ 0 & 0 \end{bmatrix}$$

then

$$A^+ = \begin{bmatrix} 1 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix} \quad \text{and} \quad (A + \delta A)^+ = \begin{bmatrix} 1 & 0 & 0 \\ 1 & 1/\epsilon & 0 \end{bmatrix}$$

and $\| A^+ - (A + \delta A)^+ \|_2 = 1/\epsilon$. The numerical determination of an LS minimizer in the presence of such discontinuities is a major challenge.

### 5.5.6 QR with Column Pivoting and Basic Solutions

Suppose $A \in \mathbb{R}^{m \times n}$ has rank $r$. QR with column pivoting (Algorithm 5.4.1) produces the factorization $AP = QR$ where

$$R = \begin{bmatrix} R_{11} & R_{12} \\ 0 & 0 \end{bmatrix}^{r \times r}$$

$$\begin{bmatrix} m - r \\ r \end{bmatrix}.$$ 

Given this reduction, the LS problem can be readily solved. Indeed, for any $x \in \mathbb{R}^n$ we have

$$\| Ax - b \|_2^2 = \| (Q^TAP)(P^Tz) - (Q^Tb) \|_2^2 = \| R_{11}y - (c - R_{12}z) \|_2^2 + \| d \|_2^2,$$
where

\[ \Pi^T x = \begin{bmatrix} y \\ z \end{bmatrix} \begin{bmatrix} r \\ n - r \end{bmatrix} \quad \text{and} \quad Q^T b = \begin{bmatrix} c \\ d \end{bmatrix} \begin{bmatrix} r \\ m - r \end{bmatrix}. \]

Thus, if \( x \) is an LS minimizer, then we must have

\[ x = \Pi \begin{bmatrix} R_{11}^{-1}(c - R_{12}z) \\ z \end{bmatrix}. \]

If \( z \) is set to zero in this expression, then we obtain the basic solution

\[ x_B = \Pi \begin{bmatrix} R_{11}^{-1}c \\ 0 \end{bmatrix}. \]

Notice that \( x_B \) has at most \( r \) nonzero components and so \( Ax_B \) involves a subset of \( A \)'s columns.

The basic solution is not the minimal 2-norm solution unless the submatrix \( R_{12} \) is zero since

\[ \| x_{LS} \|_2 = \min_{z \in \mathbb{R}^{n-r}} \left\| x_B - \Pi \begin{bmatrix} R_{11}^{-1}R_{12} \\ -I_{n-r} \end{bmatrix} z \right\|_2. \] (5.5.4)

Indeed, this characterization of \( \| x_{LS} \|_2 \) can be used to show

\[ 1 \leq \frac{\| x_B \|_2}{\| x_{LS} \|_2} \leq \sqrt{1 + \| R_{11}^{-1}R_{12} \|_2^2}. \] (5.5.5)

See Golub and Pereyra (1976) for details.

5.5.7 Numerical Rank Determination with \( A\Pi = QR \)

If Algorithm 5.4.1 is used to compute \( x_B \), then care must be exercised in the determination of rank(\( A \)). In order to appreciate the difficulty of this, suppose

\[ fl(H_k \cdots H_1 A\Pi_1 \cdots \Pi_k) = \hat{R}^{(k)} = \begin{bmatrix} \hat{R}_{11}^{(k)} & \hat{R}_{12}^{(k)} \\ 0 & \hat{R}_{22}^{(k)} \end{bmatrix} \]

is the matrix computed after \( k \) steps of the algorithm have been executed in floating point. Suppose rank(\( A \)) = \( k \). Because of roundoff error, \( \hat{R}_{22}^{(k)} \) will not be exactly zero. However, if \( \hat{R}_{22}^{(k)} \) is suitably small in norm then it is reasonable to terminate the reduction and declare \( A \) to have rank \( k \). A typical termination criteria might be

\[ \| \hat{R}_{22}^{(k)} \|_2 \leq \varepsilon_1 \| A \|_2 \] (5.5.6)
for some small machine-dependent parameter \( \epsilon_1 \). In view of the roundoff properties associated with Householder matrix computation (cf. §5.1.12), we know that \( \hat{R}^{(k)} \) is the exact \( R \) factor of a matrix \( A + E_k \), where
\[
\| E_k \|_2 \leq \epsilon_2 \| A \|_2 \quad \epsilon_2 = O(u).
\]
Using Theorem 2.5.2 we have
\[
s_{k+1}(A + E_k) = s_{k+1}(\hat{R}^{(k)}) \leq \| \hat{R}^{(k)}_{22} \|_2.
\]
Since \( s_{k+1}(A) \leq s_{k+1}(A + E_k) + \| E_k \|_2 \), it follows that
\[
s_{k+1}(A) \leq (\epsilon_1 + \epsilon_2) \| A \|_2.
\]
In other words, a relative perturbation of \( O(\epsilon_1 + \epsilon_2) \) in \( A \) can yield a rank-\( k \) matrix. With this termination criterion, we conclude that QR with column pivoting "discovers" rank degeneracy if in the course of the reduction \( \hat{R}^{(k)}_{22} \) is small for some \( k < n \).

Unfortunately, this is not always the case. A matrix can be nearly rank deficient without a single \( \hat{R}^{(k)}_{22} \) being particularly small. Thus, QR with column pivoting by itself is not entirely reliable as a method for detecting near rank deficiency. However, if a good condition estimator is applied to \( R \) it is practically impossible for near rank deficiency to go unnoticed.

**Example 5.5.1** Let \( T_n(c) \) be the matrix
\[
T_n(c) = \text{diag}(1, s, \ldots, s^{n-1})
\]
with \( c^2 + s^2 = 1 \) with \( c, s > 0 \) (See Lawson and Hanson (1974, p.31).) These matrices are unaltered by Algorithm 5.4.1 and thus \( \| R^{(k)}_{22} \|_2 \geq s^{n-1} \) for \( k = 1:n-1 \). This inequality implies (for example) that the matrix \( T_{100}(.2) \) has no particularly small trailing principal submatrix since \( s^{100} \approx .13 \). However, it can be shown that \( \sigma_n = O(10^{-8}) \).

### 5.5.8 Numerical Rank and the SVD

We now focus our attention on the ability of the SVD to handle rank-deficiency in the presence of roundoff. Recall that if \( A = U \Sigma V^T \) is the SVD of \( A \), then
\[
x_{LS} = \sum_{i=1}^{r} \frac{v_i^T b}{\sigma_i} v_i \tag{5.5.7}
\]
where \( r = \text{rank}(A) \). Denote the computed versions of \( U, V \), and \( \Sigma = \text{diag}(\sigma_i) \) by \( \hat{U}, \hat{V} \), and \( \hat{\Sigma} = \text{diag}(\hat{\sigma}_i) \). Assume that both sequences of singular
values range from largest to smallest. For a reasonably implemented SVD algorithm it can be shown that

\[ \hat{U} = W + \Delta U \quad W^TW = I_m \quad \| \Delta U \|_2 \leq \varepsilon \quad (5.5.8) \]

\[ \hat{V} = Z + \Delta V \quad Z^TZ = I_m \quad \| \Delta V \|_2 \leq \varepsilon \quad (5.5.9) \]

\[ \hat{\Sigma} = W^T(A + \Delta A)Z \quad \| \Delta A \|_2 \leq \varepsilon \| A \|_2 \quad (5.5.10) \]

where \( \varepsilon \) is a small multiple of \( u \), the machine precision. In plain English, the SVD algorithm computes the singular values of a "nearby" matrix \( A + \Delta A \).

Note that \( \hat{U} \) and \( \hat{V} \) are not necessarily close to their exact counterparts. However, we can show that \( \hat{\sigma}_k \) is close to \( \sigma_k \). Using (5.5.10) and Theorem 2.5.2 we have

\[ \sigma_k = \min_{\text{rank}(B) = k-1} \| A - B \|_2 \]

\[ = \min_{\text{rank}(B) = k-1} \| \hat{\Sigma} - B \| - W^T(\Delta A)Z \|_2. \]

Since \( \| W^T(\Delta A)Z \|_2 \leq \varepsilon \| A \|_2 = \varepsilon \sigma_1 \) and

\[ \min_{\text{rank}(B) = k-1} \| \hat{\Sigma}_k - B \|_2 = \hat{\sigma}_k \]

it follows that \( |\sigma_k - \hat{\sigma}_k| \leq \varepsilon \sigma_1 \) for \( k = 1:n \). Thus, if \( A \) has rank \( r \) then we can expect \( n - r \) of the computed singular values to be small. Near rank deficiency in \( A \) cannot escape detection when the SVD of \( A \) is computed.

Example 5.5.2 For the matrix \( T_{100}(2) \) in Example 5.5.1, \( \sigma_n \approx 0.367 \cdot 10^{-8} \).

One approach to estimating \( r = \text{rank}(A) \) from the computed singular values is to have a tolerance \( \delta > 0 \) and a convention that \( A \) has "numerical rank" \( \hat{r} \) if the \( \hat{\sigma}_i \) satisfy

\[ \hat{\sigma}_1 \geq \cdots \geq \hat{\sigma}_{\hat{r}} > \delta \geq \hat{\sigma}_{\hat{r}+1} \geq \cdots \geq \hat{\sigma}_n. \]

The tolerance \( \delta \) should be consistent with the machine precision, e.g. \( \delta = u \| A \|_{\infty} \). However, if the general level of relative error in the data is larger than \( u \), then \( \delta \) should be correspondingly bigger, e.g., \( \delta = 10^{-2} \| A \|_{\infty} \) if the entries in \( A \) are correct to two digits.

If \( \hat{r} \) is accepted as the numerical rank then we can regard

\[ x_r = \sum_{i=1}^{\hat{r}} \frac{\hat{u}_i^Tb}{\hat{\sigma}_i} \hat{v}_i \]
as an approximation to \( x_{LS} \). Since \( \| x_\ast \|_2 \approx 1/\sigma_\ast \leq 1/\delta \) then \( \delta \) may also be chosen with the intention of producing an approximate LS solution with suitably small norm. In §12.1, we discuss more sophisticated methods for doing this.

If \( \delta_\ast \gg \delta \), then we have reason to be comfortable with \( x_\ast \) because \( A \) can then be unambiguously regarded as a rank(\( A_\ast \)) matrix (modulo \( \delta \)).

On the other hand, \( \{ \delta_1, \ldots, \delta_n \} \) might not clearly split into subsets of small and large singular values, making the determination of \( \hat{r} \) by this means somewhat arbitrary. This leads to more complicated methods for estimating rank which we now discuss in the context of the LS problem.

For example, suppose \( r = n \), and assume for the moment that \( \Delta A = 0 \) in (5.5.10). Thus \( \sigma_i = \delta_\ast \) for \( i = 1:n \). Denote the \( i \)th columns of the matrices \( \hat{U}, \hat{W}, \hat{V} \), and \( Z \) by \( u_i, w_i, v_i \), and \( z_i \), respectively. Subtracting \( x_\ast \) from \( x_{LS} \) and taking norms we obtain

\[
\| x_\ast - x_{LS} \|_2 \leq \sum_{i=1}^{\hat{r}} \frac{\| (w_i^T b)z_i - (u_i^T b)v_i \|_2}{\sigma_i} + \sqrt{\sum_{i=\hat{r}+1}^{n} \left( \frac{w_i^T b}{\sigma_i} \right)^2}.
\]

From (5.5.8) and (5.5.9) it is easy to verify that

\[
\| (w_i^T b)z_i - (u_i^T b)v_i \|_2 \leq 2(1 + \epsilon)\| b \|_2
\]

and therefore

\[
\| x_\ast - x_{LS} \|_2 \leq \frac{\hat{r}}{\delta_\ast} 2(1 + \epsilon)\| b \|_2 + \sqrt{\sum_{i=\hat{r}+1}^{n} \left( \frac{w_i^T b}{\sigma_i} \right)^2}.
\]

The parameter \( \hat{r} \) can be determined as that integer which minimizes the upper bound. Notice that the first term in the bound increases with \( \hat{r} \), while the second decreases.

On occasions when minimizing the residual is more important than accuracy in the solution, we can determine \( \hat{r} \) on the basis of how close we surmise \( \| b - Ax_\ast \|_2 \) is to the true minimum. Paralleling the above analysis, it can be shown that

\[
\| b - Ax_\ast \|_2 - \| b - Ax_{LS} \|_2 \leq (n - \hat{r})\| b \|_2 + \epsilon\| b \|_2 \left( \hat{r} + \frac{\delta_1}{\delta_\ast} (1 + \epsilon) \right).
\]

Again \( \hat{r} \) could be chosen to minimize the upper bound. See Varah (1973) for practical details and also the LAPACK manual.

### 5.5.9 Some Comparisons

As we mentioned, when solving the LS problem via the SVD, only \( \Sigma \) and \( V \) have to be computed. The following table compares the efficiency of this approach with the other algorithms that we have presented.
<table>

Problems

P5.5.1 Show that if

\[
A = \begin{bmatrix} T & S \\ 0 & 0 \end{bmatrix}_m^{m-r} \begin{bmatrix} r \\ r & n-r \end{bmatrix}
\]

where \( r = \text{rank}(A) \) and \( T \) is nonsingular, then

\[
X = \begin{bmatrix} T^{-1} & 0 \\ 0 & 0 \end{bmatrix}_n^{n-r} \begin{bmatrix} r \\ r & m-r \end{bmatrix}
\]

satisfies \( AXA = A \) and \( (AX)^T = (AX) \). In this case, we say that \( X \) is a (1,3) pseudo-inverse of \( A \). Show that for general \( A \), \( x_B = Xb \) where \( X \) is a (1,3) pseudo-inverse of \( A \).

P5.5.2 Define \( B(\lambda) \in \mathbb{R}^{m \times m} \) by \( B(\lambda) = (A^T A + \lambda I)^{-1} A^T \), where \( \lambda > 0 \). Show

\[
\| B(\lambda) - A^+ \|_2 = \frac{\lambda}{\sigma_r(A)\left[\sigma_r(A)^2 + \lambda\right]} \quad r = \text{rank}(A)
\]

and therefore that \( B(\lambda) \to A^+ \) as \( \lambda \to 0 \).

P5.5.3 Consider the rank deficient LS problem

\[
\min_{y \in \mathbb{R}^r, z \in \mathbb{R}^{n-r}} \left\| \begin{bmatrix} R & S \\ 0 & 0 \end{bmatrix} \begin{bmatrix} y \\ z \end{bmatrix} - \begin{bmatrix} c \\ d \end{bmatrix} \right\|_2
\]

where \( R \in \mathbb{R}^{m \times r} \), \( S \in \mathbb{R}^{m \times n-r} \), \( y \in \mathbb{R}^r \), and \( z \in \mathbb{R}^{n-r} \). Assume that \( R \) is upper triangular and nonsingular. Show how to obtain the minimum norm solution to this problem by computing an appropriate QR factorization without pivoting and then solving for the appropriate \( y \) and \( z \).

P5.5.4 Show that if \( A_k \to A \) and \( A_k^+ \to A^+ \), then there exists an integer \( k_0 \) such that \( \text{rank}(A_k) \) is constant for all \( k \geq k_0 \).

P5.5.5 Show that if \( A \in \mathbb{R}^{m \times n} \) has rank \( n \), then so does \( A + E \) if we have the inequality \( \| E \|_2 \| A^+ \|_2 < 1 \).

Notes and References for Sec. 5.5

The pseudo-inverse literature is vast, as evidenced by the 1,775 references in

Survey treatments of LS perturbation theory may be found in Lawson and Hanson (1974), Stewart and Sun (1991), Björck (1996), and

Even for full rank problems, column pivoting seems to produce more accurate solutions. The error analysis in the following paper attempts to explain why.

Various other aspects rank deficiency are discussed in

We have more to say on the subject in §12.1 and §12.2.

## 5.6 Weighting and Iterative Improvement

The concepts of scaling and iterative improvement were introduced in the Chapter 3 context of square linear systems. Generalizations of these ideas that are applicable to the least squares problem are now offered.

### 5.6.1 Column Weighting

Suppose \( G \in \mathbb{R}^{n \times n} \) is nonsingular. A solution to the LS problem

\[
\min \| Ax - b \|_2 \quad A \in \mathbb{R}^{m \times n}, \; b \in \mathbb{R}^m
\]  

(5.6.1)

can be obtained by finding the minimum 2-norm solution \( y_{LS} \) to

\[
\min \| (AG)y - b \|_2
\]

(5.6.2)

and then setting \( x_G = Gy_{LS} \). If \( \text{rank}(A) = n \), then \( x_G = x_{LS} \). Otherwise, \( x_G \) is the minimum \( G \)-norm solution to (5.6.1), where the \( G \)-norm is defined by \( \| z \|_G = \| G^{-1}z \|_2 \).
The choice of $G$ is important. Sometimes its selection can be based on a priori knowledge of the uncertainties in $A$. On other occasions, it may be desirable to normalize the columns of $A$ by setting

$$G = G_0 \equiv \text{diag}(1/\|A(:,1)\|_2, \ldots, 1/\|A(:,n)\|_2).$$

Van der Sluis (1969) has shown that with this choice, $\kappa_2(AG)$ is approximately minimized. Since the computed accuracy of $y_{LS}$ depends on $\kappa_2(AG)$, a case can be made for setting $G = G_0$.

We remark that column weighting affects singular values. Consequently, a scheme for determining numerical rank may not return the same estimates when applied to $A$ and $AG$. See Stewart (1984b).

### 5.6.2 Row Weighting

Let $D = \text{diag}(d_1, \ldots, d_m)$ be nonsingular and consider the weighted least squares problem

$$\text{minimize } \|D(Ax - b)\|_2 \quad A \in \mathbb{R}^{m \times n}, \ b \in \mathbb{R}^m. \quad (5.6.3)$$

Assume $\text{rank}(A) = n$ and that $x_D$ solves (5.6.3). It follows that the solution $x_{LS}$ to (5.6.1) satisfies

$$x_D - x_{LS} = (A^TDA)^{-1}A^T(D^2 - I)(b - Ax_{LS}). \quad (5.6.4)$$

This shows that row weighting in the LS problem affects the solution. (An important exception occurs when $b \in \text{ran}(A)$ for then $x_D = x_{LS}$.)

One way of determining $D$ is to let $d_k$ be some measure of the uncertainty in $b_k$, e.g., the reciprocal of the standard deviation in $b_k$. The tendency is for $r_k = c_k^T(b - Ax_D)$ to be small whenever $d_k$ is large. The precise effect of $d_k$ on $r_k$ can be clarified as follows. Define

$$D(\delta) = \text{diag}(d_1, \ldots, d_{k-1}, d_k \sqrt{1 + \delta}, d_{k+1}, \ldots, d_m)$$

where $\delta > -1$. If $x(\delta)$ minimizes $\|D(\delta)(Ax - b)\|_2$ and $r_k(\delta)$ is the $k$-th component of $b - Ax(\delta)$, then it can be shown that

$$r_k(\delta) = \frac{r_k}{1 + \delta d_k^2 c_k^T A(A^TDA)^{-1}A^Tc_k}. \quad (5.6.5)$$

This explicit expression shows that $r_k(\delta)$ is a monotone decreasing function of $\delta$. Of course, how $r_k$ changes when all the weights are varied is much more complicated.

**Example 5.6.1** Suppose

$$A = \begin{bmatrix} 1 & 2 \\ 3 & 4 \\ 5 & 6 \\ 7 & 8 \end{bmatrix}, \quad b = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}.$$
If \( D = I_4 \) then \( x_D = [-1, .85]^T \) and \( r = b - Ax_D = [.3, -.4, -.1, .2]^T \). On the other hand, if \( D = \text{diag}(1000, 1, 1, 1) \) then we have \( x_D \approx [-1.43, 1.21]^T \) and \( r = b - Ax_D = [.000428, -.571428, -.142853, .285714]^T \).

### 5.6.3 Generalized Least Squares

In many estimation problems, the vector of observations \( b \) is related to \( x \) through the equation

\[
b = Ax + w
\]

where the noise vector \( w \) has zero mean and a symmetric positive definite variance-covariance matrix \( \sigma^2 W \). Assume that \( W \) is known and that \( W = BB^T \) for some \( B \in \mathbb{R}^{m \times m} \). The matrix \( B \) might be given or it might be \( W \)'s Cholesky triangle. In order that all the equations in (5.6.6) contribute equally to the determination of \( x \), statisticians frequently solve the LS problem

\[
\min \| B^{-1}(Ax - b) \|_2.
\]

(5.6.7)

An obvious computational approach to this problem is to form \( \tilde{A} = B^{-1}A \) and \( \tilde{b} = B^{-1}b \) and then apply any of our previous techniques to minimize \( \| \tilde{A}x - \tilde{b} \|_2 \). Unfortunately, \( x \) will be poorly determined by such a procedure if \( B \) is ill-conditioned.

A much more stable way of solving (5.6.7) using orthogonal transformations has been suggested by Paige (1979a, 1979b). It is based on the idea that (5.6.7) is equivalent to the generalized least squares problem,

\[
\min_{b = Ax + Bv} v^T v.
\]

(5.6.8)

Notice that this problem is defined even if \( A \) and \( B \) are rank deficient. Although Paige's technique can be applied when this is the case, we shall describe it under the assumption that both these matrices have full rank.

The first step is to compute the QR factorization of \( A \):

\[
Q^T A = \begin{bmatrix} R_1 \\ 0 \end{bmatrix}, \quad Q = \begin{bmatrix} Q_1 \\ n \end{bmatrix}, \quad Q_2 = \begin{bmatrix} Q_2 \end{bmatrix}.
\]

An orthogonal matrix \( Z \in \mathbb{R}^{m \times m} \) is then determined so that

\[
Q_2^T BZ = \begin{bmatrix} 0 & S \\ n & m-n \end{bmatrix}, \quad Z = \begin{bmatrix} Z_1 & Z_2 \\ n & m-n \end{bmatrix}
\]

where \( S \) is upper triangular. With the use of these orthogonal matrices the constraint in (5.6.8) transforms to

\[
\begin{bmatrix} Q_1^T b \\ Q_2^T b \end{bmatrix} = \begin{bmatrix} R_1 \\ 0 \end{bmatrix} x + \begin{bmatrix} Q_1^T BZ_1 & Q_1^T BZ_2 \\ 0 & S \end{bmatrix} \begin{bmatrix} Z_1^T v \\ Z_2^T v \end{bmatrix}.
\]
Notice that the "bottom half" of this equation determines $v$,

$$Su = Q_2^Tb \quad v = Z_2u,$$  \hspace{1cm} (5.6.9)

while the "top half" prescribes $x$:

$$R_1x = Q_1^Tb - (Q_1^TBZ_1Z_1^T + Q_1^TBZ_2Z_2^T)v = Q_1^Tb - Q_1^TBZ_2u.$$  \hspace{1cm} (5.6.10)

The attractiveness of this method is that all potential ill-conditioning is concentrated in triangular systems (5.6.9) and (5.6.10). Moreover, Paige (1979b) has shown that the above procedure is numerically stable, something that is not true of any method that explicitly forms $B^{-1}A$.

### 5.6.4 Iterative Improvement

A technique for refining an approximate LS solution has been analyzed by Björck (1967, 1968). It is based on the idea that if

$$\begin{bmatrix} I_m & A \\ A^T & 0 \end{bmatrix} \begin{bmatrix} r \\ x \end{bmatrix} = \begin{bmatrix} b \\ 0 \end{bmatrix} \quad A \in \mathbb{R}^{m \times n}, \ b \in \mathbb{R}^m$$  \hspace{1cm} (5.6.11)

then $\|b - Ax\|_2 = \min$. This follows because $r + Ax = b$ and $A^Tr = 0$ imply $A^TAx = A^Tb$. The above augmented system is nonsingular if $\text{rank}(A) = n$, which we hereafter assume.

By casting the LS problem in the form of a square linear system, the iterative improvement scheme (3.5.5) can be applied:

$$r^{(0)} = 0; \ x^{(0)} = 0$$

for $k = 0, 1$,

$$\begin{bmatrix} f^{(k)} \\ g^{(k)} \end{bmatrix} = \begin{bmatrix} b \\ 0 \end{bmatrix} - \begin{bmatrix} I & A \\ A^T & 0 \end{bmatrix} \begin{bmatrix} r^{(k)} \\ x^{(k)} \end{bmatrix}$$

$$\begin{bmatrix} I & A \\ A^T & 0 \end{bmatrix} \begin{bmatrix} p^{(k)} \\ z^{(k)} \end{bmatrix} = \begin{bmatrix} f^{(k)} \\ g^{(k)} \end{bmatrix}$$

$$\begin{bmatrix} r^{(k+1)} \\ x^{(k+1)} \end{bmatrix} = \begin{bmatrix} r^{(k)} \\ x^{(k)} \end{bmatrix} + \begin{bmatrix} p^{(k)} \\ z^{(k)} \end{bmatrix}$$

end

The residuals $f^{(k)}$ and $g^{(k)}$ must be computed in higher precision and an original copy of $A$ must be around for this purpose.
If the QR factorization of $A$ is available, then the solution of the augmented system is readily obtained. In particular, if $A = QR$ and $R_1 = R(1:n, 1:n)$, then a system of the form

$$
\begin{bmatrix}
I & A \\
A^T & 0
\end{bmatrix}
\begin{bmatrix}
p \\
z
\end{bmatrix}
= 
\begin{bmatrix}
f \\
g
\end{bmatrix}
$$

transforms to

$$
\begin{bmatrix}
I_n & 0 & R_1 \\
0 & I_{m-n} & 0 \\
R_1^T & 0 & 0
\end{bmatrix}
\begin{bmatrix}
h \\
f_2 \\
z
\end{bmatrix}
= 
\begin{bmatrix}
f_1 \\
f_2 \\
g
\end{bmatrix}
$$

where

$$Q^T f = 
\begin{bmatrix}
f_1 \\
f_2
\end{bmatrix}
\quad n = m-n
$$

$$Q^T p = 
\begin{bmatrix}
h \\
f_2
\end{bmatrix}
\quad n = m-n
$$

Thus, $p$ and $z$ can be determined by solving the triangular systems $R_1^T h = g$ and $R_1 z = f_1 - h$ and setting $p = Q \begin{bmatrix} h \\ f_2 \end{bmatrix}$. Assuming that $Q$ is stored in factored form, each iteration requires $8mn - 2n^2$ flops.

The key to the iteration's success is that both the LS residual and solution are updated—not just the solution. Björck (1968) shows that if $\kappa_2(A) \approx \beta^q$ and $t$-digit, $\beta$-base arithmetic is used, then $x^{(k)}$ has approximately $k(t - q)$ correct base $\beta$ digits, provided the residuals are computed in double precision. Notice that it is $\kappa_2(A)$, not $\kappa_2(A)^2$, that appears in this heuristic.

Problems

P5.6.1 Verify (5.6.4).

P5.6.2 Let $A \in \mathbb{R}^{m \times n}$ have full rank and define the diagonal matrix

$$
\Delta = \text{diag}(\underbrace{1, \ldots, 1}_{k-1}, \underbrace{(1 + \delta), 1, \ldots, 1}_{m-k})
$$

for $\delta > -1$. Denote the LS solution to $\min ||\Delta(Ax - b)||_2$ by $x(\delta)$ and its residual by $r(\delta) = b - Ax(\delta)$. (a) Show

$$r(\delta) = \left( I - \delta \frac{A(A^T A)^{-1} A^T e_k e_k^T}{1 + \delta e_k^T A(A^T A)^{-1} A^T e_k} \right) r(0).$$

(b) Letting $r_k(\delta)$ stand for the $k$th component of $r(\delta)$, show

$$r_k(\delta) = \frac{r_k(0)}{1 + \delta e_k^T A(A^T A)^{-1} A^T e_k}.$$

(c) Use (b) to verify (5.6.5).

P5.6.3 Show how the SVD can be used to solve the generalized LS problem when the matrices $A$ and $B$ in (5.6.8) are rank deficient.
P5.6.4 Let \( A \in \mathbb{R}^{m \times n} \) have rank \( n \) and for \( \alpha \geq 0 \) define
\[
M(\alpha) = \begin{bmatrix}
\alpha I_m & A \\
A^T & 0
\end{bmatrix}.
\]
Show that
\[
s_{m+n}(M(\alpha)) = \min \left\{ \alpha, \frac{-\alpha}{2} + \sqrt{\sigma_n(A)^2 + \left( \frac{\alpha}{2} \right)^2} \right\}
\]
and determine the value of \( \alpha \) that minimizes \( \kappa_2(M(\alpha)) \).

P5.6.5 Another iterative improvement method for LS problems is the following:
\[
x^{(0)} = 0 \\
\text{for } k = 0, 1, \ldots \\
x^{(k)} = b - Ax^{(k)} \quad \text{(double precision)} \\
\| Ax^{(k)} - x^{(k)} \|_2 = \min \\
x^{(k+1)} = x^{(k)} + x^{(k)} \\
\text{end}
\]
(a) Assuming that the QR factorization of \( A \) is available, how many flops per iteration are required? (b) Show that the above iteration results by setting \( g^{(k)} = 0 \) in the iterative improvement scheme given in §5.6.4.

Notes and References for Sec. 5.6

Row and column weighting in the LS problem is discussed in Lawson and Hanson (SLS, pp. 180-88). The various effects of scaling are discussed in

The theoretical and computational aspects of the generalized least squares problem appear in

Iterative improvement in the least squares context is discussed in

5.7 Square and Underdetermined Systems

The orthogonalization methods developed in this chapter can be applied to square systems and also to systems in which there are fewer equations than unknowns. In this brief section we discuss some of the various possibilities.

5.7.1 Using QR and SVD to Solve Square Systems

The least squares solvers based on the QR factorization and the SVD can be used to solve square linear systems: just set \( m = n \). However, from the flop point of view, Gaussian elimination is the cheapest way to solve a square linear system as shown in the following table which assumes that the right hand side is available at the time of factorization:

<table>
<thead>
<tr>
<th>Method</th>
<th>Flops</th>
</tr>
</thead>
<tbody>
<tr>
<td>Gaussian Elimination</td>
<td>( 2n^3/3 )</td>
</tr>
<tr>
<td>Householder Orthogonalization</td>
<td>( 4n^3/3 )</td>
</tr>
<tr>
<td>Modified Gram-Schmidt</td>
<td>( 2n^3 )</td>
</tr>
<tr>
<td>Bidiagonalization</td>
<td>( 8n^3/3 )</td>
</tr>
<tr>
<td>Singular Value Decomposition</td>
<td>( 12n^3 )</td>
</tr>
</tbody>
</table>

Nevertheless, there are three reasons why orthogonalization methods might be considered:

- The flop counts tend to exaggerate the Gaussian elimination advantage. When memory traffic and vectorization overheads are considered, the QR approach is comparable in efficiency.

- The orthogonalization methods have guaranteed stability; there is no "growth factor" to worry about as in Gaussian elimination.

- In cases of ill-conditioning, the orthogonal methods give an added measure of reliability. QR with condition estimation is very dependable and, of course, SVD is unsurpassed when it comes to producing a meaningful solution to a nearly singular system.

We are not expressing a strong preference for orthogonalization methods but merely suggesting viable alternatives to Gaussian elimination.

We also mention that the SVD entry in Table 5.7.1 assumes the availability of \( b \) at the time of decomposition. Otherwise, \( 20n^3 \) flops are required because it then becomes necessary to accumulate the \( U \) matrix.

If the QR factorization is used to solve \( Ax = b \), then we ordinarily have to carry out a back substitution: \( Rx = Q^Tb \). However, this can be avoided by "preprocessing" \( b \). Suppose \( H \) is a Householder matrix such
that \( Hb = \beta e_n \) where \( e_n \) is the last column of \( I_n \). If we compute the QR factorization of \((HA)^T\), then \( A = H^T R^T Q^T \) and the system transforms to

\[
R^T y = \beta e_n
\]

where \( y = Q^T x \). Since \( R^T \) is lower triangular, \( y = (\beta/r_{nn})e_n \) and so

\[
x = \frac{\beta}{r_{nn}} Q(:, n).
\]

### 5.7.2 Underdetermined Systems

We say that a linear system

\[
Ax = b \quad A \in \mathbb{R}^{m \times n}, \ b \in \mathbb{R}^m
\]  

(5.7.1)

is underdetermined whenever \( m < n \). Notice that such a system either has no solution or has an infinity of solutions. In the second case, it is important to distinguish between algorithms that find the minimum 2-norm solution and those that do not necessarily do so. The first algorithm we present is in the latter category. Assume that \( A \) has full row rank and that we apply QR with column pivoting to obtain:

\[
Q^T A \Pi = \begin{bmatrix} R_1 & R_2 \end{bmatrix}
\]

where \( R_1 \in \mathbb{R}^{m \times m} \) is upper triangular and \( R_2 \in \mathbb{R}^{m \times (n-m)} \). Thus, \( Ax = b \) transforms to

\[
(Q^T A \Pi)(\Pi^T x) = \begin{bmatrix} R_1 & R_2 \end{bmatrix} \begin{bmatrix} z_1 \\
  z_2
\end{bmatrix} = Q^T b
\]

where

\[
\Pi^T x = \begin{bmatrix} z_1 \\
  z_2
\end{bmatrix}
\]

with \( z_1 \in \mathbb{R}^m \) and \( z_2 \in \mathbb{R}^{(n-m)} \). By virtue of the column pivoting, \( R_1 \) is nonsingular because we are assuming that \( A \) has full row rank. One solution to the problem is therefore obtained by setting \( z_1 = R_1^{-1} Q^T b \) and \( z_2 = 0 \).

**Algorithm 5.7.1** Given \( A \in \mathbb{R}^{m \times n} \) with \( \text{rank}(A) = m \) and \( b \in \mathbb{R}^m \), the following algorithm finds an \( x \in \mathbb{R}^n \) such that \( Ax = b \).

\[
Q^T A \Pi = R \quad \text{(QR with column pivoting.)}
\]

Solve \( R(1:n, 1:m)z_1 = Q^T b \).

Set \( x = \Pi \begin{bmatrix} z_1 \\
  0
\end{bmatrix} \).
This algorithm requires $2m^2n - m^3/3$ flops. The minimum norm solution is not guaranteed. (A different $\Pi$ would render a smaller $z_1$.) However, if we compute the QR factorization

$$A^T = QR = Q \begin{bmatrix} R_1 \\ 0 \end{bmatrix}$$

with $R_1 \in \mathbb{R}^{m \times m}$, then $Ax = b$ becomes

$$(QR)^T x = \begin{bmatrix} R_1^T \\ 0 \end{bmatrix} \begin{bmatrix} z_1 \\ z_2 \end{bmatrix} = b$$

where

$$Q^T x = \begin{bmatrix} z_1 \\ z_2 \end{bmatrix} \quad z_1 \in \mathbb{R}^m, \; z_2 \in \mathbb{R}^{n-m}.$$ 

Now the minimum norm solution does follow by setting $z_2 = 0$.

Algorithm 5.7.2 Given $A \in \mathbb{R}^{m \times n}$ with $\text{rank}(A) = m$ and $b \in \mathbb{R}^m$, the following algorithm finds the minimal 2-norm solution to $Ax = b$.

- $A^T = QR$ (QR factorization)
- Solve $R(1:m, 1:m)^T z = b$.
- $x = Q(:, 1:m)z$

This algorithm requires at most $2m^2n - 2m^3/3$

The SVD can also be used to compute the minimal norm solution of an underdetermined $Ax = b$ problem. If

$$A = \sum_{i=1}^{r} \sigma_i u_i v_i^T \quad r = \text{rank}(A)$$

is $A$'s singular value expansion, then

$$x = \sum_{i=1}^{r} \frac{u_i^T b}{\sigma_i} v_i.$$ 

As in the least squares problem, the SVD approach is desirable whenever $A$ is nearly rank deficient.

5.7.3 Perturbed Underdetermined Systems

We conclude this section with a perturbation result for full-rank underdetermined systems.
Theorem 5.7.1 Suppose \( \text{rank}(A) = m \leq n \) and that \( A \in \mathbb{R}^{m \times n}, \delta A \in \mathbb{R}^{m \times n}, 0 \neq b \in \mathbb{R}^m, \) and \( \delta b \in \mathbb{R}^m \) satisfy
\[
\varepsilon = \max\{\epsilon_A, \epsilon_b\} < \sigma_m(A),
\]
where \( \epsilon_A = \|\delta A\|_2/\|A\|_2 \) and \( \epsilon_b = \|\delta b\|_2/\|b\|_2 \). If \( x \) and \( \hat{x} \) are minimum norm solutions that satisfy
\[
Ax = b \quad (A + \delta A)\hat{x} = b + \delta b
\]
then
\[
\frac{\|\hat{x} - x\|_2}{\|x\|_2} \leq \kappa_2(A)(\epsilon_A \min\{2, n - m + 1\} + \epsilon_b) + O(\varepsilon^2).
\]

Proof. Let \( E \) and \( f \) be defined by \( \delta A/\epsilon \) and \( \delta b/\epsilon \). Note that \( \text{rank}(A + tE) = m \) for all \( 0 < t < \varepsilon \) and that
\[
x(t) = (A + tE)^T((A + tE)(A + tE)^T)^{-1}(b + tf)
\]
satisfies \( (A + tE)x(t) = b + tf \). By differentiating this expression with respect to \( t \) and setting \( t = 0 \) in the result we obtain
\[
\dot{x}(0) = (I - A^T(AA^T)^{-1}A)E^T(AA^T)^{-1}b + A^T(AA^T)^{-1}(f - Ex).
\]
Since
\[
\|x\|_2 = \|A^T(AA^T)^{-1}b\|_2 \geq \sigma_m(A)\|AA^T\|^{-1}b\|_2,
\]
and
\[
\|I - A^T(AA^T)^{-1}A\|_2 = \min(1, n - m),
\]
we have
\[
\frac{\|\hat{x} - x\|_2}{\|x\|_2} = \frac{x(\varepsilon) - x(0)}{\|x(0)\|_2} = \varepsilon \frac{\|\hat{x}(0)\|_2}{\|x\|_2} + O(\varepsilon^2)
\]
\[
\leq \varepsilon \min(1, n - m) \left\{ \frac{\|E\|_2}{\|A\|_2} + \frac{\|f\|_2}{\|b\|_2} + \frac{\|E\|_2}{\|A\|_2} \right\} \kappa_2(A) + O(\varepsilon^2)
\]
from which the theorem follows. \( \square \)

Note that there is no \( \kappa_2(A)^2 \) factor as in the case of overdetermined systems.

Problems

P5.7.1 Derive the above expression for \( \hat{x}(0) \).

P5.7.2 Find the minimal norm solution to the system \( Ax = b \) where \( A = [1 2 3] \) and \( b = 1 \).

P5.7.3 Show how triangular system solving can be avoided when using the QR factorization to solve an underdetermined system.

P5.7.4 Suppose \( \delta, x \in \mathbb{R}^n \) are given. Consider the following problems:
(a) Find an unsymmetric Toeplitz matrix $T$ so $Tz = b$.
(b) Find a symmetric Toeplitz matrix $T$ so $Tz = b$.
(c) Find a circulant matrix $C$ so $Cx = b$.

Pose each problem in the form $Ap = b$ where $A$ is a matrix made up of entries from $z$ and $p$ is the vector of sought-after parameters.

Parallel Matrix Computations

§6.1 Basic Concepts
§6.2 Matrix Multiplication
§6.3 Factorizations

The parallel matrix computation area has been the focus of intense research. Although much of the work is machine/system dependent, a number of basic strategies have emerged. Our aim is to present these along with a picture of what it is like to “think parallel” during the design of a matrix computation.

The distributed and shared memory paradigms are considered. We use matrix-vector multiplication to introduce the notion of a node program in §6.1. Load balancing, speed-up, and synchronization are also discussed. In §6.2 matrix-matrix multiplication is used to show the effect of blocking on granularity and to convey the spirit of two-dimensional data flow. Two parallel implementations of the Cholesky factorization are given in §6.3.

Before You Begin

Chapter 1, §4.1, and §4.2 are assumed. Within this chapter there are the following dependencies:

§6.1 → §6.2 → §6.3

Complementary references include the books by Schönauer (1987), Hockney and Jesshope (1988), Modi (1988), Ortega (1988), Dongarra, Duff,
Sorensen, and van der Vorst (1991), and Golub and Ortega (1993) and the
excellent review papers by Haller (1978), Ortega and Voight (1985), Galli-
van, Plemmons, and Sameh (1990), and Demmel, Heath, and van der Vorst
(1993).

6.1 Basic Concepts

In this section we introduce the distributed and shared memory paradigms
using the gaxpy operation

\[ z = y + Ax, \quad A \in \mathbb{R}^{n \times n}, x, y, z \in \mathbb{R}^n \]  \hspace{1cm} (6.1.1)

as an example. In practice, there is a fuzzy line between these two styles
of parallel computing and typically a blend of our comments apply to any
particular machine.

6.1.1 Distributed Memory Systems

In a distributed memory multiprocessor each processor has a local mem-
ory and executes its own node program. The program can alter values in
the executing processor's local memory and can send data in the form of
messages to the other processors in the network. The interconnection of
the processors defines the network topology and one simple example that
is good enough for our introduction is the ring. See FIGURE 6.1.1. Other

![Figure 6.1.1 A Four-Processor Ring](image)

important interconnection schemes include the mesh and torus (for their
close correspondence with two-dimensional arrays), the hypercube (for its
generality and optimality), and the tree (for its handling of divide and
conquer procedures). See Ortega and Voigt (1985) for a discussion of the
possibilities. Our immediate goal is to develop a ring algorithm for (6.1.1).
Matrix multiplication on a torus is discussed in §6.2.

Each processor has an identification number. The \( \mu \)th processor is des-
ignated by \( \text{Proc}(\mu) \). We say that \( \text{Proc}(\lambda) \) is a neighbor of \( \text{Proc}(\mu) \) if there
is a direct physical connection between them. Thus, in a \( p \)-processor ring,
\( \text{Proc}(p - 1) \) and \( \text{Proc}(1) \) are neighbors of \( \text{Proc}(p) \).
Important factors in the design of an effective distributed memory algorithm include (a) the number of processors and the capacity of the local memories, (b) how the processors are interconnected, (c) the speed of computation relative to the speed of interprocessor communication, and (d) whether or not a node is able to compute and communicate at the same time.

### 6.1.2 Communication

To describe the sending and receiving of messages we adopt a simple notation:

```
send( {matrix} , {id of the receiving processor} )
recv( {matrix} , {id of the sending processor} )
```

Scalars and vectors are matrices and therefore messages. In our model, if Proc(μ) executes the instruction `send(V_{loc}, λ)`, then a copy of the local matrix $V_{loc}$ is sent to Proc(λ) and the execution of Proc(μ)'s node program resumes immediately. It is legal for a processor to send a message to itself. To emphasize that a matrix is stored in a local memory we use the subscript "loc."

If Proc(μ) executes the instruction `recv(U_{loc}, λ)`, then the execution of its node program is suspended until a message is received from Proc(λ). Once received, the message is placed in a local matrix $U_{loc}$ and Proc(μ) resumes execution of its node program.

Although the syntax and semantics of our send/receive notation is adequate for our purposes, it does suppress a number of important details:

- **Message assembly overhead.** In practice, there may be a penalty associated with the transmission of a matrix whose entries are not contiguous in the sender's local memory. We ignore this detail.

- **Message tagging.** Messages need not arrive in the order they are sent, and a system of message tagging is necessary so that the receiver is not "confused." We ignore this detail by assuming that messages do arrive in the order that they are sent.

- **Message interpretation overhead.** In practice a message is a bit string, and a header must be provided that indicates to the receiver the dimensions of the matrix and the format of the floating point words that are used to represent its entries. Going from message to stored matrix takes time, but it is an overhead that we do not try to quantify.

These simplifications enable us to focus on high-level algorithmic ideas. But it should be remembered that the success of a particular implementation may hinge upon the control of these hidden overheads.
6.1.3 Some Distributed Data Structures

Before we can specify our first distributed memory algorithm, we must consider the matter of data layout. How are the participating matrices and vectors distributed around the network?

Suppose $x \in \mathbb{R}^n$ is to be distributed among the local memories of a $p$-processor network. Assume for the moment that $n = rp$. Two "canonical" approaches to this problem are store-by-row and store-by-column.

In store-by-column we regard the vector $x$ as an $r$-by-$p$ matrix,

$$x_{r \times p} = \begin{bmatrix} x(1:r) & x(r + 1:2r) & \cdots & x(1 + (p - 1)r:n) \end{bmatrix},$$

and store each column in a processor, i.e., $x(1 + (\mu - 1)r:\mu r) \in \text{Proc}(\mu)$. (In this context "e" means "is stored in.") Note that each processor houses a contiguous portion of $x$.

In the store-by-row scheme we regard $x$ as a $p$-by-$r$ matrix

$$x_{p \times r} = \begin{bmatrix} x(1:p) & x(p + 1:2p) & \cdots & x((r - 1)p + 1:n) \end{bmatrix},$$

and store each row in a processor, i.e., $x(\mu:p:n) \in \text{Proc}(\mu)$. Store-by-row is sometimes referred to as the wrap method of distributing a vector because the components of $x$ can be thought of as cards in a deck that are "dealt" to the processors in wrap-around fashion.

If $n$ is not an exact multiple of $p$, then these ideas go through with minor modification. Consider store-by-column with $n = 14$ and $p = 4$:

$$x^T = \begin{bmatrix} x_1 & x_2 & x_3 & x_4 \\ x_5 & x_6 & x_7 & x_8 \\ x_9 & x_{10} & x_{11} \\ x_{12} & x_{13} & x_{14} \end{bmatrix}. $$

In Proc(1)

Proc(2)

Proc(3)

Proc(4)

In general, if $n = pr + q$ with $0 \leq q < p$, then Proc(1), ..., Proc(q) can each house $r + 1$ components and Proc(q + 1), ..., Proc(p) can house $r$ components. In store-by-row we simply let Proc($\mu$) house $x(\mu:p:n)$.

Similar options apply to the layout of a matrix. There are four obvious possibilities if $A \in \mathbb{R}^{n \times n}$ and (for simplicity) $n = rp$:

<table>
<thead>
<tr>
<th>Orientation</th>
<th>Style</th>
<th>What is in Proc($\mu$)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Column</td>
<td>Contiguous</td>
<td>$A(:,1 + (\mu - 1)r:\mu r)$</td>
</tr>
<tr>
<td>Column</td>
<td>Wrap</td>
<td>$A(:,\mu:p:n)$</td>
</tr>
<tr>
<td>Row</td>
<td>Contiguous</td>
<td>$A(1 + (\mu - 1)r: r, :)$</td>
</tr>
<tr>
<td>Row</td>
<td>Wrap</td>
<td>$A(\mu:p:,:)$.</td>
</tr>
</tbody>
</table>

These strategies have block analogs. For example, if $A = [A_1, \ldots, A_N]$ is a block column partitioning, then we could arrange to have Proc($\mu$) store $A_i$ for $i = \mu:p:N$. 
6.1.4 Gaxpy on a Ring

We are now set to develop a ring algorithm for the gaxpy \( z = y + Ax \) \( (A \in \mathbb{R}^{n \times n}, x, y \in \mathbb{R}^n) \). For clarity, assume that \( n = rp \) where \( p \) is the size of the ring. Partition the gaxpy as

\[
\begin{bmatrix}
  z_1 \\
  \vdots \\
  z_p 
\end{bmatrix}
= \begin{bmatrix}
  y_1 \\
  \vdots \\
  y_p 
\end{bmatrix}
+ \begin{bmatrix}
  A_{11} & \cdots & A_{1p} \\
  \vdots & \ddots & \vdots \\
  A_{p1} & \cdots & A_{pp}
\end{bmatrix}
\begin{bmatrix}
  x_1 \\
  \vdots \\
  x_p 
\end{bmatrix}
\]  

(6.1.2)

where \( A_{ij} \in \mathbb{R}^{r \times r} \) and \( x_i, y_i, z_i \in \mathbb{R}^r \). We assume that at the start of computation \( \text{Proc}(\mu) \) houses \( x_\mu, y_\mu \), and the \( \mu \)th block row of \( A \). Upon completion we set as our goal the overwriting of \( y_\mu \) by \( z_\mu \). From the \( \text{Proc}(\mu) \) perspective, the computation of

\[
z_\mu = y_\mu + \sum_{r=1}^{p} A_{\mu r} x_r
\]

involves local data \( (A_{\mu r}, y_\mu, x_\mu) \) and nonlocal data \( (x_r, r \neq \mu) \). To make the nonlocal portions of \( x \) available, we circulate its subvectors around the ring. For example, in the \( p = 3 \) case we rotate the \( x_1, x_2, \) and \( x_3 \) as follows:

<table>
<thead>
<tr>
<th>step</th>
<th>Proc(1)</th>
<th>Proc(2)</th>
<th>Proc(3)</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>( x_3 )</td>
<td>( x_1 )</td>
<td>( x_2 )</td>
</tr>
<tr>
<td>2</td>
<td>( x_2 )</td>
<td>( x_3 )</td>
<td>( x_1 )</td>
</tr>
<tr>
<td>3</td>
<td>( x_1 )</td>
<td>( x_2 )</td>
<td>( x_3 )</td>
</tr>
</tbody>
</table>

When a subvector of \( x \) "visits", the host processor must incorporate the appropriate term into its running sum:

<table>
<thead>
<tr>
<th>step</th>
<th>Proc(1)</th>
<th>Proc(2)</th>
<th>Proc(3)</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>( y_1 = y_1 + A_{13} x_3 )</td>
<td>( y_2 = y_2 + A_{21} x_1 )</td>
<td>( y_3 = y_3 + A_{32} x_2 )</td>
</tr>
<tr>
<td>2</td>
<td>( y_1 = y_1 + A_{12} x_2 )</td>
<td>( y_2 = y_2 + A_{23} x_3 )</td>
<td>( y_3 = y_3 + A_{31} x_1 )</td>
</tr>
<tr>
<td>3</td>
<td>( y_1 = y_1 + A_{11} x_1 )</td>
<td>( y_2 = y_2 + A_{22} x_2 )</td>
<td>( y_3 = y_3 + A_{33} x_3 )</td>
</tr>
</tbody>
</table>

In general, the "merry-go-round" of \( x \) subvectors makes \( p \) "stops." For each received \( x \)-subvector, a processor performs an \( r \)-by-\( r \) gaxpy.

Algorithm 6.1.1 Suppose \( A \in \mathbb{R}^{n \times n}, x \in \mathbb{R}^n \), and \( y \in \mathbb{R}^n \) are given and that \( z = y + Ax \). If each processor in a \( p \)-processor ring executes the following node program and \( n = rp \), then upon completion \( \text{Proc}(\mu) \) houses \( x(1+(\mu-1)r:rp) \) in \( y_{\text{loc}} \). Assume the following local memory initializations:

- \( p \), \( \mu \) (the node id), \( \text{left} \) and \( \text{right} \) (the neighbor id's), \( n, \text{row} = 1+(\mu-1)r:rp \),
- \( A_{\text{loc}} = A(\text{row}, :) \), \( x_{\text{loc}} = x(\text{row}) \), \( y_{\text{loc}} = y(\text{row}) \).
for $t = 1:p$
  send($x_{loc}$, right)
  recv($x_{loc}$, left)
  $\tau = \mu - t$
  if $\tau \leq 0$
    $\tau = \tau + p$
  end
  \{ $x_{loc} = x(1 + (\tau - 1)r:tt)$ \}
  $y_{loc} = y_{loc} + A_{loc}(:,1 + (\tau - 1)r:tt)x_{loc}$
end

The index $\tau$ names the currently available $x$ subvector. Once it is computed it is possible to carry out the update of the locally housed portion of $y$. The send-recv pair passes the currently housed $x$ subvector to the right and waits to receive the next one from the left. Synchronization is achieved because the local $y$ update cannot begin until the “new” $x$ subvector arrives. It is impossible for one processor to “race ahead” of the others or for an $x$ subvector to pass another in the merry-go-round. The algorithm is tailored to the ring topology in that only nearest neighbor communication is involved. The computation is also perfectly load balanced meaning that each processor has the same amount of computation and communication. Load imbalance is discussed further in §6.1.7.

The design of a parallel program involves subtleties that do not arise in the uniprocessor setting. For example, if we inadvertently reverse the order of the send and the recv, then each processor starts its node program by waiting for a message from its left neighbor. Since that neighbor in turn is waiting for a message from its left neighbor, a state of deadlock results.

### 6.1.5 The Cost of Communication

Communication overheads can be estimated if we model the cost of sending and receiving a message. To that end we assume that a send or recv involving $m$ floating point numbers requires

$$\tau(m) = \alpha_d + \beta_d m$$  \hspace{1cm} (6.1.3)

seconds to carry out. Here $\alpha_d$ is the time required to initiate the send or recv and $\beta_d$ is the reciprocal of the rate that a message can be transferred. Note that this model does not take into consideration the “distance” between the sender and receiver. Clearly, it takes longer to pass a message halfway around a ring than to a neighbor. That is why it is always desirable to arrange (if possible) a distributed computation so that communication is just between neighbors.

During each step in Algorithm 6.1.1 an $r$-vector is sent and received and $2r^2$ flops are performed. If the computation proceeds at $R$ flops per second
and there is no idle waiting associated with the recv, then each $y_{oc}$ update requires approximately $(2\tau^2/R) + 2(\alpha_d + \beta_d)\tau)$ seconds.

Another instructive statistic is the computation-to-communication ratio. For Algorithm 6.1.1 this is prescribed by

$$\frac{\text{Time spent computing}}{\text{Time spent communicating}} \approx \frac{2\tau^2/R}{2(\alpha_d + \beta_d)\tau}.$$  

This fraction quantifies the overhead of communication relative to the volume of computation. Clearly, as $\tau = n/p$ grows, the fraction of time spent computing increases.\(^1\)

### 6.1.6 Efficiency and Speed-Up

The **efficiency** of a $p$-processor parallel algorithm is given by

$$E = \frac{T(1)}{pT(p)}$$

where $T(k)$ is the time required to execute the program on $k$ processors. If computation proceeds at $R$ fops/sec and communication is modeled by (6.1.3), then a reasonable estimate of $T(k)$ for Algorithm 6.1.1 is given by

$$T(k) = \sum_{i=1}^{k} \frac{2(n/k)^2}{R} + 2(\alpha_d + \beta_d(n/k)) = \frac{2n^2}{Rk} + 2\alpha_d k + 2\beta_d n$$

for $k > 1$. This assumes no idle waiting. If $k = 1$, then no communication is required and $T(1) = 2n^2/R$. It follows that the efficiency

$$E = \frac{1}{1 + \frac{pR}{n} \left( \frac{\alpha_d p}{n} + \beta \right)}$$

improves with increasing $n$ and degrades with increasing $p$ or $R$. In practice, benchmarking is the only dependable way to assess efficiency.

A concept related to efficiency is speed-up. We say that a parallel algorithm for a particular problem achieves speed-up $S$ if

$$S = T_{seq}/T_{par}$$

where $T_{par}$ is the time required for execution of the parallel program and $T_{seq}$ is the time required by one processor when the best uniprocessor procedure is used. For some problems, the fastest sequential algorithm does not parallelize and so two distinct algorithms are involved in the speed-up assessment.

\(^1\)We mention that these simple measures are not particularly illuminating in systems where the nodes are able to overlap computation and communication.
6.1.7 The Challenge of Load Balancing

If we apply Algorithm 6.1.1 to a matrix \( A \in \mathbb{R}^{n \times n} \) that is lower triangular, then approximately half of the flops associated with the \( y_{loc} \) updates are unnecessary because half of the \( A_{ij} \) in (6.1.2) are zero. In particular, in the \( \mu \)th processor, \( A_{loc}(\cdot, 1 + (\tau - 1)\tau \tau) \) is zero if \( \tau > \mu \). Thus, if we guard the \( y_{loc} \) update as follows,

\[
\text{if } \tau \leq \mu \\
y_{loc} = y_{loc} + A_{loc}(\cdot, 1 + (\tau - 1)\tau \tau)x_{loc}
\]

end

then the overall number of flops is halved. This solves the superfluous flops problem but it creates a load imbalance problem. \( \text{Proc}(\mu) \) oversees about \( \mu \tau^2 / 2 \) flops, an increasing function of the processor id \( \mu \). Consider the following \( \tau = p = 3 \) example:

\[
\begin{bmatrix}
z_1 \\
z_2 \\
z_3 \\
z_4 \\
z_5 \\
z_6 \\
z_7 \\
z_8 \\
z_9
\end{bmatrix}
= 
\begin{bmatrix}
\alpha & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
\alpha & \alpha & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
\alpha & \alpha & \alpha & 0 & 0 & 0 & 0 & 0 & 0 \\
\beta & \beta & \beta & \beta & 0 & 0 & 0 & 0 & 0 \\
\beta & \beta & \beta & \beta & \beta & 0 & 0 & 0 & 0 \\
\gamma & \gamma & \gamma & \gamma & \gamma & \gamma & 0 & 0 & 0 \\
\gamma & \gamma & \gamma & \gamma & \gamma & \gamma & \gamma & 0 & 0 \\
\gamma & \gamma & \gamma & \gamma & \gamma & \gamma & \gamma & \gamma & 0
\end{bmatrix}
\begin{bmatrix}
x_1 \\
x_2 \\
x_3 \\
x_4 \\
x_5 \\
x_6 \\
x_7 \\
x_8 \\
x_9
\end{bmatrix}
+ 
\begin{bmatrix}
y_1 \\
y_2 \\
y_3 \\
y_4 \\
y_5 \\
y_6 \\
y_7 \\
y_8 \\
y_9
\end{bmatrix}
\]

Here, \( \text{Proc}(1) \) handles the \( \alpha \) part, \( \text{Proc}(2) \) handles the \( \beta \) part, and \( \text{Proc}(3) \) handles the \( \gamma \) part.

However, if processors 1, 2, and 3 compute \((z_1, z_4, z_7), (z_2, z_5, z_8), \) and \((z_3, z_6, z_9)\), respectively, then approximate load balancing results:

\[
\begin{bmatrix}
z_1 \\
z_4 \\
z_7 \\
z_2 \\
z_5 \\
z_8 \\
z_3 \\
z_6 \\
z_9
\end{bmatrix}
= 
\begin{bmatrix}
\alpha & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
\beta & \beta & \beta & \beta & 0 & 0 & 0 & 0 & 0 \\
\gamma & \gamma & \gamma & \gamma & \gamma & \gamma & 0 & 0 & 0 \\
\alpha & \alpha & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
\beta & \beta & \beta & \beta & \beta & 0 & 0 & 0 & 0 \\
\gamma & \gamma & \gamma & \gamma & \gamma & \gamma & \gamma & 0 & 0 \\
\alpha & \alpha & \alpha & 0 & 0 & 0 & 0 & 0 & 0 \\
\beta & \beta & \beta & \beta & \beta & \beta & \beta & 0 & 0 \\
\gamma & \gamma & \gamma & \gamma & \gamma & \gamma & \gamma & \gamma & 0
\end{bmatrix}
\begin{bmatrix}
x_1 \\
x_2 \\
x_3 \\
x_4 \\
x_5 \\
x_6 \\
x_7 \\
x_8 \\
x_9
\end{bmatrix}
+ 
\begin{bmatrix}
y_1 \\
y_2 \\
y_3 \\
y_4 \\
y_5 \\
y_6 \\
y_7 \\
y_8 \\
y_9
\end{bmatrix}
\]

The amount of arithmetic still increases with \( \mu \), but the effect is not noticeable if \( n \gg p \).

The development of the general algorithm requires some index manipulation. Assume that \( \text{Proc}(\mu) \) is initialized with \( A_{loc} = A(\mu:p:n,:) \) and
\[ y_{\text{loc}} = y(\mu:p:n), \text{ and assume that the contiguous } x\text{-subvectors circulate as before. If at some stage } x_{\text{loc}} \text{ contains } x(1 + (\tau - 1)r:rr), \text{ then the update} \]

\[ y_{\text{loc}} = y_{\text{loc}} + A_{\text{loc}}(:, 1 + (\tau - 1)r:rr)x_{\text{loc}} \]

implements

\[ y(\mu:p:n) = y(\mu:p:n) + A(\mu:p:n, 1 + (\tau - 1)r:rr)x(1 + (\tau - 1)r:rr). \]

To exploit the triangular structure of \( A \) in the \( y_{\text{loc}} \) computation, we express the gaxpy as a double loop:

\[
\text{for } \alpha = 1:r \\
\quad \text{for } \beta = 1:r \\
\quad \quad y_{\text{loc}}(\alpha) = y_{\text{loc}}(\alpha) + A_{\text{loc}}(\alpha, \beta + (\tau - 1)r)x_{\text{loc}}(\beta) \\
\text{end} \\
\text{end}
\]

The \( A_{\text{loc}} \) reference refers to \( A(\mu + (\alpha - 1)p, \beta + (\tau - 1)r) \) which is zero unless the column index is less than or equal to the row index. Abbreviating the inner loop range with this in mind we obtain

Algorithm 6.1.2 Suppose \( A \in \mathbb{R}^{n \times n} \), \( x \in \mathbb{R}^{n} \) and \( y \in \mathbb{R}^{n} \) are given and that \( z = y + Ax \). Assume that \( n = rp \) and that \( A \) is lower triangular. If each processor in a \( p \)-processor ring executes the following node program, then upon completion \( \text{Proc}(\mu) \) houses \( z(\mu:p:n) \) in \( y_{\text{loc}} \). Assume the following local memory initializations: \( p, \mu \) (the node id), \( \text{left} \) and \( \text{right} \) (the neighbor id's), \( n, A_{\text{loc}} = A(\mu:p:n,:), y_{\text{loc}} = y(\mu:p:n), \) and \( x_{\text{loc}} = x(1 + (\mu - 1)r:mu) \).

\[
r = n/p \\
\text{for } t = 1:p \\
\quad \text{send}(x_{\text{loc}}, \text{right}) \\
\quad \text{recv}(x_{\text{loc}}, \text{left}) \\
\quad \tau = \mu - t \\
\quad \text{if } \tau \leq 0 \\
\quad \quad \tau = \tau + p \\
\text{end} \\
\{x_{\text{loc}} = x(1 + (\tau - 1)r:rr)\} \\
\text{for } \alpha = 1:r \\
\quad \text{for } \beta = 1:mu + (\alpha - 1)p - (\tau - 1)r \\
\quad \quad y_{\text{loc}}(\alpha) = y_{\text{loc}}(\alpha) + A_{\text{loc}}(\alpha, \beta + (\tau - 1)r)x_{\text{loc}}(\beta) \\
\text{end} \\
\text{end}
\]

Having to map indices back and forth between "node space" and "global space" is one aspect of distributed matrix computations that requires care and (hopefully) compiler assistance.
6.1.8 Tradeoffs

As we did in §1.1, let us develop a column-oriented gaxpy and anticipate its performance. With the block column partitioning

\[ A = [A_1, \ldots, A_p] \quad A_i \in \mathbb{R}^{n \times r}, \quad r = n/p \]

the gaxpy \( z = y + Ax \) becomes

\[ z = y + \sum_{\mu=1}^{p} A_\mu x_\mu \]

where \( x_\mu = x(1 + (\mu - 1)r; \mu r) \). Assume that Proc(\( \mu \)) contains \( A_\mu \) and \( x_\mu \). Its contribution to the gaxpy is the product \( A_\mu x_\mu \) and involves local data. However, these products must be summed. We assign this task to Proc(1) which we assume contains \( y \). The strategy is thus for each processor to compute \( A_\mu x_\mu \) and to send the result to Proc(1).

Algorithm 6.1.3 Suppose \( A \in \mathbb{R}^{n \times n} \), \( x \in \mathbb{R}^n \) and \( y \in \mathbb{R}^n \) are given and that \( z = y + Ax \). If each processor in a \( p \)-processor network executes the following node program and \( n = rp \), then upon completion Proc(1) houses \( z \). Assume the following local memory initializations: \( p, \mu \) (the node id), \( n, x_{\text{loc}} = x(1 + (\mu - 1)r; \mu r), A_{\text{loc}} = A(:, 1 + (\mu - 1)r; \mu r) \), and (in Proc(1) only) \( y_{\text{loc}} = y \).

if \( \mu = 1 \)
\[ y_{\text{loc}} = y_{\text{loc}} + A_{\text{loc}} x_{\text{loc}} \]
for \( t = 2:p \)
\[ \text{recv}(w_{\text{loc}}, t) \]
\[ y_{\text{loc}} = y_{\text{loc}} + w_{\text{loc}} \]
end
else
\[ w_{\text{loc}} = A_{\text{loc}} x_{\text{loc}} \]
\[ \text{send}(w_{\text{loc}}, 1) \]
end

At first glance this seems to be much less attractive than the row-oriented Algorithm 6.1.1. The additional responsibilities of Proc(1) mean that it has more arithmetic to perform by a factor of about

\[ \frac{2n^2/p + np}{2n^2/p} = 1 + \frac{p^2}{2n} \]

and more messages to process by a factor of about \( p \). This imbalance becomes less critical if \( n \gg p \) and the communication parameters \( \alpha_d \) and \( \beta_d \) factors are small enough. Another possible mitigating factor is that Algorithm 6.1.3 manipulates length \( n \) vectors whereas Algorithm 6.1.1 works
with length \( n/p \) vectors. If the nodes are capable of vector arithmetic, then the longer vectors may raise the level of performance.

This brief comparison of Algorithms 6.1.1 and 6.1.3 reminds us once again that different implementations of the same computation can have very different performance characteristics.

6.1.9 Shared Memory Systems

We now discuss the gaxpy problem for a shared memory multiprocessor. In this environment each processor has access to a common, global memory as depicted in Figure 6.1.2. Communication between processors is achieved by reading and writing to *global variables* that reside in the global memory. Each processor executes its own *local program* and has its own *local memory*. Data flows to and from the global memory during execution.

All the concerns that attend distributed memory computation are with us in modified form. The overall procedure should be *load balanced* and the computations should be arranged so that the individual processors have to wait as little as possible for something useful to compute. The traffic between the global and local memories must be managed carefully, because the extent of such data transfers is typically a significant overhead. (It corresponds to interprocessor communication in the distributed memory setting and to data motion up and down a memory hierarchy as discussed in §1.4.5.) The nature of the physical connection between the processors and the shared memory is very important and can effect algorithmic development. However, for simplicity we regard this aspect of the system as a black box as shown in Figure 6.1.2.
6.1.10  A Shared Memory Gaxpy

Consider the following partitioning of the \( n \times n \) gaxpy problem \( z = y + Ax \):

\[
\begin{bmatrix}
 z_1 \\
 \vdots \\
 z_p 
\end{bmatrix} = \begin{bmatrix}
 y_1 \\
 \vdots \\
 y_p 
\end{bmatrix} + \begin{bmatrix}
 A_1 \\
 \vdots \\
 A_p 
\end{bmatrix} z. 
\]

(6.1.4)

Here we assume that \( n = rp \) and that \( A_\mu \in \mathbb{R}^{r \times n} \), \( y_\mu \in \mathbb{R}^r \), and \( z_\mu \in \mathbb{R}^r \). We use the following algorithm to introduce the basic ideas and notations.

**Algorithm 6.1.4** Suppose \( A \in \mathbb{R}^{n \times n} \), \( x \in \mathbb{R}^n \), and \( y \in \mathbb{R}^n \) reside in a global memory accessible to \( p \) processors. If \( n = rp \) and each processor executes the following algorithm, then upon completion, \( y \) is overwritten by \( z = y + Ax \). Assume the following initializations in each local memory: \( p, \mu \) (the node id), and \( n \).

\[
\begin{align*}
\tau &= n/p \\
\text{row} &= 1 + (\mu - 1)r : \mu r \\
x_{\text{loc}} &= x \\
y_{\text{loc}} &= y(\text{row}) \\
\text{for } j = 1:n \\
& \quad a_{\text{loc}} = A(\text{row}, j) \\
& \quad y_{\text{loc}} = y_{\text{loc}} + a_{\text{loc}} x_{\text{loc}}(j) \\
\text{end} \\
y(\text{row}) &= y_{\text{loc}}
\end{align*}
\]

We assume that a copy of this program resides in each processor. Floating point variables that are local to an individual processor have a "loc" subscript.

Data is transferred to and from the global memory during the execution of Algorithm 6.1.4. There are two global memory reads before the loop \((x_{\text{loc}} = x \text{ and } y_{\text{loc}} = y(\text{row}))\), one read each time through the loop \((a_{\text{loc}} = A(\text{row}, j))\), and one write after the loop \((y(\text{row}) = y_{\text{loc}})\).

Only one processor writes to a given global memory location in \( y \), and so there is no need to synchronize the participating processors. Each has a completely independent part of the overall gaxpy operation and does not have to monitor the progress of the other processors. The computation is statically scheduled because the partitioning of work is determined before execution.

If \( A \) is lower triangular, then steps have to be taken to preserve the load balancing in Algorithm 6.1.4. As we discovered in §6.1.7, the wrap mapping is a vehicle for doing this. Assigning \( \text{Proc}(\mu) \) the computation of \( z(\mu:p:n) = y(\mu:p:n) + A(\mu:p:n,:)x \) effectively partitions the \( n^2 \) flops among the \( p \) processors.
6.1.11 Memory Traffic Overhead

It is important to recognize that overall performance depends strongly on the overheads associated with the reads and writes to the global memory. If such a data transfer involves \( m \) floating point numbers, then we model the transfer time by

\[
\tau(m) = \alpha_s + \beta_s m.
\]

(6.1.5)

The parameter \( \alpha_s \) represents a start-up overhead and \( \beta_s \) is the reciprocal transfer rate. We modelled interprocessor communication in the distributed environment exactly the same way. (See (6.1.3).)

Accounting for all the shared memory reads and writes in Algorithm 6.1.4 we see that each processor spends time

\[
T \approx (n + 3)\alpha_s + \frac{n^2}{p} \beta_s
\]

communicating with global memory.

We organized the computation so that one column of \( A(\text{row},:) \) is read at a time from shared memory. If the local memory is large enough, then the loop in Algorithm 6.1.4 can be replaced with

\[
A_{loc} = A(\text{row},:)
\]

\[
y_{loc} = y_{loc} + A_{loc} x_{loc}
\]

This changes the communication overhead to

\[
\tilde{T} \approx 3\alpha_s + \frac{n^2}{p} \beta_s,
\]

a significant improvement if the start-up parameter \( \alpha_s \) is large.

6.1.12 Barrier Synchronization

Let us consider the shared memory version of Algorithm 6.1.4 in which the gaxpy is column oriented. Assume \( n = rp \) and \( \text{col} = 1 + (\mu - 1)r : \mu r \). A reasonable idea is to use a global array \( W(1:n, 1:p) \) to house the products \( A(:, \text{col}) x(\text{col}) \) produced by each processor, and then have some chosen processor (say Proc(1)) add its columns:

\[
A_{loc} = A(:, \text{col});
\]

\[
x_{loc} = x(\text{col});
\]

\[
w_{loc} = A_{loc} x_{loc};
\]

\[
W(:, \mu) = w_{loc}
\]

if \( \mu = 1 \)

\[
y_{loc} = y
\]

for \( j = 1:p \)

\[
w_{loc} = W(:, j)
\]

\[
y_{loc} = y_{loc} + w_{loc}
\]

end

\[
y = y_{loc}
\]

end
However, this strategy is seriously flawed because there is no guarantee that $W(1:n, 1:p)$ is fully initialized when Proc(1) begins the summation process.

What we need is a synchronization construct that can delay the Proc(1) summation until all the processors have computed and stored their contributions in the $W$ array. For this purpose many shared memory systems support some version of the barrier construct which we introduce in the following algorithm:

Algorithm 6.1.5 Suppose $A \in \mathbb{R}^{n \times n}$, $x \in \mathbb{R}^n$, and $y \in \mathbb{R}^n$ reside in a global memory accessible to $p$ processors. If $n = rp$ and each processor executes the following algorithm, then upon completion $y$ is overwritten by $y + Ax$. Assume the following initializations in each local memory: $p$, $\mu$ (the node id), and $n$.

\[
\begin{align*}
  r &= n/p; \text{col} = 1 + (\mu - 1)r; \mu^r; A_{loc} = A(:, \text{col}); x_{loc} = x(\text{col}) \\
  w_{loc} &= A_{loc}x_{loc} \\
  W(:, \mu) &= w_{loc} \\
  \text{barrier} \\
  \text{if } \mu = 1 \\
  &\quad y_{loc} = y \\
  &\quad \text{for } j = 1:p \\
  &\quad \quad w_{loc} = W(:, j) \\
  &\quad \quad y_{loc} = y_{loc} + w_{loc} \\
  &\quad \text{end} \\
  &\quad y = y_{loc} \\
  \text{end}
\end{align*}
\]

To understand the barrier, it is convenient to regard a processor as either blocked or free. A processor is blocked and suspends execution when it executes the barrier. After the $p$th processor is blocked, all the processors return to the "free state" and resume execution. Think of the barrier as treacherous stream to be traversed by all $p$ processors. For safety, they all congregate on the bank before attempting to cross. When the last member of the party arrives, they ford the stream in unison and resume their individual treks.

In Algorithm 6.1.5, the processors are blocked after computing their portion of the matrix-vector product. We cannot predict the order in which these blockings occur, but once the last processor reaches the barrier, they are all released and Proc(1) can carry out the vector summation.

6.1.13 Dynamic Scheduling

Instead of having one processor in charge of the vector summation, it is tempting to have each processor add its contribution directly to the global variable $y$. For Proc($\mu$), this means executing the following:
6.1. Basic Concepts

\[ r = n/p; \alpha_0 = 1 + (\mu - 1)r; \mu \tau; A_{loc} = A(:,\alpha_0); x_{loc} = x(\alpha_0) \]
\[ w_{loc} = A_{loc}x_{loc} \]
\[ y_{loc} = y; y_{loc} = y_{loc} + w_{loc}; y = y_{loc} \]

However, a problem concerns the read-update-write triplet

\[ y_{loc} = y; y_{loc} = y_{loc} + w_{loc}; y = y_{loc} \]

Indeed, if more than one processor is executing this code fragment at the same time, then there may be a loss of information. Consider the following sequence:

Proc(1) reads y
Proc(2) reads y
Proc(1) writes y
Proc(2) writes y

The contribution of Proc(1) is lost because Proc(1) and Proc(2) obtain the same version of y. As a result, the effect of the Proc(1) write is erased by the Proc(2) write.

To prevent this kind of thing from happening most shared memory systems support the idea of a critical section. These are special, isolated portions of a node program that require a "key" to enter. Throughout the system, there is only one key and so the net effect is that only one processor can be executing in a critical section at any given time.

Algorithm 6.1.6 Suppose \( A \in \mathbb{R}^{n \times n} \), \( x \in \mathbb{R}^n \), and \( y \in \mathbb{R}^n \) reside in a global memory accessible to \( p \) processors. If \( n = pr \) and each processor executes the following algorithm, then upon completion, \( y \) is overwritten by \( y + Ax \). Assume the following initializations in each local memory: \( p, \mu \) (the node id), and \( n \).

\[ r = n/p; \alpha_0 = 1 + (\mu - 1)r; \mu \tau; A_{loc} = A(:,\alpha_0); x_{loc} = x(\alpha_0) \]
\[ w_{loc} = A_{loc}x_{loc} \]
begin critical section
\[ y_{loc} = y \]
\[ y_{loc} = y_{loc} + w_{loc} \]
\[ y = y_{loc} \]
end critical section

This use of the critical section concept controls the update of \( y \) in a way that ensures correctness. The algorithm is dynamically scheduled because the order in which the summations occur is determined as the computation unfolds. Dynamic scheduling is very important in problems with irregular structure.
Problems

P6.1.1 Modify Algorithm 6.1.1 so that it can handle arbitrary \( n \).

P6.1.2 Modify Algorithm 6.1.2 so that it efficiently handles the upper triangular case.

P6.1.3 (a) Modify Algorithms 6.1.3 and 6.1.4 so that they overwrite \( y \) with \( z = y + A^m x \)
for a given positive integer \( m \) that is available to each processor. (b) Modify Algorithms
6.1.3 and 6.1.4 so that \( y \) is overwritten by \( z = y + A^T A x \).

P6.1.4 Modify Algorithm 6.1.3 so that upon completion, the local array \( A_{i,n} \) in Proc(\( i \))
houses the \( i \)th block column of \( A + z y^T \).

P6.1.5 Modify Algorithm 6.1.4 so that (a) \( A \) is overwritten by the outer product update
\( A + z y^T \), (b) \( z \) is overwritten with \( A^2 x \), (c) \( y \) is overwritten by a unit 2-norm vector in
the direction of \( y + A^2 x \), and (d) it efficiently handles the case when \( A \) is lower triangular.

Notes and References for Sec. 6.1

General references on parallel computations that include several chapters on matrix
computations include

G. C. Fox, M. A. Johnson, G. A. Lyzenga, S. W. Otto, J. K. Salmon and D. W. Walker

Here are some general references that are more specific to parallel matrix computations:

6.1. Basic Concepts

Managing and modelling communication in a distributed memory environment is an important, difficult problem. See

For snapshots of basic linear algebra computation on a distributed memory system, see

The implementation of a parallel algorithm is usually very challenging. It is important to have compilers and related tools that are able to handle the details. See

6.2 Matrix Multiplication

In this section we develop two parallel algorithms for matrix-matrix multiplication. A shared memory implementation is used to illustrate the effect of blocking on granularity and load balancing. A torus implementation is designed to convey the spirit of two-dimensional data flow.

6.2.1 A Block Gaxpy Procedure

Suppose \( A, B, C \in \mathbb{R}^{n \times n} \) with \( B \) upper triangular and consider the computation of the matrix multiply update

\[
D = C + AB
\]  

(6.2.1)
on a shared memory computer with \( p \) processors. Assume that \( n = rkp \) and partition the update

\[
[D_1, \ldots, D_{k:p}] = [C_1, \ldots, C_{k:p}] + [A_1, \ldots, A_{k:p}] [B_1, \ldots, B_{k:p}] \tag{6.2.2}
\]

where each block column has width \( r = n/(kp) \). If

\[
B_j = \begin{bmatrix}
B_{ij} \\
\vdots \\
B_{jj} \\
0 \\
\vdots \\
0
\end{bmatrix}, \quad B_{ij} \in \mathbb{R}^{r \times r},
\]

then

\[
D_j = C_j + AB_j = C_j + \sum_{r=1}^{j} A_r B_{r:j}. \tag{6.2.3}
\]

The number of flops required to compute \( D_j \) is given by

\[
f_j = 2nr^2 j = \left( \frac{2n^3}{k^2 p^2} \right) j.
\]

This is an increasing function of \( j \) because \( B \) is upper triangular. As we discovered in the previous section, the wrap mapping is the way to solve load imbalance problems that result from triangular matrix structure. This suggests that we assign \( \text{Proc} (\mu) \) the task of computing \( D_j \) for \( j = \mu;p:kp \).

Algorithm 6.2.1 Suppose \( A, B, \) and \( C \) are \( n \)-by-\( n \) matrices that reside in a global memory accessible to \( p \) processors. Assume that \( B \) is upper triangular and \( n = rkp \). If each processor executes the following algorithm,
then upon completion $C$ is overwritten by $D = C + AB$. Assume the following initializations in each local memory: $n$, $r$, $k$, $p$ and $\mu$ (the node id).

$$
\text{for } j = \mu:p:kp \\
\quad \{ \text{Compute } D_j \} \\
\quad B_{loc} = B(1:j, 1 + (j - 1)r:jr) \\
\quad C_{loc} = C(1 + (j - 1)r:jr) \\
\quad \text{for } r = 1:j \\
\quad \quad \text{col} = 1 + (r - 1)r:rr \\
\quad \quad A_{loc} = A(:, \text{col}) \\
\quad \quad C_{loc} = C_{loc} + A_{loc}B_{loc}(\text{col}, :) \\
\quad \text{end} \\
\quad C(:, 1 + (j - 1)r:jr) = C_{loc} \\
\text{end}
$$

Let us examine the degree of load balancing as a function of the parameter $k$. For Proc($\mu$), the number of flops required is given by

$$
F(\mu) = \sum_{i=1}^{k} f_{\mu+(i-1)p} \approx \left(k\mu + \frac{k^2p}{2}\right) \frac{2n^3}{k^2p^2}.
$$

The quotient $F(p)/F(1)$ is a measure of load balancing from the flop point of view. Since

$$
\frac{F(p)}{F(1)} = \frac{kp + k^2p/2}{k + k^2p/2} = 1 + \frac{2(p - 1)}{2 + kp}
$$

we see that arithmetic balance improves with increasing $k$. A similar analysis shows that the communication overheads are well balanced as $k$ increases.

On the other hand, the total number of global memory reads and writes associated with Algorithm 6.2.1 increases with the square of $k$. If the start-up parameter $\alpha_\ast$ in (6.1.5) is large, then performance can degrade with increased $k$.

The optimum choice for $k$ given these two opposing forces is system dependant. If communication is fast, then smaller tasks can be supported without penalty and this makes it easier to achieve load balancing. A multiprocessor with this attribute supports fine-grained parallelism. However, if granularity is too fine in a system with high-performance nodes, then it may be impossible for the node programs to perform at level-2 or level-3 speeds simply because there just is not enough local linear algebra. Again, benchmarking is the only way to clarify these issues.

### 6.2.2 Torus

A torus is a two-dimensional processor array in which each row and column is a ring. See Figure 6.2.1. A Processor id in this context is an
ordered pair and each processor has four neighbors. In the displayed exam-
ple, Proc(1,3) has west neighbor Proc(1,2), east neighbor Proc(1,4), south
neighbor Proc(2,3), and north neighbor Proc(4,3).

To show what it is like to organize a toroidal matrix computation, we
develop an algorithm for the matrix multiplication $D = C + AB$ where
$A, B, C \in \mathbb{R}^{n \times n}$. Assume that the torus is $p_1$-by-$p_1$ and that $n = rp_1$.
Regard $A = (A_{ij})$, $B = (B_{ij})$, and $C = (C_{ij})$ as $p_1$-by-$p_1$ block matrices
with $r$-by-$r$ blocks. Assume that Proc$(i,j)$ contains $A_{ij}$, $B_{ij}$, and $C_{ij}$ and
that its mission is to overwrite $C_{ij}$ with

$$D_{ij} = C_{ij} + \sum_{k=1}^{p_1} A_{ik}B_{kj}. $$

We develop the general algorithm from the $p_1 = 3$ case, displaying the torus
in cellular form as follows:
Let us focus attention on Proc(1,1) and the calculation of

\[ D_{11} = C_{11} + A_{11}B_{11} + A_{12}B_{21} + A_{13}B_{31}. \]

Suppose the six inputs that define this block dot product are positioned within the torus as follows:

<table>
<thead>
<tr>
<th>A_{11}</th>
<th>B_{11}</th>
<th>A_{12}</th>
<th>\cdot</th>
<th>A_{13}</th>
<th>\cdot</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>B_{21}</td>
<td>\cdot</td>
<td>\cdot</td>
<td>\cdot</td>
<td></td>
</tr>
<tr>
<td></td>
<td>B_{31}</td>
<td>\cdot</td>
<td>\cdot</td>
<td>\cdot</td>
<td></td>
</tr>
</tbody>
</table>

(Pay no attention to the "dots." They are later replaced by various \( A_{ij} \) and \( B_{ij} \)).

Our plan is to "ratchet" the first block row of \( A \) and the first block column of \( B \) through Proc(1,1) in a coordinated fashion. The pairs \( A_{11} \) and \( B_{11} \), \( A_{12} \) and \( B_{21} \), and \( A_{13} \) and \( B_{31} \) meet, are multiplied, and added into a running sum array \( C_{loc} \):

\[
C_{loc} = C_{loc} + A_{12}B_{21}
\]

\[
C_{loc} = C_{loc} + A_{13}B_{31}
\]

\[
C_{loc} = C_{loc} + A_{11}B_{11}
\]
Thus, after three steps, the local array $C_{loc}$ in Proc(1,1) houses $D_{11}$.

We have organized the flow of data so that the $A_{1j}$ migrate westwards and the $B_{i1}$ migrate northwards through the torus. It is thus apparent that Proc(1,1) must execute a node program of the form:

$$\text{for } t = 1:3$$
$$\text{send}(A_{loc}, \text{west})$$
$$\text{send}(B_{loc}, \text{north})$$
$$\text{recv}(A_{loc}, \text{east})$$
$$\text{recv}(B_{loc}, \text{south})$$
$$C_{loc} = C_{loc} + A_{loc}B_{loc}$$
$$\text{end}$$

The send-receive-send-receive sequence

$$\text{for } t = 1:3$$
$$\text{send}(A_{loc}, \text{west})$$
$$\text{recv}(A_{loc}, \text{east})$$
$$\text{send}(B_{loc}, \text{north})$$
$$\text{recv}(B_{loc}, \text{south})$$
$$C_{loc} = C_{loc} + A_{loc}B_{loc}$$
$$\text{end}$$

also works. However, this induces unnecessary delays into the process because the $B$ submatrix is not sent until the new $A$ submatrix arrives.

We next consider the activity in Proc(1,2), Proc(1,3), Proc(2,1), and Proc(3,1). At this point in the development, these processors merely help circulate blocks $A_{11}$, $A_{12}$, and $A_{13}$ and $B_{11}$, $B_{21}$, and $B_{31}$, respectively. If $B_{32}$, $B_{12}$, and $B_{22}$ flowed through Proc(1,2) during these steps, then

$$D_{12} = C_{12} + A_{13}B_{32} + A_{11}B_{12} + A_{12}B_{22}$$

could be formed. Likewise, Proc(1,3) could compute

$$D_{13} = C_{13} + A_{11}B_{13} + A_{12}B_{23} + A_{13}B_{33}$$

if $B_{13}$, $B_{23}$, and $B_{33}$ are available during $t = 1:3$. To this end we initialize the torus as follows

<table>
<thead>
<tr>
<th></th>
<th>$A_{11}$</th>
<th>$B_{11}$</th>
<th>$A_{12}$</th>
<th>$B_{22}$</th>
<th>$A_{13}$</th>
<th>$B_{33}$</th>
</tr>
</thead>
<tbody>
<tr>
<td>$B_{21}$</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>$B_{31}$</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

With northward flow of the $B_{ij}$ we get
Thus, if \( B \) is mapped onto the torus in a “staggered start” fashion, we can arrange for the first row of processors to compute the first row of \( C \).

If we stagger the second and third rows of \( A \) in a similar fashion, then we can arrange for all nine processors to perform a multiply-add at each step. In particular, if we set

then with westward flow of the \( A_{ij} \) and northward flow of the \( B_{ij} \) we obtain
From this example we are ready to specify the general algorithm. We assume that at the start, Proc(i, j) houses \( A_{ij}, B_{ij}, \) and \( C_{ij} \). To obtain the necessary staggering of the \( A \) data, we note that in processor row \( i \) the \( A_{ij} \) should be circulated westward \( i - 1 \) positions. Likewise, in the \( j \)th column of processors, the \( B_{ij} \) should be circulated northward \( j - 1 \) positions. This gives the following algorithm:

**Algorithm 6.2.2** Suppose \( A \in \mathbf{R}^{n \times n}, B \in \mathbf{R}^{n \times n}, \) and \( C \in \mathbf{R}^{n \times n} \) are given and that \( D = C + AB \). If each processor in a \( p_1 \)-by-\( p_1 \) torus executes the following algorithm and \( n = p_1 r \), then upon completion Proc(\( \mu, \lambda \)) houses \( D_{\mu\lambda} \) in local variable \( C_{\text{loc}} \). Assume the following local memory initializations: \( p_1, (\mu, \lambda) \) (the node id), \( \text{north}, \text{east}, \text{south}, \) and \( \text{west} \), (the four neighbor id's), \( \text{row} = 1 + (\mu - 1) r : \mu r, \) \( \text{col} = 1 + (\lambda - 1) r : \lambda r \), \( A_{\text{loc}} = A(\text{row}, \text{col}), B_{\text{loc}} = B(\text{row}, \text{col}), \) and \( C_{\text{loc}} = C(\text{row}, \text{col}) \).

\[
\{\text{Stagger the } A_{\mu\lambda} \text{ and } B_{i\lambda}. \}\]

for \( k = 1: \mu - 1 \)
send(\( A_{\text{loc}}, \text{west} \)); recv(\( A_{\text{loc}}, \text{east} \))
end

for \( k = 1: \lambda - 1 \)
send(\( B_{\text{loc}}, \text{north} \)); recv(\( B_{\text{loc}}, \text{south} \))
end

for \( k = 1: p_1 \)
\[
C_{\text{loc}} = C_{\text{loc}} + A_{\text{loc}} B_{\text{loc}}
\]
send(\( A_{\text{loc}}, \text{west} \))
send(\( B_{\text{loc}}, \text{north} \))
recv(\( A_{\text{loc}}, \text{east} \))
recv(\( B_{\text{loc}}, \text{south} \))
end
{Unstagger the $A_{ij}$ and $B_{ik}$.}
for $k = 1; \mu - 1$
    send($A_{loc}, east$); recv($A_{loc}, west$)
end
for $k = 1; \lambda - 1$
    send($B_{loc}, south$); recv($B_{loc}, north$)
end

It is not hard to show that the computation-to-communication ratio for
this algorithm goes to zero as $n/p_1$ increases.

Problems

P6.2.1 Develop a ring implementation for Algorithm 6.2.1.

P6.2.2 An upper triangular matrix can be overwritten with its square without any
additional workspace. Write a dynamically scheduled, shared-memory procedure for
doing this.

6.3 Factorizations

In this section we present a pair of parallel Cholesky factorizations. To illustrate what a distributed memory factorization looks like, we implement the gaxpy Cholesky algorithm on a ring. A shared memory implementation of outer product Cholesky is also detailed.

6.3.1 A Ring Cholesky

Let us see how the Cholesky factorization procedure can be distributed on a ring of $p$ processors. The starting point is the equation

$$G(\mu, \mu)G(\mu:n, \mu) = A(\mu:n, \mu) - \sum_{j=1}^{\mu-1} G(\mu, j)G(\mu:n, j) \equiv v(\mu:n).$$

This equation is obtained by equating the $\mu$th column in the $n$-by-$n$ equation $A = GG^T$. Once the vector $v(\mu:n)$ is found then $G(\mu:n, \mu)$ is a simple scaling:

$$G(\mu:n, \mu) = v(\mu:n)/\sqrt{v(\mu)}.$$

For clarity, we first assume that $n = p$ and that Proc($\mu$) initially houses $A(\mu:n, \mu)$. Upon completion, each processor overwrites its $A$-column with the corresponding $G$-column. For Proc($\mu$) this process involves $\mu - 1$ saxpy updates of the form

$$A(\mu:n, \mu) \leftarrow A(\mu:n, \mu) - G(\mu, j)G(\mu:n, j)$$

followed by a square root and a scaling. The general structure of Proc($\mu$)'s node program is therefore as follows:

```
for j = 1:μ - 1
    Receive a G-column from the left neighbor.
    If necessary, send a copy of the received G-column to the right neighbor.
    Update A(μ:n, μ).
end
Generate G(μ:n, μ) and, if necessary, send it to the right neighbor.
```

Thus Proc(1) immediately computes $G(1:n, 1) = A(1:n, 1)/\sqrt{A(1, 1)}$ and sends it to Proc(2). As soon as Proc(2) receives this column it can generate $G(2:n, 2)$ and pass it to Proc(3) etc.. With this pipelining arrangement we can assert that once a processor computes its $G$-column, it can quit. It also follows that each processor receives $G$-columns in ascending order, i.e., $G(1:n, 1)$, $G(2:n, 2)$, etc. Based on these observations we have
6.3. Factorizations

\( j = 1 \)
\[ \text{while } j < \mu \]
\[ \text{recv}(g_{loc}(j:n), left) \]
\[ \text{if } \mu < n \]
\[ \text{send}(g_{loc}(j:n), right) \]
\[ \text{end} \]
\[ A_{loc}(\mu:n) = A_{loc}(\mu:n) - g_{loc}(\mu)g(\mu:n) \]
\[ j = j + 1 \]
\[ \text{end} \]
\[ A_{loc}(\mu:n) = A_{loc}(\mu:n) / \sqrt{A_{loc}(\mu)} \]
\[ \text{if } \mu < n \]
\[ \text{send}(A_{loc}(\mu:n), right) \]
\[ \text{end} \]

Note that the number of received \( G \)-columns is given by \( j - 1 \). If \( j = \mu \), then it is time for \( \text{Proc}(\mu) \) to generate and send \( G(\mu:n, \mu) \).

We now extend this strategy to the general \( n \) case. There are two obvious ways to distribute the computation. We could require each processor to compute a contiguous set of \( G \)-columns. For example, if \( n = 11, p = 3 \), and \( A = [a_1, \ldots, a_{11}] \), then we could distribute \( A \) as follows

\[
\begin{bmatrix}
  a_1 & a_2 & a_3 & a_4 & | & a_5 & a_6 & a_7 & a_8 & | & a_9 & a_{10} & a_{11} \\
\text{Proc(1)} & & & & | & \text{Proc(2)} & & & & | & \text{Proc(3)} & & & & \\
\end{bmatrix}
\]

Each processor could then proceed to find the corresponding \( G \) columns. The trouble with this approach is that (for example) \( \text{Proc}(1) \) is idle after the fourth column of \( G \) is found even though much work remains.

Greater load balancing results if we distribute the computational tasks using the wrap mapping, i.e.,

\[
\begin{bmatrix}
  a_1 & a_4 & a_7 & a_{10} & | & a_2 & a_5 & a_8 & a_{11} & | & a_3 & a_6 & a_9 \\
\text{Proc(1)} & & & & | & \text{Proc(2)} & & & & | & \text{Proc(3)} & & & & \\
\end{bmatrix}
\]

In this scheme \( \text{Proc}(\mu) \) carries out the construction of \( G(:, \mu:p:n) \). When a given processor finishes computing its \( G \)-columns, each of the other processors has at most one more \( G \) column to find. Thus if \( n/p \gg 1 \), then all of the processors are busy most of the time.

Let us examine the details of a wrap-distributed Cholesky procedure. Each processor maintains a pair of counters. The counter \( j \) is the index of the next \( G \)-column to be received by \( \text{Proc}(\mu) \). A processor also needs to know the index of the next \( G \)-column that it is to produce. Note that if \( \text{col} = \mu:p:n \), then \( \text{Proc}(\mu) \) is responsible for \( G(:, \text{col}) \) and that \( L = \text{length}(\text{col}) \) is the number of the \( G \)-columns that it must compute. We use \( q \) to indicate the status of \( G \)-column production. At any instant,
Algorithm 6.3.1 Suppose $A \in \mathbb{R}^{n\times n}$ is symmetric and positive definite and that $A = G G^T$ is its Cholesky factorization. If each node in a $p$-processor ring executes the following program, then upon completion Proc($\mu$) houses $G(k:n,k)$ for $k = \mu:p:n$ in a local array $A_{loc}(1:n,L)$ where $L = \text{length}(\text{col})$ and col = $\mu:p:n$. In particular, $G(\text{col}(q):n,\text{col}(q))$ is housed in $A_{loc}(\text{col}(q):n,q)$ for $q = 1:L$. Assume the following local memory initializations: $p$, $\mu$ (the node id), left and right (the neighbor id's), $n$, and $A_{loc} = A(\mu:p:n,:)$.

\[ j = 1; \; q = 1; \; \text{col} = \mu:p:n; \; L = \text{length}(\text{col}) \]

while $q \leq L$

if $j = \text{col}(q)$

\{ Form $G(j:n,j)$ \}

\[ A_{loc}(j:n,q) = A_{loc}(j:n,q)/\sqrt{A_{loc}(j,q)} \]

if $j < n$

send($A_{loc}(j:n,q)$, right)

end

\[ j = j + 1 \]

\{ Update local columns. \}

for $k = q + 1:L$

\[ r = \text{col}(k) \]

\[ A_{loc}(r:n,k) = A_{loc}(r:n,k) - A_{loc}(r,q)A_{loc}(r:n,q) \]

end

\[ q = q + 1 \]

else

recv($g_{loc}(j:n)$, left)

Compute $\alpha$, the id of the processor that generated the received $G$-column.

Compute $\beta$, the index of Proc(right)'s final column.

if $\text{right} \neq \alpha \land j < \beta$

send($g_{loc}(j:n)$, right)

end

\{ Update local columns. \}

for $k = q:L$

\[ r = \text{col}(k) \]

\[ A_{loc}(r:n,k) = A_{loc}(r:n,k) - g_{loc}(r)g_{loc}(r:n) \]

end

\[ j = j + 1 \]

end

end

To illustrate the logic of the pointer system we consider a sample 3-processor situation with $n = 10$. Assume that the three local values of $q$ are 3, 2, and
2 and that the corresponding values of \( \alpha(q) \) are 7, 5, and 6:

\[
\begin{bmatrix}
\overbrace{a_1 \ a_4 \ a_7}^\text{Proc(1)} & \overbrace{a_2 \ a_5 \ a_8}^\text{Proc(2)} & \overbrace{a_3 \ a_6}^\text{Proc(3)}
\end{bmatrix}
\]

Proc(2) now generates the fifth \( G \)-column and increment its \( q \) to 3.

The decision to pass a received \( G \)-column to the right neighbor needs to be explained. Two conditions must be fulfilled:

- The right neighbor must not be the processor which generated the \( G \) column. This way the circulation of the received \( G \)-column is properly terminated.

- The right neighbor must still have more \( G \)-columns to generate. Otherwise, a \( G \)-column will be sent to an inactive processor.

This kind of reasoning is quite typical in distributed memory matrix computations.

Let us examine the behavior of Algorithm 6.3.1 under the assumption that \( n \gg p \). It is not hard to show that Proc(\( \mu \)) performs

\[
F(\mu) = \sum_{k=1}^{L} 2(n - (\mu + (k - 1)p))(\mu + (k - 1)p) \approx \frac{n^3}{3p}
\]

flops. Each processor receives and sends just about every \( G \)-column. Using our communication overhead model (6.1.3), we see that the time each processor spends communicating is given by

\[
m_\mu = \sum_{j=1}^{n} 2(\alpha_d + \beta_d(n - j)) \approx 2\alpha_d n + \beta_d n^2.
\]

If we assume that computation proceeds at \( R \) flops per second, then the computation/communication ratio for Algorithm 6.3.1 is approximately given by \( (n/p)(1/3R\beta_d) \). Thus, communication overheads diminish in importance as \( n/p \) grows.

### 6.3.2 A Shared Memory Cholesky

Next we consider a shared memory implementation of the outer product Cholesky algorithm:

```plaintext
for k = 1:n
    A(k:n, k) = A(k:n, k) / sqrt(A(k, k))
for j = k + 1:n
    A(j:n, j) = A(j:n, j) - A(j:n, k)A(j, k)
end
end
```
The $j$-loop oversees an outer product update. The $n - k$ saxpy operations that make up its body are independent and easily parallelized. The scaling $A(k:n, k)$ can be carried out by a single processor with no threat to load balancing.

\textbf{Algorithm 6.3.2} Suppose $A \in \mathbb{R}^{n \times n}$ is a symmetric positive definite matrix stored in a shared memory accessible to $p$ processors. If each processor executes the following algorithm, then upon completion the lower triangular part of $A$ is overwritten with its Cholesky factor. Assume the following initializations in each local memory: $n$, $p$ and $\mu$ (the node id).

\begin{verbatim}
for $k = 1:n$
  if $\mu = 1$
    $v_{loc}(k:n) = A(k:n)$
    $v_{loc}(k:n) = v_{loc}(k:n)/\sqrt{v_{loc}(k)}$
    $A(k:n, k) = v_{loc}(k:n)$
  barrier
  $v_{loc}(k + 1:n) = A(k + 1:n, k)$
  for $j = (k + \mu):p:n$
    $w_{loc}(j:n) = A(j:n, j)$
    $w_{loc}(j:n) = w_{loc}(j:n) - v_{loc}(j)v_{loc}(j:n)$
    $A(j:n, j) = w_{loc}(j:n)$
  barrier
\end{verbatim}

The scaling before the $j$-loop represents very little work compared to the outer product update and so it is reasonable to assign that portion of the computation to a single processor. Notice that two barrier statements are required. The first ensures that a processor does not begin working on the $k$th outer product update until the $k$th column of $G$ is made available by Proc(1). The second barrier prevents the processing of the $k+1$st step to begin until the $k$th step is completely finished.

\textbf{Problems}

\textbf{P6.3.1} It is possible to formulate a block version of Algorithm 6.3.1. Suppose $n = rN$. For $k = 1:N$ we (a) have Proc(1) generate $G(1, 1 + (k - 1)r:kr)$ and (b) have all processors participate in the rank $r$ update of the trailing submatrix $A(kr + 1:n, kr + 1:n)$. See §4.2.6. The coarser granularity may improve performance if the individual processors like level-3 operations.

\textbf{P6.3.2} Develop a shared memory QR factorization patterned after Algorithm 6.3.2. Proc(1) should generate the Householder vectors and all processors should share in the ensuing Householder update.

Chapter 7

The Unsymmetric Eigenvalue Problem

§7.1 Properties and Decompositions
§7.2 Perturbation Theory
§7.3 Power Iterations
§7.4 The Hessenberg and Real Schur Forms
§7.5 The Practical QR Algorithm
§7.6 Invariant Subspace Computations
§7.7 The QZ Method for $Ax = \lambda Bx$

Having discussed linear equations and least squares, we now direct our attention to the third major problem area in matrix computations, the algebraic eigenvalue problem. The unsymmetric problem is considered in this chapter and the more agreeable symmetric case in the next.

Our first task is to present the decompositions of Schur and Jordan along with the basic properties of eigenvalues and invariant subspaces. The contrasting behavior of these two decompositions sets the stage for §7.2 in which we investigate how the eigenvalues and invariant subspaces of a matrix are affected by perturbation. Condition numbers are developed that permit estimation of the errors that can be expected to arise because of roundoff.

The key algorithm of the chapter is the justly famous QR algorithm. This procedure is the most complex algorithm presented in this book and its development is spread over three sections. We derive the basic QR iteration in §7.3 as a natural generalization of the simple power method. The next
two sections are devoted to making this basic iteration computationally feasible. This involves the introduction of the Hessenberg decomposition in §7.4 and the notion of origin shifts in §7.5.

The QR algorithm computes the real Schur form of a matrix, a canonical form that displays eigenvalues but not eigenvectors. Consequently, additional computations usually must be performed if information regarding invariant subspaces is desired. In §7.6, which could be subtitled, "What to Do after the Real Schur Form is Calculated," we discuss various invariant subspace calculations that can follow the QR algorithm.

Finally, in the last section we consider the generalized eigenvalue problem $Ax = \lambda Bx$ and a variant of the QR algorithm that has been devised to solve it. This algorithm, called the QZ algorithm, underscores the importance of orthogonal matrices in the eigenproblem, a central theme of the chapter.

It is appropriate at this time to make a remark about complex versus real arithmetic. In this book, we focus on the development of real arithmetic algorithms for real matrix problems. This chapter is no exception even though a real unsymmetric matrix can have complex eigenvalues. However, in the derivation of the practical, real arithmetic QR algorithm and in the mathematical analysis of the eigenproblem itself, it is convenient to work in the complex field. Thus, the reader will find that we have switched to complex notation in §7.1, §7.2, and §7.3. In these sections, we use complex versions of the QR factorization, the singular value decomposition, and the CS decomposition.

Before You Begin

Chapters 1-3 and §§5.1-5.2 are assumed. Within this chapter there are the following dependencies:

\[ §7.1 \rightarrow §7.2 \rightarrow §7.3 \rightarrow §7.4 \rightarrow §7.5 \rightarrow §7.6 \rightarrow §7.7 \]

7.1 Properties and Decompositions

In this section we survey the mathematical background necessary to develop and analyze the eigenvalue algorithms that follow.

7.1.1 Eigenvalues and Invariant Subspaces

The eigenvalues of a matrix \( A \in \mathbb{C}^{n \times n} \) are the \( n \) roots of its characteristic polynomial \( p(z) = \det(zI - A) \). The set of these roots is called the spectrum and is denoted by \( \lambda(A) \). If \( \lambda(A) = \{\lambda_1, \ldots, \lambda_n\} \), then it follows that

\[
\det(A) = \lambda_1 \lambda_2 \cdots \lambda_n.
\]

Moreover, if we define the trace of \( A \) by

\[
\text{tr}(A) = \sum_{i=1}^{n} a_{ii},
\]

then \( \text{tr}(A) = \lambda_1 + \cdots + \lambda_n \). This follows by looking at the coefficient of \( z^{n-1} \) in the characteristic polynomial.

If \( \lambda \in \lambda(A) \), then the nonzero vectors \( x \in \mathbb{C}^n \) that satisfy

\[
Ax = \lambda x
\]
are referred to as eigenvectors. More precisely, \( x \) is a right eigenvector for \( \lambda \) if \( Ax = \lambda x \) and a left eigenvector if \( x^H A = \lambda x^H \). Unless otherwise stated, "eigenvector" means "right eigenvector."

An eigenvector defines a one-dimensional subspace that is invariant with respect to premultiplication by \( A \). More generally, a subspace \( S \subseteq \mathbb{C}^n \) with the property that

\[
x \in S \implies Ax \in S
\]
is said to be invariant (for \( A \)). Note that if

\[
AX = XB, \quad B \in \mathbb{C}^{k \times k}, \quad X \in \mathbb{C}^{n \times k},
\]

then \( \text{ran}(X) \) is invariant and \( By = \lambda y \implies A(Xy) = \lambda (Xy) \). Thus, if \( X \) has full column rank, then \( AX = XB \) implies that \( \lambda(B) \subseteq \lambda(A) \). If \( X \) is square and nonsingular, then \( \lambda(A) = \lambda(B) \) and we say that \( A \) and \( B = X^{-1}AX \) are similar. In this context, \( X \) is called a similarity transformation.

### 7.1.2 Decoupling

Many eigenvalue computations involve breaking the given problem down into a collection of smaller eigenproblems. The following result is the basis for these reductions.

**Lemma 7.1.1** If \( T \in \mathbb{C}^{n \times n} \) is partitioned as follows,

\[
T = \begin{bmatrix} T_{11} & T_{12} \\ 0 & T_{22} \end{bmatrix} \begin{bmatrix} p \\ q \end{bmatrix}
\]

then \( \lambda(T) = \lambda(T_{11}) \cup \lambda(T_{22}) \).

**Proof.** Suppose

\[
Tx = \begin{bmatrix} T_{11} & T_{12} \\ 0 & T_{22} \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \lambda \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}
\]

where \( x_1 \in \mathbb{C}^p \) and \( x_2 \in \mathbb{C}^q \). If \( x_2 \neq 0 \), then \( T_{22}x_2 = \lambda x_2 \) and so \( \lambda \in \lambda(T_{22}) \). If \( x_2 = 0 \), then \( T_{11}x_1 = \lambda x_1 \) and so \( \lambda \in \lambda(T_{11}) \). It follows that \( \lambda(T) \subseteq \lambda(T_{11}) \cup \lambda(T_{22}) \). But since both \( \lambda(T) \) and \( \lambda(T_{11}) \cup \lambda(T_{22}) \) have the same cardinality, the two sets are equal. \( \square \)

### 7.1.3 The Basic Unitary Decompositions

By using similarity transformations, it is possible to reduce a given matrix to any one of several canonical forms. The canonical forms differ in how they display the eigenvalues and in the kind of invariant subspace information that they provide. Because of their numerical stability we begin by discussing the reductions that can be achieved with unitary similarity.
Lemma 7.1.2 If $A \in \mathbb{C}^{n \times n}$, $B \in \mathbb{C}^{p \times p}$, and $X \in \mathbb{C}^{n \times p}$ satisfy
\[AX = XB, \quad \text{rank}(X) = p,
\] (7.1.1)
then there exists a unitary $Q \in \mathbb{C}^{n \times n}$ such that
\[Q^H A Q = T = \begin{bmatrix} T_{11} & T_{12} \\ T_{21} & T_{22} \end{bmatrix} \begin{bmatrix} p \\ n-p \end{bmatrix} \] (7.1.2)
where $\lambda(T_{11}) = \lambda(A) \cap \lambda(B)$.

**Proof.** Let
\[X = Q \begin{bmatrix} R_1 \\ 0 \end{bmatrix} \quad Q \in \mathbb{C}^{n \times n}, \ R_1 \in \mathbb{C}^{p \times p}
\]
be a QR factorization of $X$. By substituting this into (7.1.1) and rearranging we have
\[\begin{bmatrix} T_{11} & T_{12} \\ T_{21} & T_{22} \end{bmatrix} \begin{bmatrix} R_1 \\ 0 \end{bmatrix} = \begin{bmatrix} R_1 \\ 0 \end{bmatrix} B
\]
where
\[Q^H A Q = \begin{bmatrix} T_{11} & T_{12} \\ T_{21} & T_{22} \end{bmatrix} \begin{bmatrix} p \\ n-p \end{bmatrix}.
\]
By using the nonsingularity of $R_1$ and the equations $T_{21} R_1 = 0$ and $T_{11} R_1 = R_1 B$, we can conclude that $T_{21} = 0$ and $\lambda(T_{11}) = \lambda(B)$. The conclusion now follows because from Lemma 7.1.1 $\lambda(A) = \lambda(T) = \lambda(T_{11}) \cup \lambda(T_{22})$. □

**Example 7.1.1** If
\[A = \begin{bmatrix} 67.00 & 177.60 & -63.20 \\ -20.40 & 95.88 & -87.16 \\ 22.80 & 67.84 & 12.12 \end{bmatrix},
\]
$X = [20, -9, -12]^T$ and $B = [25]$, then $AX = XB$. Moreover, if the orthogonal matrix $Q$ is defined by
\[Q = \begin{bmatrix} -0.80 & 0.360 & 0.480 \\ 0.360 & 0.928 & -0.096 \\ 0.480 & -0.096 & 0.872 \end{bmatrix},
\]
then $Q^T X = [-25, 0, 0]^T$ and
\[Q^T A Q = T = \begin{bmatrix} 25 & -90 & 5 \\ 0 & 147 & -104 \\ 0 & 146 & 3 \end{bmatrix}.
\]
A calculation shows that $\lambda(A) = \{25, 75 + 100i, 75 - 100i\}$.

Lemma 7.1.2 says that a matrix can be reduced to block triangular form using unitary similarity transformations if we know one of its invariant subspaces. By induction we can readily establish the decomposition of Schur (1909).
Theorem 7.1.3 (Schur Decomposition) If $A \in \mathbb{C}^{n \times n}$, then there exists a unitary $Q \in \mathbb{C}^{n \times n}$ such that

$$Q^H A Q = T = D + N$$

(7.1.3)

where $D = \text{diag}(\lambda_1, \ldots, \lambda_n)$ and $N \in \mathbb{C}^{n \times n}$ is strictly upper triangular. Furthermore, $Q$ can be chosen so that the eigenvalues $\lambda_i$ appear in any order along the diagonal.

Proof. The theorem obviously holds when $n = 1$. Suppose it holds for all matrices of order $n - 1$ or less. If $Ax = \lambda x$, where $x \neq 0$, then by Lemma 7.1.2 (with $B = (\lambda)$) there exists a unitary $U$ such that:

$$U^H A U = \begin{bmatrix} \lambda & w^H \\ 0 & C \end{bmatrix} \begin{bmatrix} 1 \\ n-1 \end{bmatrix}.$$

By induction there is a unitary $\bar{U}$ such that $\bar{U}^H C \bar{U}$ is upper triangular. Thus, if $Q = U \text{diag}(1, \bar{U})$, then $Q^H A Q$ is upper triangular. \qed

Example 7.1.2 If

$$A = \begin{bmatrix} 3 & 8 \\ -2 & 3 \end{bmatrix} \quad \text{and} \quad Q = \begin{bmatrix} .8944i & .4472 \\ -.4472 & -.8944i \end{bmatrix},$$

then $Q$ is unitary and

$$Q^H A Q = \begin{bmatrix} 3 + 4i & -6 \\ 0 & 3 - 4i \end{bmatrix}.$$

If $Q = [q_1, \ldots, q_n]$ is a column partitioning of the unitary matrix $Q$ in (7.1.3), then the $q_i$ are referred to as Schur vectors. By equating columns in the equations $AQ = QT$ we see that the Schur vectors satisfy

$$A q_k = \lambda_k q_k + \sum_{i=1}^{k-1} n_{ik} q_i \quad k = 1:n.$$ 

(7.1.4)

From this we conclude that the subspaces

$$S_k = \text{span}\{q_1, \ldots, q_k\} \quad k = 1:n$$

are invariant. Moreover, it is not hard to show that if $Q_k = [q_1, \ldots, q_k]$, then $\lambda(Q_k^H A Q_k) = \{\lambda_1, \ldots, \lambda_k\}$. Since the eigenvalues in (7.1.3) can be arbitrarily ordered, it follows that there is at least one $k$-dimensional invariant subspace associated with each subset of $k$ eigenvalues.

Another conclusion to be drawn from (7.1.4) is that the Schur vector $q_k$ is an eigenvector if and only if the $k$-th column of $N$ is zero. This turns out to be the case for $k = 1:n$ whenever $A^H A = AA^H$. Matrices that satisfy this property are called normal.
Corollary 7.1.4 \( A \in \mathbb{C}^{n \times n} \) is normal if and only if there exists a unitary \( Q \in \mathbb{C}^{n \times n} \) such that \( Q^H A Q = \text{diag}(\lambda_1, \ldots, \lambda_n) \).

**Proof.** It is easy to show that if \( A \) is unitarily similar to a diagonal matrix, then \( A \) is normal. On the other hand, if \( A \) is normal and \( Q^H A Q = T \) is its Schur decomposition, then \( T \) is also normal. The corollary follows by showing that a normal, upper triangular matrix is diagonal. \( \square \)

Note that if \( Q^H A Q = T = \text{diag}(\lambda_i) + N \) is a Schur decomposition of a general \( n \)-by-\( n \) matrix \( A \), then \( \| N \|_F \) is independent of the choice of \( Q \):

\[
\| N \|_F^2 = \| A \|_F^2 - \sum_{i=1}^{n} |\lambda_i|^2 \equiv \Delta^2(A).
\]

This quantity is referred to as \( A \)'s departure from normality. Thus, to make \( T \) "more diagonal," it is necessary to rely on nonunitary similarity transformations.

7.1.4 Nonunitary Reductions

To see what is involved in nonunitary similarity reduction, we examine the block diagonalization of a 2-by-2 block triangular matrix.

**Lemma 7.1.5** Let \( T \in \mathbb{C}^{n \times n} \) be partitioned as follows:

\[
T = \begin{bmatrix} T_{11} & T_{12} \\ 0 & T_{22} \end{bmatrix} \begin{bmatrix} p \\ q \end{bmatrix}.
\]

Define the linear transformation \( \phi: \mathbb{C}^{p \times q} \to \mathbb{C}^{p \times q} \) by

\[
\phi(X) = T_{11}X - X T_{22}
\]

where \( X \in \mathbb{C}^{p \times q} \). Then \( \phi \) is nonsingular if and only if \( \lambda(T_{11}) \cap \lambda(T_{22}) = \emptyset \). If \( \phi \) is nonsingular and \( Y \) is defined by

\[
Y = \begin{bmatrix} I_p & Z \\ 0 & I_q \end{bmatrix} \quad \phi(Z) = -T_{12}
\]

then \( Y^{-1}TY = \text{diag}(T_{11}, T_{22}) \).

**Proof.** Suppose \( \phi(X) = 0 \) for \( X \neq 0 \) and that

\[
U^H XV = \begin{bmatrix} \Sigma_r & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} r \\ q - r \end{bmatrix} \]

where \( U \) and \( V \) are unitary matrices.
is the SVD of $X$ with $\Sigma_r = \text{diag}(\sigma_i)$, $r = \text{rank}(X)$. Substituting this into the equation $T_{11}X = XT_{22}$ gives

$$
\begin{bmatrix}
A_{11} & A_{12} \\
A_{21} & A_{22}
\end{bmatrix}
\begin{bmatrix}
\Sigma_r & 0 \\
0 & 0
\end{bmatrix}
= 
\begin{bmatrix}
\Sigma_r & 0 \\
0 & 0
\end{bmatrix}
\begin{bmatrix}
B_{11} & B_{12} \\
B_{21} & B_{22}
\end{bmatrix}
$$

where $U^HT_{11}U = (A_{ij})$ and $V^HT_{22}V = (B_{ij})$. By comparing blocks we see that $A_{21} = 0$, $B_{12} = 0$, and $\lambda(A_{11}) = \lambda(B_{11})$. Consequently,

$$\emptyset \neq \lambda(A_{11}) = \lambda(B_{11}) \subseteq \lambda(T_{11}) \cap \lambda(T_{22}).$$

On the other hand, if $\lambda \in \lambda(T_{11}) \cap \lambda(T_{22})$ then we have nonzero vectors $x$ and $y$ so $T_{11}x = \lambda x$ and $y^HT_{22} = \lambda y^H$. A calculation shows that $\phi(xy^H) = 0$. Finally, if $\phi$ is nonsingular then the matrix $Z$ above exists and

$$Y^{-1}TY = \begin{bmatrix}
I & -Z \\
0 & I
\end{bmatrix}
\begin{bmatrix}
T_{11} & T_{12} \\
0 & T_{22}
\end{bmatrix}
\begin{bmatrix}
I & Z \\
0 & I
\end{bmatrix}
= 
\begin{bmatrix}
T_{11} & T_{12} - ZT_{22} + T_{12} \\
0 & T_{22}
\end{bmatrix} 
= \begin{bmatrix}
T_{11} & 0 \\
0 & T_{22}
\end{bmatrix}. \quad \Box
$$

Example 7.1.3 If

$$T = \begin{bmatrix}
1 & 2 & 3 \\
0 & 3 & 8 \\
0 & -2 & 3
\end{bmatrix} \quad \text{and} \quad Y = \begin{bmatrix}
1.0 & 0.5 & -0.5 \\
0.0 & 1.0 & 0.0 \\
0.0 & 0.0 & 1.0
\end{bmatrix},$$

then

$$Y^{-1}TY = \begin{bmatrix}
1 & 0 & 0 \\
0 & 3 & 8 \\
0 & -2 & 3
\end{bmatrix}.$$
Proof. A proof can be obtained by using Lemma 7.1.5 and induction. \( \square \)

If each diagonal block \( T_{ii} \) is associated with a distinct eigenvalue, then we obtain

**Corollary 7.1.7** If \( A \in \mathbb{C}^{n \times n} \) then there exists a nonsingular \( X \) such that

\[
X^{-1}AX = \text{diag}(\lambda_1 I + N_1, \ldots, \lambda_q I + N_q) \quad N_i \in \mathbb{C}^{n_i \times n_i}
\]

(7.1.7)

where \( \lambda_1, \ldots, \lambda_q \) are distinct, the integers \( n_1, \ldots, n_q \) satisfy \( n_1 + \cdots + n_q = n \), and each \( N_i \) is strictly upper triangular.

A number of important terms are connected with decomposition (7.1.7). The integer \( n_i \) is referred to as the algebraic multiplicity of \( \lambda_i \). If \( n_i = 1 \), then \( \lambda_i \) is said to be simple. The geometric multiplicity of \( \lambda_i \) equals the dimensions of \( \text{null}(N_i) \), i.e., the number of linearly independent eigenvectors associated with \( \lambda_i \). If the algebraic multiplicity of \( \lambda_i \) exceeds its geometric multiplicity, then \( \lambda_i \) is said to be a defective eigenvalue. A matrix with a defective eigenvalue is referred to as a defective matrix. Nondefective matrices are also said to be diagonalizable in light of the following result:

**Corollary 7.1.8 (Diagonal Form)** \( A \in \mathbb{C}^{n \times n} \) is nondefective if and only if there exists a nonsingular \( X \in \mathbb{C}^{n \times n} \) such that

\[
X^{-1}AX = \text{diag}(\lambda_1, \ldots, \lambda_n).
\]

(7.1.8)

**Proof.** \( A \) is nondefective if and only if there exist independent vectors \( x_1, \ldots, x_n \in \mathbb{C}^{n} \) and scalars \( \lambda_1, \ldots, \lambda_n \) such that \( Ax_i = \lambda_i x_i \) for \( i = 1:n \). This is equivalent to the existence of a nonsingular \( X = [x_1, \ldots, x_n] \in \mathbb{C}^{n \times n} \) such that \( AX = XD \) where \( D = \text{diag}(\lambda_1, \ldots, \lambda_n) \). \( \square \)

Note that if \( y_i^H \) is the \( i \)th row of \( X^{-1} \), then \( y_i^H A = \lambda_i y_i^H \). Thus, the columns of \( X^{-T} \) are left eigenvectors and the columns of \( X \) are right eigenvectors.

**Example 7.1.4** If

\[
A = \begin{bmatrix} 5 & -1 \\ -2 & 6 \end{bmatrix}
\]

and

\[
X = \begin{bmatrix} 1 & 1 \\ 1 & -2 \end{bmatrix}
\]

then \( X^{-1}AX = \text{diag}(4, 7) \).

If we partition the matrix \( X \) in (7.1.7),

\[
X = \begin{bmatrix} X_1 & \ldots & X_q \end{bmatrix}
\]

\[
n_1 \quad n_q
\]

then \( \mathbb{C}^{n} = \text{ran}(X_1) \oplus \ldots \oplus \text{ran}(X_q) \), a direct sum of invariant subspaces. If the bases for these subspaces are chosen in a special way, then it is possible to introduce even more zeroes into the upper triangular portion of \( X^{-1}AX \).
Theorem 7.1.9 (Jordan Decomposition) If \( A \in \mathbb{C}^{n \times n} \), then there exists a nonsingular \( X \in \mathbb{C}^{n \times n} \) such that \( X^{-1}AX = \text{diag}(J_1, \ldots, J_t) \) where

\[
J_i = \begin{bmatrix}
\lambda_i & 1 & \cdots & 0 \\
0 & \lambda_i & \cdots & 1 \\
& \ddots & \ddots & \ddots \\
& & \ddots & 1 \\
0 & \cdots & 0 & \lambda_i
\end{bmatrix}
\]

is \( m_i \)-by-\( m_i \) and \( m_1 + \cdots + m_t = n \).

Proof. See Halmos (1958, pp. 112 ff.) □

The \( J_i \) are referred to as Jordan blocks. The number and dimensions of the Jordan blocks associated with each distinct eigenvalue is unique, although their ordering along the diagonal is not.

7.1.5 Some Comments on Nonunitary Similarity

The Jordan block structure of a defective matrix is difficult to determine numerically. The set of \( n \)-by-\( n \) diagonalizable matrices is dense in \( \mathbb{C}^{n \times n} \), and thus, small changes in a defective matrix can radically alter its Jordan form. We have more to say about this in §7.6.5.

A related difficulty that arises in the eigenvalue problem is that a nearly defective matrix can have a poorly conditioned matrix of eigenvectors. For example, any matrix \( X \) that diagonalizes

\[
A = \begin{bmatrix}
1 + \epsilon & 1 \\
0 & 1 - \epsilon
\end{bmatrix}, \quad 0 < \epsilon \ll 1
\]

has a 2-norm condition of order \( 1/\epsilon \).

These observations serve to highlight the difficulties associated with ill-conditioned similarity transformations. Since

\[
fl(X^{-1}AX) = X^{-1}AX + E,
\]

where

\[
\| E \|_2 \approx \| \kappa_2(X) \| A \|_2
\]

is it clear that large errors can be introduced into an eigenvalue calculation when we depart from unitary similarity.
7.1.6 Singular Values and Eigenvalues

Since the singular values of $A$ and its Schur decomposition $Q^H A Q = \text{diag}(\lambda_i) + N$ are the same, it follows that

$$\sigma_{\text{min}}(A) \leq \min_i |\lambda_i| \leq \max_i |\lambda_i| \leq \sigma_{\text{max}}(A).$$

From what we know about the condition of triangular matrices, it may be the case that

$$\max_{i,j} \frac{|\lambda_i|}{|\lambda_j|} \ll \kappa_2(A).$$

This is a reminder that for nonnormal matrices, eigenvalues do not have the "predictive power" of singular values when it comes to $Ax = b$ sensitivity matters. Eigenvalues of nonnormal matrices have other shortcomings. See §11.3.4.

Problems

P7.1.1 Show that if $T \in \mathbb{C}^{n \times n}$ is upper triangular and normal, then $T$ is diagonal.

P7.1.2 Verify that if $X$ diagonalizes the 2-by-2 matrix in (7.1.9) and $\epsilon \leq 1/2$ then $\kappa_1(X) \geq 1/\epsilon$.

P7.1.3 Suppose $A \in \mathbb{C}^{n \times n}$ has distinct eigenvalues. Show that if $Q^H A Q = T$ is its Schur decomposition and $AB = BA$, then $Q^H B Q$ is upper triangular.

P7.1.4 Show that if $A$ and $B^H$ are in $\mathbb{C}^{m \times n}$ with $m \geq n$, then:

$$\lambda(AB) = \lambda(BA) \cup \{0, \ldots, 0\}_{m-n}.$$

P7.1.5 Given $A \in \mathbb{C}^{n \times n}$, use the Schur decomposition to show that for every $\epsilon > 0$, there exists a diagonalizable matrix $B$ such that $\|A - B\|_2 \leq \epsilon$. This shows that the set of diagonalizable matrices is dense in $\mathbb{C}^{n \times n}$ and that the Jordan canonical form is not a continuous matrix decomposition.

P7.1.6 Suppose $A_k \rightarrow A$ and that $Q_k^H A_k Q_k = T_k$ is a Schur decomposition of $A_k$. Show that $\{Q_k\}$ has a converging subsequence $\{Q_{k_i}\}$ with the property that

$$\lim_{i \to \infty} Q_{k_i} = Q$$

where $Q^H A Q = T$ is upper triangular. This shows that the eigenvalues of a matrix are continuous functions of its entries.

P7.1.7 Justify (7.1.10) and (7.1.11).

P7.1.8 Show how to compute the eigenvalues of

$$M = \begin{bmatrix} A & C \\ B & D \end{bmatrix}^{k-j}$$

where $A$, $B$, $C$, and $D$ are given real diagonal matrices.

P7.1.9 Use the JCF to show that if all the eigenvalues of a matrix $A$ are strictly less
than unity, then \( \lim_{k \to \infty} A_k = 0 \).

**P7.1.10** The initial value problem
\[
\begin{align*}
\dot{x}(t) &= y(t) \quad x(0) = 1 \\
\dot{y}(t) &= -x(t) \quad y(0) = 0
\end{align*}
\]
has solution \( x(t) = \cos(t) \) and \( y(t) = \sin(t) \). Let \( h > 0 \). Here are three reasonable iterations that can be used to compute approximations \( x_k \approx x(kh) \) and \( y_k \approx y(kh) \) assuming that \( x_0 = 1 \) and \( y_0 = 0 \):

**Method 1:**
\[
\begin{align*}
x_{k+1} &= 1 + hy_k \\
y_{k+1} &= 1 - hx_k
\end{align*}
\]

**Method 2:**
\[
\begin{align*}
x_{k+1} &= 1 + hy_k \\
y_{k+1} &= 1 - hx_{k+1}
\end{align*}
\]

**Method 3:**
\[
\begin{align*}
x_{k+1} &= 1 + hy_{k+1} \\
y_{k+1} &= 1 - hx_{k+1}
\end{align*}
\]

Express each method in the form
\[
\begin{bmatrix}
x_{k+1} \\
y_{k+1}
\end{bmatrix} = A_n 
\begin{bmatrix}
x_k \\
y_k
\end{bmatrix}
\]
where \( A_n \) is a 2-by-2 matrix. For each case, compute \( \lambda(A_n) \) and use the previous problem to discuss \( \lim x_k \) and \( \lim y_k \) as \( k \to \infty \).

**P7.1.11** If \( J \in \mathbb{R}^{d \times d} \) is a Jordan block, what is \( \kappa_\infty(J) \)?

**P7.1.12** Show that if
\[
R = \begin{bmatrix}
R_{11} & R_{12} \\
0 & R_{22}
\end{bmatrix}
\]
\[
p \quad q
\]
is normal and \( \lambda(R_{11}) \cap \lambda(R_{22}) = \emptyset \), then \( R_{12} = 0 \).

**Notes and References for Sec. 7.1**

The mathematical properties of the algebraic eigenvalue problem are elegantly covered in Wilkinson (1965, chapter 1) and Stewart (1973, chapter 6). For those who need further review we also recommend:

The Schur decomposition originally appeared in

A proof very similar to ours is given on page 105 of

Connections between singular values, eigenvalues, and pseudoeigenvalues (see §11.3.4) are discussed in

### 7.2 Perturbation Theory

The act of computing eigenvalues is the act of computing zeros of the characteristic polynomial. Galois theory tells us that such a process has to be iterative if $n > 4$ and so errors will arise because of finite termination. In order to develop intelligent stopping criteria we need an informative perturbation theory that tells us how to think about approximate eigenvalues and invariant subspaces.

#### 7.2.1 Eigenvalue Sensitivity

Several eigenvalue routines produce a sequence of similarity transformations $X_k$ with the property that the matrices $X_k^{-1} AX_k$ are progressively "more diagonal." The question naturally arises, how well do the diagonal elements of a matrix approximate its eigenvalues?

**Theorem 7.2.1 (Gershgorin Circle Theorem)** If $X^{-1} AX = D + F$ where $D = \text{diag}(d_1, \ldots, d_n)$ and $F$ has zero diagonal entries, then

$$
\lambda(A) \subseteq \bigcup_{i=1}^{n} D_i
$$

where $D_i = \{ z \in \mathbb{C} : |z - d_i| \leq \sum_{j=1}^{n} |f_{ij}| \}$.

**Proof.** Suppose $\lambda \in \lambda(A)$ and assume without loss of generality that $\lambda \neq d_i$ for $i = 1:n$. Since $(D - \lambda I) + F$ is singular, it follows from Lemma 2.3.3 that

$$
1 \leq \| (D - \lambda I)^{-1} F \|_\infty = \sum_{j=1}^{n} \frac{|f_{kj}|}{|d_k - \lambda|}
$$

for some $k$, $1 \leq k \leq n$. But this implies that $\lambda \in D_k$. □

It can also be shown that if the Gershgorin disk $D_i$ is isolated from the other disks, then it contains precisely one of $A$'s eigenvalues. See Wilkinson (1965,
Example 7.2.1 If

\[ A = \begin{bmatrix} 10 & 2 & 3 \\ -1 & 0 & 2 \\ 1 & -2 & 1 \end{bmatrix} \]

then \( \lambda(A) \approx \{10.226, 3.870 + 2.2216i, 3.870 - 2.2216i\} \) and the Gershgorin disks are \( D_1 = \{ |z| : |z - 10| \leq 5 \} \), \( D_2 = \{ |z| : |z| \leq 3 \} \), and \( D_3 = \{ |z| : |z - 1| \leq 3 \} \).

For some very important eigenvalue routines it is possible to show that the computed eigenvalues are the exact eigenvalues of a matrix \( A + E \) where \( E \) is small in norm. Consequently, we must understand how the eigenvalues of a matrix can be affected by small perturbations. A sample result that sheds light on this issue is the following theorem.

**Theorem 7.2.2 (Bauer-Fike)** If \( \mu \) is an eigenvalue of \( A + E \in \mathbb{C}^{n \times n} \) and \( X^{-1}AX = D = \text{diag}(\lambda_1, \ldots, \lambda_n) \), then

\[
\min_{\lambda \in \lambda(A)} |\lambda - \mu| \leq \kappa_p(X) \| E \|_p
\]

where \( \| \cdot \|_p \) denotes any of the \( p \)-norms.

**Proof.** We need only consider the case when \( \mu \) is not in \( \lambda(A) \). If the matrix \( X^{-1}(A + E - \mu I)X \) is singular, then so is \( I + (D - \mu I)^{-1}(X^{-1}EX) \). Thus, from Lemma 2.3.3 we obtain

\[
1 \leq \| (D - \mu I)^{-1}(X^{-1}EX) \|_p \leq \| (D - \mu I)^{-1} \|_p \| X \|_p \| E \|_p \| X^{-1} \|_p.
\]

Since \( (D - \mu I)^{-1} \) is diagonal and the \( p \)-norm of a diagonal matrix is the absolute value of the largest diagonal entry, it follows that

\[
\| (D - \mu I)^{-1} \|_p = \min_{\lambda \in \lambda(A)} \frac{1}{|\lambda - \mu|}
\]

from which the theorem follows. \( \square \)

An analogous result can be obtained via the Schur decomposition:

**Theorem 7.2.3** Let \( Q^H A Q = D + N \) be a Schur decomposition of \( A \in \mathbb{C}^{n \times n} \) as in (7.1.3). If \( \mu \in \lambda(A + E) \) and \( p \) is the smallest positive integer such that \( |N|^p = 0 \), then

\[
\min_{\lambda \in \lambda(A)} |\lambda - \mu| \leq \max(\theta, \theta^{1/p})
\]

where

\[
\theta = \| E \|_2 \sum_{k=0}^{p-1} \| N \|_2^k.
\]
Proof. Define
\[ \delta = \min_{\lambda \in \lambda(A)} |\lambda - \mu| = \frac{1}{\| (\mu I - D)^{-1} \|_2}. \]

The theorem is clearly true if \( \delta = 0 \). If \( \delta > 0 \) then \( I - (\mu I - A)^{-1}E \) is singular and by Lemma 2.3.3 we have
\[ 1 \leq \| (\mu I - A)^{-1}E \|_2 \leq \| (\mu I - A)^{-1} \|_2 \| E \|_2 \quad (7.2.1) \]
\[ = \| ((\mu I - D) - N)^{-1} \|_2 \| E \|_2 . \]

Since \((\mu I - D)^{-1}\) is diagonal and \(|N|^p = 0\) it is not hard to show that \(((\mu I - D)^{-1}N)^p = 0\). Thus,
\[ ((\mu I - D) - N)^{-1} = \sum_{k=0}^{p-1} ((\mu I - D)^{-1}N)^k (\mu I - D)^{-1} \]
and so
\[ \| ((\mu I - D) - N)^{-1} \|_2 \leq \frac{1}{\delta} \sum_{k=0}^{p-1} \left( \frac{\| N \|_2}{\delta} \right)^k . \]

If \( \delta > 1 \) then
\[ \| (\mu I - D) - N)^{-1} \|_2 \leq \frac{1}{\delta} \sum_{k=0}^{p-1} \| N \|_2^k \]
and so from (7.2.1), \( \delta \leq \theta \). If \( \delta \leq 1 \) then
\[ \| (\mu I - D) - N)^{-1} \|_2 \leq \frac{1}{\delta^p} \sum_{k=0}^{p-1} \| N \|_2^k \]
and so from (7.2.1), \( \delta^p \leq \theta \). Thus, \( \delta \leq \max(\theta, \theta^{1/p}) \). \( \Box \)

Example 7.2.2 If
\[ A = \begin{bmatrix} 1 & 2 & 3 \\ 0 & 4 & 5 \\ 0 & 0 & 4.001 \end{bmatrix} \quad \text{and} \quad E = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ .001 & 0 & 0 \end{bmatrix}, \]
then \( \lambda(A + E) \approx \{ 1.000, 4.0582, 3.9427 \} \) and \( A \)'s matrix of eigenvectors satisfies \( \kappa_2(X) \approx 10^7 \). The Bauer-Fike bound in Theorem 7.2.2 has order \( 10^4 \), while the Schur bound in Theorem 7.2.3 has order \( 10^0 \).

Theorems 7.2.2 and 7.2.3 each indicate potential eigenvalue sensitivity if \( A \) is nonnormal. Specifically, if \( \kappa_2(X) \) or \( \| N \|_2^{p-1} \) is large, then small changes in \( A \) can induce large changes in the eigenvalues.

Example 7.2.3 If
\[ A = \begin{bmatrix} 0 & J_9 \\ 0 & 0 \end{bmatrix} \quad \text{and} \quad E = \begin{bmatrix} 0 & 0 \\ 10^{-10} & 0 \end{bmatrix}, \]
then for all \( \lambda \in \lambda(A) \) and \( \mu \in \lambda(A + E) \), \(|\lambda - \mu| = 10^{-1}\). In this example a change of order \( 10^{-10} \) in \( A \) results in a change of order \( 10^{-1} \) in its eigenvalues.

### 7.2.2 The Condition of a Simple Eigenvalue

Extreme eigenvalue sensitivity for a matrix \( A \) cannot occur if \( A \) is normal. On the other hand, nonnormality does not necessarily imply eigenvalue sensitivity. Indeed, a nonnormal matrix can have a mixture of well-conditioned and ill-conditioned eigenvalues. For this reason, it is beneficial to refine our perturbation theory so that it is applicable to individual eigenvalues and not the spectrum as a whole.

To this end, suppose that \( \lambda \) is a simple eigenvalue of \( A \in \mathbb{C}^{n \times n} \) and that \( x \) and \( y \) satisfy \( Ax = \lambda x \) and \( y^H A = \lambda y^H \) with \( \| x \|_2 = \| y \|_2 = 1 \). If \( Y^H AX = J \) is the Jordan decomposition with \( Y^H = X^{-1} \), then \( y \) and \( x \) are nonzero multiples of \( X(:, i) \) and \( Y(:, i) \) for some \( i \). It follows from \( 1 = Y(:, i)^H X(:, i) \) that \( y^H x \neq 0 \), a fact that we shall use shortly.

Using classical results from function theory, it can be shown that in a neighborhood of the origin there exist differentiable \( x(\epsilon) \) and \( \lambda(\epsilon) \) such that

\[
(A + \epsilon F)x(\epsilon) = \lambda(\epsilon)x(\epsilon) \quad \| F \|_2 = 1
\]

where \( \lambda(0) = \lambda \) and \( x(0) = x \). By differentiating this equation with respect to \( \epsilon \) and setting \( \epsilon = 0 \) in the result, we obtain

\[
A\dot{x}(0) + Fx = \dot{\lambda}(0)x + \lambda\dot{x}(0).
\]

Applying \( y^H \) to both sides of this equation, dividing by \( y^H x \), and taking absolute values gives

\[
|\dot{\lambda}(0)| = \left| \frac{y^H Fx}{y^H x} \right| \leq \frac{1}{|y^H x|}.
\]

The upper bound is attained if \( F = yx^H \). For this reason we refer to the reciprocal of

\[
s(\lambda) = |y^H x|
\]

as the condition of the eigenvalue \( \lambda \).

Roughly speaking, the above analysis shows that if order \( \epsilon \) perturbations are made in \( A \), then an eigenvalue \( \lambda \) may be perturbed by an amount \( \epsilon/s(\lambda) \). Thus, if \( s(\lambda) \) is small, then \( \lambda \) is appropriately regarded as ill-conditioned. Note that \( s(\lambda) \) is the cosine of the angle between the left and right eigenvectors associated with \( \lambda \) and is unique only if \( \lambda \) is simple.

A small \( s(\lambda) \) implies that \( A \) is near a matrix having a multiple eigenvalue. In particular, if \( \lambda \) is distinct and \( s(\lambda) < 1 \), then there exists an \( E \) such that \( \lambda \) is a repeated eigenvalue of \( A + E \) and

\[
\frac{\| E \|_2}{\| A \|_2} \leq \frac{s(\lambda)}{\sqrt{1 - s(\lambda)^2}}.
\]
This result is proved in Wilkinson (1972).

Example 7.2.4 If

$$A = \begin{bmatrix} 1 & 2 & 3 \\ 0 & 4 & 5 \\ 0 & 0 & 4.001 \end{bmatrix} \quad \text{and} \quad E = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ .001 & 0 \end{bmatrix},$$

then $\lambda(A + E) \approx \{1.0001, 4.0582, 3.9427\}$ and $s(1) \approx .8 \times 10^0$, $s(4) \approx .2 \times 10^{-3}$, and $s(4.001) \approx .2 \times 10^{-3}$. Observe that $\| E \|_2 / s(\lambda)$ is a good estimate of the perturbation that each eigenvalue undergoes.

7.2.3 Sensitivity of Repeated Eigenvalues

If $\lambda$ is a repeated eigenvalue, then the eigenvalue sensitivity question is more complicated. For example, if

$$A = \begin{bmatrix} 1 & a \\ 0 & 1 \end{bmatrix} \quad \text{and} \quad F = \begin{bmatrix} 0 & 0 \\ 1 & 0 \end{bmatrix},$$

then $\lambda(A + \epsilon F) \approx \{1 \pm \sqrt{\epsilon a}\}$. Note that if $a \neq 0$, then it follows that the eigenvalues of $A + \epsilon F$ are not differentiable at zero; their rate of change at the origin is infinite. In general, if $\lambda$ is a defective eigenvalue of $A$, then $O(\epsilon)$ perturbations in $A$ can result in $O(\epsilon^{1/p})$ perturbations in $\lambda$ if $\lambda$ is associated with a $p$-dimensional Jordan block. See Wilkinson (1965, pp. 77ff.) for a more detailed discussion.

7.2.4 Invariant Subspace Sensitivity

A collection of sensitive eigenvectors can define an insensitive invariant subspace provided the corresponding cluster of eigenvalues is isolated. To be precise, suppose

$$Q^H A Q = \begin{bmatrix} T_{11} & T_{12} \\ 0 & T_{22} \end{bmatrix} \begin{bmatrix} r \\ n-r \end{bmatrix}$$

is a Schur decomposition of $A$ with

$$Q = \begin{bmatrix} Q_1 & Q_2 \end{bmatrix} \begin{bmatrix} r \\ n-r \end{bmatrix}.$$  \hfill (7.2.2)

It is clear from our discussion of eigenvector perturbation that the sensitivity of the invariant subspace $\text{ran}(Q_1)$ depends on the distance between $\lambda(T_{11})$ and $\lambda(T_{22})$. The proper measure of this distance turns out to be the smallest singular value of the linear transformation $X \rightarrow T_{11} X - X T_{22}$.  \hfill (7.2.3)
(Recall that this transformation figures in Lemma 7.1.5.) In particular, if we define the separation between the matrices $T_{11}$ and $T_{22}$ by

$$\text{sep}(T_{11}, T_{22}) = \min_{X \neq 0} \frac{\| T_{11}X - XT_{22} \|_F}{\| X \|_F}, \quad (7.2.4)$$

then we have the following general result:

**Theorem 7.2.4** Suppose that (7.2.2) and (7.2.3) hold and that for any matrix $E \in \mathbb{C}^{n \times n}$ we partition $Q^H EQ$ as follows:

$$Q^H EQ = \begin{bmatrix} E_{11} & E_{12} \\ E_{21} & E_{22} \end{bmatrix} \begin{bmatrix} r \\ n-r \end{bmatrix}.$$  

If $\text{sep}(T_{11}, T_{22}) > 0$ and

$$\| E \|_2 \left( 1 + \frac{5 \| T_{12} \|_2}{\text{sep}(T_{11}, T_{22})} \right) \leq \frac{\text{sep}(T_{11}, T_{22})}{5},$$

then there exists a $P \in \mathbb{C}^{(n-r) \times r}$ with

$$\| P \|_2 \leq 4 \| E_{21} \|_2 \| E_{22} \|_2$$

such that the columns of $\hat{Q}_1 = (Q_1 + Q_2 P)(I + P^H P)^{-1/2}$ are an orthonormal basis for a subspace invariant for $A + E$.

**Proof.** This result is a slight recasting of Theorem 4.11 in Stewart (1973) which should be consulted for proof details. See also Stewart and Sun (1990, p.230). The matrix $(I + P^H P)^{-1/2}$ is the inverse of the square root of the symmetric positive definite matrix $I + P^H P$. See §4.2.10. □

**Corollary 7.2.5** If the assumptions in Theorem 7.2.4 hold, then

$$\text{dist}(\text{ran}(Q_1), \text{ran}(\hat{Q}_1)) \leq 4 \| E_{21} \|_2 \| E_{22} \|_2 \text{sep}(T_{11}, T_{22}).$$

**Proof.** Using the SVD of $P$, it can be shown that

$$\| P(I + P^H P)^{-1/2} \|_2 \leq \| P \|_2.$$  

(7.2.5)

The corollary follows because the required distance is the norm of $Q_2^H \hat{Q}_1 = P(I + P^H P)^{-1/2}$. □

Thus, the reciprocal of $\text{sep}(T_{11}, T_{22})$ can be thought of as a condition number that measures the sensitivity of $\text{ran}(Q_1)$ as an invariant subspace.

**Example 7.2.5** Suppose

$$T_{11} = \begin{bmatrix} 3 & 10 \\ 0 & 1 \end{bmatrix}, \quad T_{22} = \begin{bmatrix} 0 & -20 \\ 0 & 3.01 \end{bmatrix}, \quad \text{and} \quad T_{12} = \begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix}$$
and that
\[ A = T = \begin{bmatrix} T_{11} & T_{12} \\ 0 & T_{22} \end{bmatrix}. \]

Observe that \( AQ_1 = Q_1 T_{11} \) where \( Q_1 = [e_1, e_2] \in \mathbb{R}^{4 \times 2} \). A calculation shows that \( \text{sep}(T_{11}, T_{22}) \approx .0003 \). If
\[ E_{21} = 10^{-6} \begin{bmatrix} 1 \\ 1 \\ 1 \\ 1 \end{bmatrix} \]
and we examine the Schur decomposition of
\[ A + E = \begin{bmatrix} T_{11} & T_{12} \\ E_{21} & T_{22} \end{bmatrix}, \]
then we find that \( Q_1 \) gets perturbed to
\[ \tilde{Q}_1 = \begin{bmatrix} -.9999 & -.0003 \\ .0003 & -.9999 \\ -.0005 & -.0026 \\ .0000 & .0003 \end{bmatrix}. \]

Thus, we have \( \text{dist}(\text{ran}(\tilde{Q}_1), \text{ran}(Q_1)) \approx .0027 \approx 10^{-6}/\text{sep}(T_{11}, T_{22}) \).

### 7.2.5 Eigenvector Sensitivity

If we set \( r = 1 \) in the preceding subsection, then the analysis addresses the issue of eigenvector sensitivity.

**Corollary 7.2.6** Suppose \( A, E \in \mathbb{C}^{n \times n} \) and that \( Q = [q_1 \ q_2] \in \mathbb{C}^{n \times n} \) is unitary with \( q_1 \in \mathbb{C}^n \). Assume
\[
Q^H A Q = \begin{bmatrix} \lambda & v^H \\ 0 & T_{22} \end{bmatrix} \begin{bmatrix} 1 \\ n-1 \end{bmatrix} \quad Q^H E Q = \begin{bmatrix} \varepsilon & \gamma^H \\ \delta & E_{22} \end{bmatrix} \begin{bmatrix} 1 \\ n-1 \end{bmatrix}.
\]

(Thus, \( q_1 \) is an eigenvector.) If \( \sigma = \sigma_{\min}(T_{22} - \lambda I) > 0 \) and
\[
\| E \|_2 \left( 1 + \frac{5\| v \|_2}{\sigma} \right) \leq \frac{\sigma}{5},
\]
then there exists \( p \in \mathbb{C}^{n-1} \) with
\[
\| p \|_2 \leq 4 \frac{\| \delta \|_2}{\sigma}
\]
such that \( \hat{q}_1 = (q_1 + Q_2 p)/\sqrt{1 + p^H p} \) is a unit 2-norm eigenvector for \( A + E \). Moreover,
\[
\text{dist}(\text{span}\{q_1\}, \text{span}\{\hat{q}_1\}) \leq 4 \frac{\| \delta \|_2}{\sigma}.
\]

**Proof.** The result follows from Theorem 7.2.4, Corollary 7.2.5 and the observation that if \( T_{11} = \lambda \), then \( \text{sep}(T_{11}, T_{22}) = \sigma_{\min}(T_{22} - \lambda I) \). \( \square \)
7.2. Perturbation Theory

Note that $\sigma_{\text{min}}(T_{22} - \lambda I)$ roughly measures the separation of $\lambda$ from the eigenvalues of $T_{22}$. We have to say "roughly" because

$$\text{sep}(\lambda, T_{22}) = \sigma_{\text{min}}(T_{22} - \lambda I) \leq \min_{\mu \in \lambda(T_{22})} |\mu - \lambda|$$

and the upper bound can be a gross overestimate.

That the separation of the eigenvalues should have a bearing upon eigenvector sensitivity should come as no surprise. Indeed, if $\lambda$ is a nondefective, repeated eigenvalue, then there are an infinite number of possible eigenvector bases for the associated invariant subspace. The preceding analysis merely indicates that this indeterminancy begins to be felt as the eigenvalues coalesce. In other words, the eigenvectors associated with nearly eigenvalues are "wobbly."

Example 7.2.6 If

$$A = \begin{bmatrix} 1.01 & 0.01 \\ 0.00 & 0.99 \end{bmatrix}$$

then the eigenvalue $\lambda = .99$ has condition $1/s(.99) \approx 1.118$ and associated eigenvector $x = [.4472, -.8944]^T$. On the other hand, the eigenvalue $\tilde{\lambda} = 1.00$ of the "nearby" matrix

$$A + E = \begin{bmatrix} 1.01 & 0.01 \\ 0.00 & 1.00 \end{bmatrix}$$

has an eigenvector $\tilde{x} = [.7071, -.7071]^T$.

Problems

P7.2.1 Suppose $Q^H A = \text{diag}(\lambda_1) + N$ is a Schur decomposition of $A \in \mathbb{C}^{n \times n}$ and define $\nu(A) = \| A^H A - AA^H \|_F$. The upper and lower bounds in

$$\frac{\nu(A)^2}{6\| A \|_F^2} \leq \| N \|_F^2 \leq \sqrt{\frac{n^3 - n}{12}} \nu(A)$$

are established by Henrici (1962) and Eberlein (1965), respectively. Verify these results for the case $n = 2$.

P7.2.2 Suppose $A \in \mathbb{C}^{n \times n}$ and $X^{-1}AX = \text{diag}(\lambda_1, \ldots, \lambda_n)$ with distinct $\lambda_i$. Show that if the columns of $X$ have unit 2-norm, then $\kappa_F(X)^2 = n \sum_{i=1}^{n} (1/s(\lambda_i))^2$

P7.2.3 Suppose $Q^H A = \text{diag}(\lambda_1) + N$ is a Schur decomposition of $A$ and that $X^{-1}AX = \text{diag}(\lambda_1)$. Show $\kappa_2(X)^2 \geq 1 + (\| N \|_F / \| A \|_F)^2$. See Loizou (1969).

P7.2.4 If $X^{-1}AX = \text{diag}(\lambda_1)$ and $|\lambda_1| \geq \cdots \geq |\lambda_n|$, then

$$\frac{\sigma_1(A)}{\kappa_2(X)} \leq |\lambda_1| \leq \kappa_2(X) \sigma_1(A).$$

Prove this result for the $n = 2$ case. See Ruhe (1975).

P7.2.5 Show that if $A = \begin{bmatrix} a & c \\ 0 & b \end{bmatrix}$ and $a \neq b$, then $s(a) = s(b) = (1 + |c/(a-b)|^2)^{-1/2}$. 

**P7.2.6** Suppose

\[ A = \begin{bmatrix} \lambda & v^T \\ 0 & T_{22} \end{bmatrix} \]

and that \( \lambda \notin \lambda(T_{22}) \). Show that if \( \sigma = \text{sep}(\lambda, T_{22}) \), then

\[ s(\lambda) = \frac{1}{\sqrt{1 + \| (T_{22} - \lambda I)^{-1} v \|_2^2}} \leq \frac{\sigma}{\sqrt{\sigma^2 + \| v \|_2^2}}. \]

**P7.2.7** Show that the condition of a simple eigenvalue is preserved under unitary similarity transformations.

**P7.2.8** With the same hypothesis as in the Bauer-Fike theorem (Theorem 7.2.2), show that \( \min_{\lambda \in \lambda(A)} |\lambda - \mu| \leq \| |X^{-1}| |E| |X| \|_F \).

**P7.2.9** Verify (7.2.5).

**P7.2.10** Show that if \( B \in \mathbb{C}^{m \times m} \) and \( C \in \mathbb{C}^{n \times n} \), then \( \text{sep}(B, C) \) is less than or equal to \( |\lambda - \mu| \) for all \( \lambda \in \lambda(B) \) and \( \mu \in \lambda(C) \).

**Notes and References for Sec. 7.2**

Many of the results presented in this section may be found in Wilkinson (1965, chapter 2), Stewart and Sun (1990) as well as in

The following papers are concerned with the effect of perturbations on the eigenvalues of a general matrix:

Wilkinson's work on nearest defective matrices is typical of a growing body of literature that is concerned with "nearness" problems. See

7.2. Perturbation Theory

Aspects of eigenvalue condition are discussed in

The relationship between the eigenvalue condition number, the departure from normality, and the condition of the eigenvector matrix is discussed in

The paper by Henrici also contains a result similar to Theorem 7.2.3. Penetrating treatments of invariant subspace perturbation include

Detailed analyses of the function sep(.,.) and the map $X \rightarrow AX + XAT$ are given in

Gerschgorin’s Theorem can be used to derive a comprehensive perturbation theory. See Wilkinson (1965, chapter 2). The theorem itself can be generalized and extended in various ways; see
7.3 Power Iterations

Suppose that we are given $A \in \mathbb{C}^{n \times n}$ and a unitary $U_0 \in \mathbb{C}^{n \times n}$. Assume that Householder orthogonalization (Algorithm 5.2.1) can be extended to complex matrices (it can) and consider the following iteration:

$$T_0 = U_0^H A U_0$$
for $k = 1, 2, \ldots$

$$T_{k-1} = U_k R_k \quad \text{(QR factorization)}$$
$$T_k = R_k U_k$$

end

Since $T_k = R_k U_k = U_k^H (U_k R_k) U_k = U_k^H T_{k-1} U_k$ it follows by induction that

$$T_k = (U_0 U_1 \cdots U_k)^H A (U_0 U_1 \cdots U_k). \quad (7.3.2)$$

Thus, each $T_k$ is unitarily similar to $A$. Not so obvious, and what is the central theme of this section, is that the $T_k$ almost always converge to upper triangular form. That is, (7.3.2) almost always “converges” to a Schur decomposition of $A$.

Iteration (7.3.1) is called the QR iteration, and it forms the backbone of the most effective algorithm for computing the Schur decomposition. In order to motivate the method and to derive its convergence properties, two other eigenvalue iterations that are important in their own right are presented first: the power method and the method of orthogonal iteration.

7.3.1 The Power Method

Suppose $A \in \mathbb{C}^{n \times n}$ is diagonalizable, that $X^{-1} A X = \text{diag}(\lambda_1, \ldots, \lambda_n)$ with $X = [x_1, \ldots, x_n]$, and $|\lambda_1| > |\lambda_2| \geq \cdots \geq |\lambda_n|$. Given a unit 2-norm $q^{(0)} \in \mathbb{C}^n$, the power method produces a sequence of vectors $q^{(k)}$ as follows:

$$\text{for } k = 1, 2, \ldots$$
$$z^{(k)} = A q^{(k-1)}$$
$$q^{(k)} = z^{(k)}/\|z^{(k)}\|_2$$
$$\lambda^{(k)} = [q^{(k)}]^H A q^{(k)} \quad (7.3.3)$$

end

There is nothing special about doing a 2-norm normalization except that it imparts a greater unity on the overall discussion in this section.
Let us examine the convergence properties of the power iteration. If
\[ q^{(0)} = a_1 x_1 + a_2 x_2 + \cdots + a_n x_n \]
and \( a_1 \neq 0 \), then it follows that
\[ A^k q^{(0)} = a_1 \lambda_1^k \left( x_1 + \sum_{j=2}^{n} \frac{a_j}{a_1} \left( \frac{\lambda_j}{\lambda_1} \right)^k x_j \right). \]
Since \( q^{(k)} \in \text{span}\{A^k q^{(0)}\} \) we conclude that
\[ \text{dist}\left(\text{span}\{q^{(k)}\}, \text{span}\{x_1\}\right) = O\left(\left|\frac{\lambda_2}{\lambda_1}\right|^k\right) \]
and moreover,
\[ |\lambda_1 - \lambda^{(k)}| = O\left(\left|\frac{\lambda_2}{\lambda_1}\right|^k\right). \]
If \( |\lambda_1| > |\lambda_2| \geq \cdots \geq |\lambda_n| \) then we say that \( \lambda_1 \) is a dominant eigenvalue. Thus, the power method converges if \( \lambda_1 \) is dominant and if \( q^{(0)} \) has a component in the direction of the corresponding dominant eigenvector \( x_1 \).

The behavior of the iteration without these assumptions is discussed in Wilkinson (1965, p.570) and Parlett and Poole (1973).

**Example 7.3.1** If
\[ A = \begin{bmatrix} -261 & 209 & -49 \\ -530 & 422 & -98 \\ -800 & 631 & -144 \end{bmatrix} \]
then \( \lambda(A) = \{10, 4, 3\} \). Applying (7.3.3) with \( q^{(0)} = [1, 0, 0]^T \) we find
\[
\begin{array}{c|c}
 k & \lambda^{(k)} \\
\hline
 1 & 13.0806 \\
 2 & 10.7191 \\
 3 & 10.2073 \\
 4 & 10.0633 \\
 5 & 10.0198 \\
 6 & 10.0063 \\
 7 & 10.0020 \\
 8 & 10.0007 \\
 9 & 10.0002 \\
\end{array}
\]

In practice, the usefulness of the power method depends upon the ratio \( |\lambda_2|/|\lambda_1| \), since it dictates the rate of convergence. The danger that \( q^{(0)} \) is deficient in \( x_1 \) is a less worrisome matter because rounding errors sustained during the iteration typically ensure that the subsequent \( q^{(k)} \) have a component in this direction. Moreover, it is typically the case in applications...
where the dominant eigenvalue and eigenvector are desired that an à priori estimate of $x_1$ is known. Normally, by setting $q^{(0)}$ to be this estimate, the dangers of a small $a_1$ are minimized.

Note that the only thing required to implement the power method is a subroutine capable of computing matrix-vector products of the form $Aq$. It is not necessary to store $A$ in an $n$-by-$n$ array. For this reason, the algorithm can be of interest when $A$ is large and sparse and when there is a sufficient gap between $|\lambda_1|$ and $|\lambda_2|$. Estimates for the error $|\lambda^{(k)} - \lambda_1|$ can be obtained by applying the perturbation theory developed in the previous section. Define the vector $r^{(k)} = Aq^{(k)} - \lambda^{(k)}q^{(k)}$ and observe that $(A + E^{(k)})q^{(k)} = \lambda^{(k)}q^{(k)}$ where $E^{(k)} = -r^{(k)}[q^{(k)}]^H$. Thus $\lambda^{(k)}$ is an eigenvalue of $A + E^{(k)}$ and

$$
|\lambda^{(k)} - \lambda_1| \approx \frac{\|E^{(k)}\|_2}{s(\lambda_1)} = \frac{\|r^{(k)}\|_2}{s(\lambda_1)}.
$$

If we use the power method to generate approximate right and left dominant eigenvectors, then it is possible to obtain an estimate of $s(\lambda_1)$. In particular, if $w^{(k)}$ is a unit 2-norm vector in the direction of $(A^H)^kw^{(0)}$, then we can use the approximation $s(\lambda_1) \approx |w^{(k)}Hq^{(k)}|$.

### 7.3.2 Orthogonal Iteration

A straightforward generalization of the power method can be used to compute higher-dimensional invariant subspaces. Let $r$ be a chosen integer satisfying $1 \leq r \leq n$. Given an $n$-by-$r$ matrix $Q_0$ with orthonormal columns, the method of orthogonal iteration generates a sequence of matrices $\{Q_k\} \subseteq \mathbb{C}^{n \times r}$ as follows:

$$
\text{for } k = 1, 2, \ldots \\
\quad Z_k = AQ_{k-1} \\
\quad Q_kR_k = Z_k \quad \text{(QR factorization)} \\
\text{end}
$$

(7.3.4)

Note that if $r = 1$, then this is just the power method. Moreover, the sequence $\{Q_ke_1\}$ is precisely the sequence of vectors produced by the power iteration with starting vector $q^{(0)} = Q_0e_1$.

In order to analyze the behavior of this iteration, suppose that

$$
Q^HAQ = T = \text{diag}(\lambda_i) + N \quad |\lambda_1| \geq |\lambda_2| \geq \cdots \geq |\lambda_n|
$$

(7.3.5)

is a Schur decomposition of $A \in \mathbb{C}^{n \times n}$. Assume that $1 \leq r < n$ and partition $Q, T$, and $N$ as follows:

$$
\begin{bmatrix}
Q_\alpha & Q_\beta \\
r & n-r
\end{bmatrix} \quad \begin{bmatrix}
T_{11} & T_{12} \\
r & n-r
\end{bmatrix}^r
$$

(7.3.6)
\[ N = \begin{bmatrix} N_{11} & N_{12} \\ 0 & N_{22} \end{bmatrix} \begin{bmatrix} r \\ r \end{bmatrix} = \begin{bmatrix} n-r \\ n-r \end{bmatrix}. \]

If \(|\lambda_r| > |\lambda_{r+1}|\), then the subspace \(D_r(A) = \text{ran}(Q_\alpha)\) is said to be a dominant invariant subspace. It is the unique invariant subspace associated with the eigenvalues \(\lambda_1, \ldots, \lambda_r\). The following theorem shows that with reasonable assumptions, the subspaces \(\text{ran}(Q_k)\) generated by (7.3.4) converge to \(D_r(A)\) at a rate proportional to \(|\lambda_{r+1}/\lambda_r|^k\).

**Theorem 7.3.1** Let the Schur decomposition of \(A \in \mathbb{C}^{n \times n}\) be given by (7.3.5) and (7.3.6) with \(n \geq 2\). Assume that \(|\lambda_r| > |\lambda_{r+1}|\) and that \(\theta \geq 0\) satisfies

\[(1 + \theta)|\lambda_r| > \| N \|_F.\]

If \(Q_0 \in \mathbb{C}^{n \times r}\) has orthonormal columns and

\[d = \text{dist}(D_r(A^H), \text{ran}(Q_0)) < 1,\]

then the matrices \(Q_k\) generated by (7.3.4) satisfy

\[\text{dist}(D_r(A), \text{ran}(Q_k)) \leq \frac{(1 + \theta)^{n-2}}{\sqrt{1 - d^2}} \left(1 + \frac{\| T_{12} \|_F}{\text{sep}(T_{11}, T_{22})} \right) \left(\frac{|\lambda_{r+1}| + \| N \|_F/(1 + \theta)}{|\lambda_r| - \| N \|_F/(1 + \theta)}\right)^k.\]

**Proof.** The proof is given in an appendix at the end of this section. □

The condition \(d < 1\) in Theorem 7.3.1 ensures that the initial \(Q\) matrix is not deficient in certain eigendirections:

\[d < 1 \iff D_r(A^H) \perp \cap \text{ran}(Q_0) = \{0\}.\]

The theorem essentially says that if this condition holds and if \(\theta\) is chosen large enough, then

\[\text{dist}(D_r(A), \text{ran}(Q_k)) \leq c \left| \frac{\lambda_{r+1}}{\lambda_r} \right|^k\]

where \(c\) depends on \(\text{sep}(T_{11}, T_{22})\) and \(A\)'s departure from normality. Needless to say, convergence can be very slow if the gap between \(|\lambda_r|\) and \(|\lambda_{r+1}|\) is not sufficiently wide.

**Example 7.3.2** If (7.3.4) is applied to the matrix \(A\) in Example 7.3.1, with \(Q_0 = [e_1, e_2]\), we find:

<table>
<thead>
<tr>
<th>(k)</th>
<th>(\text{dist}(D_2(A), \text{ran}(Q_k)))</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>.0052</td>
</tr>
<tr>
<td>2</td>
<td>.0047</td>
</tr>
<tr>
<td>3</td>
<td>.0039</td>
</tr>
<tr>
<td>4</td>
<td>.0030</td>
</tr>
<tr>
<td>5</td>
<td>.0023</td>
</tr>
<tr>
<td>6</td>
<td>.0017</td>
</tr>
<tr>
<td>7</td>
<td>.0013</td>
</tr>
</tbody>
</table>
The error is tending to zero with rate \((\lambda_3/\lambda_2)^k = (3/4)^k\).

It is possible to accelerate the convergence in orthogonal iteration using a technique described in Stewart (1976). In the accelerated scheme, the approximate eigenvalue \(\lambda_i^{(k)}\) satisfies

\[
|\lambda_i^{(k)} - \lambda_i| \approx \left| \frac{\lambda_{i+1}}{\lambda_i} \right|^k, \quad i = 1:r.
\]

(Without the acceleration, the right-hand side is \(|\lambda_{i+1}/\lambda_i|^k\).) Stewart's algorithm involves computing the Schur decomposition of the matrices \(Q_k^T AQ_k\) every so often. The method can be very useful in situations where \(A\) is large and sparse and a few of its largest eigenvalues are required.

### 7.3.3 The QR Iteration

We now "derive" the QR iteration (7.3.1) and examine its convergence. Suppose \(r = n\) in (7.3.4) and the eigenvalues of \(A\) satisfy

\[
|\lambda_1| > |\lambda_2| > \cdots > |\lambda_n|.
\]

Partition the matrix \(Q\) in (7.3.5) and \(Q_k\) in (7.3.4) as follows:

\[
Q = \begin{bmatrix} q_1, \ldots, q_n \end{bmatrix} \quad Q_k = \begin{bmatrix} q_1^{(k)}, \ldots, q_n^{(k)} \end{bmatrix}
\]

If

\[
\text{dist}(D_k(A^H), \text{span}\{q_1^{(0)}, \ldots, q_i^{(0)}\}) < 1, \quad i = 1:n \tag{7.3.7}
\]

then it follows from Theorem 7.3.1 that

\[
\text{dist}(\text{span}\{q_1^{(k)}, \ldots, q_i^{(k)}\}, \text{span}\{q_1, \ldots, q_i\}) \to 0
\]

for \(i = 1:n\). This implies that the matrices \(T_k\) defined by

\[
T_k = Q_k^H AQ_k
\]

are converging to upper triangular form. Thus, it can be said that the method of orthogonal iteration computes a Schur decomposition provided the original iterate \(Q_0 \in \mathbb{C}^{n \times n}\) is not deficient in the sense of (7.3.7).

The QR iteration arises naturally by considering how to compute the matrix \(T_k\) directly from its predecessor \(T_{k-1}\). On the one hand, we have from (7.3.4) and the definition of \(T_{k-1}\) that

\[
T_{k-1} = Q_{k-1}^H AQ_{k-1} = Q_{k-1}^H (AQ_{k-1}) = (Q_{k-1}^H Q_k) R_k.
\]

On the other hand

\[
T_k = Q_k^H AQ_k = (Q_k^H AQ_{k-1})(Q_k^H Q_k) = R_k (Q_{k-1}^H Q_k).
\]
Thus, $T_k$ is determined by computing the QR factorization of $T_{k-1}$ and then multiplying the factors together in reverse order. This is precisely what is done in (7.3.1).

**Example 7.3.3** If the iteration:

```plaintext
for $k = 1, 2, \ldots$
   $A = QR$
   $A = RQ$
end
```

is applied to the matrix of Example 7.3.1, then the strictly lower triangular elements diminish as follows:

| $k$ | $O(|a_{21}|)$ | $O(|a_{31}|)$ | $O(|a_{32}|)$ |
|-----|---------------|---------------|---------------|
| 1   | $10^{-1}$     | $10^{-1}$     | $10^{-2}$     |
| 2   | $10^{-2}$     | $10^{-2}$     | $10^{-3}$     |
| 3   | $10^{-2}$     | $10^{-3}$     | $10^{-3}$     |
| 4   | $10^{-3}$     | $10^{-3}$     | $10^{-3}$     |
| 5   | $10^{-3}$     | $10^{-4}$     | $10^{-3}$     |
| 6   | $10^{-4}$     | $10^{-5}$     | $10^{-3}$     |
| 7   | $10^{-4}$     | $10^{-5}$     | $10^{-3}$     |
| 8   | $10^{-5}$     | $10^{-6}$     | $10^{-4}$     |
| 9   | $10^{-5}$     | $10^{-7}$     | $10^{-4}$     |
| 10  | $10^{-6}$     | $10^{-8}$     | $10^{-4}$     |

Note that a single QR iteration is an $O(n^3)$ calculation. Moreover, since convergence is only linear (when it exists), it is clear that the method is a prohibitively expensive way to compute Schur decompositions. Fortunately these practical difficulties can be overcome, as we show in §7.4 and §7.5.

### 7.3.4 LR Iterations

We conclude with some remarks about power iterations that rely on the LU factorization rather than the QR factorization. Let $G_0 \in \mathbb{C}^{n \times r}$ have rank $r$. Corresponding to (7.3.4) we have the following iteration:

```plaintext
for $k = 1, 2, \ldots$
   $Z_k = AG_{k-1}$
   $Z_k = G_k R_k$ \hspace{1cm} (LU factorization)
end
```

Suppose $r = n$ and that we define the matrices $T_k$ by

$$ T_k = G_k^{-1} A G_k. \hspace{1cm} (7.3.9) $$

It can be shown that if we set $L_0 = G_0$, then the $T_k$ can be generated as follows:
\[ T_0 = L_0^{-1} A L_0 \]
for \( k = 1, 2, \ldots \)  
\[ T_{k-1} = L_k R_k \quad \text{(LU factorization)} \]
\[ T_k = R_k L_k \quad \text{end} \]

Iterations (7.3.8) and (7.3.10) are known as \textit{treppeniteration} and the \textit{LR iteration}, respectively. Under reasonable assumptions, the \( T_k \) converge to upper triangular form. To successfully implement either method, it is necessary to pivot. See Wilkinson (1965, p.602).

\section*{Appendix}

In order to establish Theorem 7.3.1 we need the following lemma which is concerned with bounding the powers of a matrix and its inverse.

\textbf{Lemma 7.3.2} Let \( Q^H A Q = T = D + N \) be a Schur decomposition of \( A \in \mathbb{C}^{n \times n} \) where \( D \) is diagonal and \( N \) strictly upper triangular. Let \( \lambda \) and \( \mu \) denote the largest and smallest eigenvalues of \( A \) in absolute value. If \( \theta \geq 0 \) then for all \( k \geq 0 \) we have

\[ \| A^k \|_2 \leq (1 + \theta)^{n-1} \left( |\lambda| + \frac{\| N \|_F}{1 + \theta} \right)^k. \]  
(7.3.11)

If \( A \) is nonsingular and \( \theta \geq 0 \) satisfies \( (1 + \theta)|\mu| > \| N \|_F \), then for all \( k \geq 0 \) we also have

\[ \| A^{-k} \|_2 \leq (1 + \theta)^{n-1} \left( \frac{1}{|\mu| - \| N \|_F/(1 + \theta)} \right)^k. \]  
(7.3.12)

\textbf{Proof.} For \( \theta \geq 0 \), define the diagonal matrix \( \Delta \) by

\[ \Delta = \text{diag} \left( (1, (1 + \theta), (1 + \theta)^2, \ldots, (1 + \theta)^{n-1} \right) \]

and note that \( \kappa_2(\Delta) = (1 + \theta)^{n-1} \). Since \( N \) is strictly upper triangular, it is easy to verify that \( \| \Delta N \Delta^{-1} \|_F \leq \| N \|_F/(1 + \theta) \). Thus,

\[ \| A^k \|_2 = \| T^k \|_2 = \| \Delta^{-1} (D + \Delta N \Delta^{-1})^k \Delta \|_2 \leq \kappa_2(\Delta) \left( \| D \|_2 + \| \Delta N \Delta^{-1} \|_2 \right)^k \leq (1 + \theta)^{n-1} \left( |\lambda| + \frac{\| N \|_F}{1 + \theta} \right)^k. \]

On the other hand, if \( A \) is nonsingular and \( (1 + \theta)|\mu| > \| N \|_F \), then \( \| \Delta D^{-1} N \Delta^{-1} \|_2 < 1 \) and using Lemma 2.3.3 we obtain

\[ \| A^{-k} \|_2 = \| T^{-k} \|_2 = \| \Delta^{-1} [(I + \Delta D^{-1} N \Delta^{-1})^{-1} D^{-1}]^k \Delta \|_2 \]
\[ \leq \kappa_2(\Delta) \left( \frac{\| D^{-1}\|_2}{1 - \| \Delta D^{-1} N \Delta^{-1}\|_2} \right)^k \]

\[ \leq (1 + \theta)^{n-1} \left( \frac{1}{|\mu| - \| N \|_F/(1 + \theta)} \right)^k. \]

\textbf{Proof of Theorem 7.3.1}

It is easy to show by induction that \( A^k Q_0 = Q_k(R_k \cdots R_1) \). By substituting (7.3.5) and 7.3.6) into this equality we obtain

\[ T^k \begin{bmatrix} V_0 \\ W_0 \end{bmatrix} = \begin{bmatrix} V_k \\ W_k \end{bmatrix}(R_k \cdots R_1) \]

where \( V_k = Q^H_{\alpha} Q_k \) and \( W_k = Q^H_{\beta} Q_k \). Using Lemma 7.1.5 we know that a matrix \( X \in \mathbb{C}^{r \times (n-r)} \) exists such that

\[ \begin{bmatrix} I_r & X \\ 0 & I_{n-r} \end{bmatrix}^{-1} \begin{bmatrix} T_{11} & T_{12} \\ 0 & T_{22} \end{bmatrix} \begin{bmatrix} I_r & X \\ 0 & I_{n-r} \end{bmatrix} = \begin{bmatrix} T_{11} & 0 \\ 0 & T_{22} \end{bmatrix} \]

and so

\[ \begin{bmatrix} T_{11} & 0 \\ 0 & T_{22}^k \end{bmatrix} \begin{bmatrix} V_0 - X W_0 \\ W_0 \end{bmatrix} = \begin{bmatrix} V_k - X W_k \\ W_k \end{bmatrix}(R_k \cdots R_1). \]

Below we establish that the matrix \( V_0 - X W_0 \) is nonsingular and this enables us to obtain the following expression:

\[ W_k = T_{22}^k W_0 (V_0 - X W_0)^{-1} T_{11}^{-1} \begin{bmatrix} I_r & -X \end{bmatrix} \begin{bmatrix} V_k \\ W_k \end{bmatrix}. \]

Recalling the definition of distance between subspaces from §2.6.3,

\[ \text{dist}(D_r(A), \text{ran}(Q_k)) = \| Q^H_{\beta} Q_k \|_2 = \| W_k \|_2. \]

Since

\[ \| [I_r, -X] \|_2 \leq 1 + \| X \|_F \]

we have

\[ \text{dist}(D_r(A), \text{ran}(Q_k)) \leq \| T_{22}^k \|_2 \| (V_0 - X W_0)^{-1} \|_2 \| T_{11}^{-k} \|_2 (1 + \| X \|_F). \]  \hspace{1cm} (7.3.13)

To prove the theorem we must look at each of the four factors in the upper bound.

Since \( \text{sep}(T_{11}, T_{22}) \) is the smallest singular value of the linear transformation \( \phi(X) = T_{11}X - XT_{22} \) it readily follows from \( \phi(X) = -T_{12} \) that

\[ \| X \|_F \leq \frac{\| T_{12} \|_F}{\text{sep}(T_{11}, T_{22})}. \]  \hspace{1cm} (7.3.14)
Using Lemma 7.3.2, it can be shown that
\[ \| T_{22}^k \|_2 \leq (1 + \theta)^{n-r-1} \left( |\lambda_{r+1}| + \frac{\| N \|_F}{1 + \theta} \right)^k \] (7.3.15)
and
\[ \| T_{11}^{-k} \|_2 \leq (1 + \theta)^{r-1} \left( |\lambda_r| - \frac{\| N \|_F}{1 + \theta} \right)^k. \] (7.3.16)

Finally, we turn our attention to the \( \| (V_0 - XW_0)^{-1} \| \) factor. Note that
\[
V_0 - XW_0 = Q^H_\alpha Q_0 - XQ^H_\beta Q_0 \\
= [I_r, -X] \begin{bmatrix} Q^H_\alpha & Q^H_\beta \end{bmatrix} Q_0 \\
= \begin{bmatrix} [Q_\alpha Q_\beta] & I_r \\ -X^H \end{bmatrix}^H Q_0 \\
= (I_r + XX^H)^{1/2}(Z^H Q_0)
\]
where
\[ Z = [Q_\alpha Q_\beta] \begin{bmatrix} I_r \\ -X^H \end{bmatrix} (I_r + XX^H)^{-1/2} \]
\[ = (Q_\alpha - Q_\beta X^H)(I_r + XX^H)^{-1/2}. \]
The columns of this matrix are orthonormal. They are also a basis for \( D_r(A^H) \) because
\[ A^H(Q_\alpha - Q_\beta X^H) = (Q_\alpha - Q_\beta X^H)T_{11}^H. \]
This last fact follows from the equation \( A^H Q = QT^H \).

From Theorem 2.6.1
\[ d = \text{dist}(D_r(A^H), \text{range}(Q_0)) = \sqrt{1 - \sigma_r(Z^H Q_0)^2} \]
and since \( d < 1 \) by hypothesis,
\[ \sigma_r(Z^H Q_0) > 0. \]
This shows that
\[ (V_0 - XW_0) = (I_r + XX^H)^{1/2}(Z^H Q_0) \]
is nonsingular and thus,
\[
\| (V_0 - XW_0)^{-1} \|_2 \leq \| (I_r + XX^H)^{-1/2} \|_2 \| (Z^H Q_0)^{-1} \|_2 \\
\leq 1/\sqrt{1 - d^2}.
\] (7.3.17)
The theorem follows by substituting (7.3.14)-(7.3.17) into (7.3.13). □

Problems

P7.3.1 (a) Show that if \( X \in \mathbb{C}^{m \times n} \) is nonsingular, then \( \| A \|_X = \| X^{-1} AX \|_2 \) defines a matrix norm with the property that \( \| AB \|_X \leq \| A \|_X \| B \|_X \). (b) Let \( A \in \mathbb{C}^{m \times n} \) and set \( \rho = \max |\lambda_i| \). Show that for any \( \epsilon > 0 \) there exists a nonsingular \( X \in \mathbb{C}^{m \times n} \) such that \( \| A \|_X = \| X^{-1} AX \|_2 \leq \rho + \epsilon \). Conclude that there is a constant \( M \) such that \( \| A^k \|_2 \leq M(\rho + \epsilon)^k \) for all non-negative integers \( k \). (Hint: Set \( X = Q \text{ diag}(1,a,\ldots,a^{n-1}) \) where \( Q^H AQ = D + N \) is \( A \)'s Schur decomposition.)

P7.3.2 Verify that (7.3.10) calculates the matrices \( T_k \) defined by (7.3.9).

P7.3.3 Suppose \( A \in \mathbb{C}^{m \times n} \) is nonsingular and that \( Q_0 \in \mathbb{C}^{m \times p} \) has orthonormal columns. The following iteration is referred to as inverse orthogonal iteration.

\[
\begin{align*}
\text{for } k = 1, 2, \ldots \\
&AZ_k = Q_{k-1} \\
&Z_k = Q_k R_k \\
&\text{(QR factorization)}
\end{align*}
\]

Explain why this iteration can usually be used to compute the \( p \) smallest eigenvalues of \( A \) in absolute value. Note that to implement this iteration it is necessary to be able to solve linear systems that involve \( A \). When \( p = 1 \), the method is referred to as the inverse power method.

P7.3.4 Assume \( A \in \mathbb{R}^{n \times n} \) has eigenvalues \( \lambda_1, \ldots, \lambda_n \) that satisfy

\[
\lambda = \lambda_1 = \lambda_2 = \lambda_3 = \lambda_4 > |\lambda_5| \geq \cdots \geq |\lambda_n|
\]

where \( \lambda \) is positive. Assume that \( A \) has two Jordan blocks of the form

\[
\begin{bmatrix}
\lambda & 1 \\
0 & \lambda
\end{bmatrix}
\]

Discuss the convergence properties of the power method when applied to this matrix. Discuss how the convergence might be accelerated.

Notes and References for Sec. 7.3

A detailed, practical discussion of the power method is given in Wilkinson (1965, chapter 10). Methods are discussed for accelerating the basic iteration, for calculating non-dominant eigenvalues, and for handling complex conjugate eigenvalue pairs. The connections among the various power iterations are discussed in

The QR iteration was concurrently developed in

As can be deduced from the title of the first paper, the LR iteration predates the QR iteration. The former very fundamental algorithm was proposed by

Numerous papers on the convergence of the QR iteration have appeared. Several of these are:

Wilkinson (AEP, chapter 9) also discusses the convergence theory for this important algorithm.

Deeper insight into the convergence of the QR algorithm and its connection to other important algorithms can be attained by reading

The following papers are concerned with various practical and theoretical aspects of simultaneous iteration:

See also chapter 10 of

Simultaneous iteration and the Lanczos algorithm (cf. Chapter 9) are the principal methods for finding a few eigenvalues of a general sparse matrix.
7.4 The Hessenberg and Real Schur Forms

In this and the next section we show how to make the QR iteration (7.3.1) a fast, effective method for computing Schur decompositions. Because the majority of eigenvalue/invariant subspace problems involve real data, we concentrate on developing the real analog of (7.3.1) which we write as follows:

\[ H_0 = U_0^T A U_0 \]

for \( k = 1, 2, \ldots \)

\[ H_{k-1} = U_k R_k \]  
\[ H_k = R_k U_k \]  

(QR factorization)  \hspace{1cm} (7.4.1)

Here, \( A \in \mathbb{R}^{n \times n} \), each \( U_k \in \mathbb{R}^{n \times n} \) is orthogonal, and each \( R_k \in \mathbb{R}^{n \times n} \) is upper triangular. A difficulty associated with this real iteration is that the \( H_k \) can never converge to strict, "eigenvalue revealing," triangular form in the event that \( A \) has complex eigenvalues. For this reason, we must lower our expectations and be content with the calculation of an alternative decomposition known as the real Schur decomposition.

In order to compute the real Schur decomposition efficiently we must carefully choose the initial orthogonal similarity transformation \( U_0 \) in (7.4.1). In particular, if we choose \( U_0 \) so that \( H_0 \) is upper Hessenberg, then the amount of work per iteration is reduced from \( O(n^3) \) to \( O(n^2) \). The initial reduction to Hessenberg form (the \( U_0 \) computation) is a very important computation in its own right and can be realized by a sequence of Householder matrix operations.

7.4.1 The Real Schur Decomposition

A block upper triangular matrix with either 1-by-1 or 2-by-2 diagonal blocks is upper quasi-triangular. The real Schur decomposition amounts to a real reduction to upper quasi-triangular form.

Theorem 7.4.1 (Real Schur Decomposition) If \( A \in \mathbb{R}^{n \times n} \), then there exists an orthogonal \( Q \in \mathbb{R}^{n \times n} \) such that

\[ Q^T A Q = \begin{bmatrix} R_{11} & R_{12} & \cdots & R_{1m} \\ 0 & R_{22} & \cdots & R_{2m} \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & R_{mm} \end{bmatrix} \]  \hspace{1cm} (7.4.2)

where each \( R_{ii} \) is either a 1-by-1 matrix or a 2-by-2 matrix having complex conjugate eigenvalues.

Proof. The complex eigenvalues of \( A \) must come in conjugate pairs, since the characteristic polynomial \( \det(zI - A) \) has real coefficients. Let \( k \) be
the number of complex conjugate pairs in \( \lambda(A) \). We prove the theorem by induction on \( k \). Observe first that Lemma 7.1.2 and Theorem 7.1.3 have obvious real analogs. Thus, the theorem holds if \( k = 0 \). Now suppose that \( k \geq 1 \). If \( \lambda = \gamma + i\mu \in \lambda(A) \) and \( \mu \neq 0 \), then there exist vectors \( y \) and \( z \) in \( \mathbb{R}^n(z \neq 0) \) such that 
\[
A \begin{bmatrix} y & z \end{bmatrix} = \begin{bmatrix} y & z \end{bmatrix} \begin{bmatrix} \gamma & \mu \\ -\mu & \gamma \end{bmatrix}.
\]

The assumption that \( \mu \neq 0 \) implies that \( y \) and \( z \) span a two-dimensional, real invariant subspace for \( A \). It then follows from Lemma 7.1.2 that an orthogonal \( U \in \mathbb{R}^{n \times n} \) exists such that 
\[
U^T A U = \begin{bmatrix} T_{11} & T_{12} \\ 0 & T_{22} \end{bmatrix}^2 \quad n - 2
\]

where \( \lambda(T_{11}) = \{\lambda, \bar{\lambda}\} \). By induction, there exists an orthogonal \( \bar{U} \) so \( \bar{U}^T T_{22} \bar{U} \) has the required structure. The theorem follows by setting \( Q = U \) \diag(I_2, \bar{U}) \). \( \square \)

The theorem shows that any real matrix is orthogonally similar to an upper quasi-triangular matrix. It is clear that the real and imaginary part of the complex eigenvalues can be easily obtained from the 2-by-2 diagonal blocks.

### 7.4.2 A Hessenberg QR Step

We now turn our attention to the speedy calculation of a single QR step in (7.4.1). In this regard, the most glaring shortcoming associated with (7.4.1) is that each step requires a full QR factorization costing \( O(n^3) \) flops. Fortunately, the amount of work per iteration can be reduced by an order of magnitude if the orthogonal matrix \( U_0 \) is judiciously chosen. In particular, if \( U_0^T A U_0 = H_0 = (h_{ij}) \) is upper Hessenberg \( (h_{ij} = 0, i > j + 1) \), then each subsequent \( H_k \) requires only \( O(n^2) \) flops to calculate. To see this we look at the computations \( H = QR \) and \( H_+ = RQ \) when \( H \) is upper Hessenberg. As described in §5.2.4, we can upper triangularize \( H \) with a sequence of \( n - 1 \) Givens rotations: \( Q^T H \equiv G_{n-1}^T \cdots G_1^T H = R \). Here, \( G_i = G(i, i+1, \theta_i) \).

For the \( n = 4 \) case there are three Givens premultiplications:

\[
\begin{bmatrix}
0 & 0 & x & x \\
x & x & x & x \\
x & x & x & x \\
0 & x & x & x
\end{bmatrix} \rightarrow \begin{bmatrix}
0 & 0 & x & x \\
x & x & x & x \\
0 & 0 & x & x \\
0 & 0 & x & x
\end{bmatrix} \rightarrow \begin{bmatrix}
0 & 0 & x & x \\
x & x & x & x \\
0 & 0 & x & x \\
0 & 0 & 0 & x
\end{bmatrix}.
\]
See Algorithm 5.2.3.

The computation $RQ = R(G_1 \cdots G_{n-1})$ is equally easy to implement. In the $n = 4$ case there are three Givens post-multiplications:

\[
\begin{bmatrix}
  x & x & x & x \\
  0 & x & x & x \\
  0 & 0 & x & x \\
  0 & 0 & 0 & x \\
\end{bmatrix}
\rightarrow
\begin{bmatrix}
  x & x & x & x \\
  0 & 0 & x & x \\
  0 & 0 & 0 & x \\
\end{bmatrix}
\rightarrow
\begin{bmatrix}
  x & x & x & x \\
  0 & x & x & x \\
  0 & 0 & 0 & x \\
\end{bmatrix}
\rightarrow
\begin{bmatrix}
  x & x & x \\
  0 & x & x \\
  0 & 0 & x \\
\end{bmatrix}
\]

Overall we obtain the following algorithm:

Algorithm 7.4.1 If $H$ is an $n$-by-$n$ upper Hessenberg matrix, then this algorithm overwrites $H$ with $H_+ = RQ$ where $H = QR$ is the QR factorization of $H$.

\begin{verbatim}
for $k = 1:n - 1$
\quad $[c(k), s(k)] = \text{givens}(H(k,k), H(k + 1, k))$
\quad $H(k:k + 1, k:n) = \begin{bmatrix} c(k) & s(k) \\ -s(k) & c(k) \end{bmatrix}^T H(k:k + 1, k:n)$
end
for $k = 1:n - 1$
\quad $H(1:k + 1, k:k + 1) = H(1:k + 1, k:k + 1) \begin{bmatrix} c(k) & s(k) \\ -s(k) & c(k) \end{bmatrix}$
end
\end{verbatim}

Let $G_k = G(k, k + 1, \theta_k)$ be the $k$th Givens rotation. It is easy to confirm that the matrix $Q = G_1 \cdots G_{n-1}$ is upper Hessenberg. Thus, $RQ = H_+$ is also upper Hessenberg. The algorithm requires about $6n^2$ flops and thus is an order-of-magnitude quicker than a full matrix QR step (7.3.1).

Example 7.4.1 If Algorithm 7.4.1 is applied to:

\[
H = \begin{bmatrix}
  3 & 1 & 2 \\
  4 & 2 & 3 \\
  0 & .01 & 1 \\
\end{bmatrix},
\]

then

\[
G_1 = \begin{bmatrix}
  .6 & -.8 & 0 \\
  .8 & .6 & 0 \\
  0 & 0 & 1 \\
\end{bmatrix}, \quad G_2 = \begin{bmatrix}
  1 & 0 & 0 \\
  0 & .9996 & -.0249 \\
  0 & .0249 & .9996 \\
\end{bmatrix},
\]

and

\[
H_+ = \begin{bmatrix}
  4.7600 & -2.5442 & 5.4653 \\
  .3200 & .8156 & -2.1796 \\
  .0000 & .0263 & 1.0540 \\
\end{bmatrix}.
\]
7.4.3 The Hessenberg Reduction

It remains for us to show how the Hessenberg decomposition

$$U_0^T A U_0 = H \quad U_0^T U_0 = I$$

(7.4.3)

can be computed. The transformation $U_0$ can be computed as a product of Householder matrices $P_1, \ldots, P_{n-2}$. The role of $P_k$ is to zero the $k$th column below the subdiagonal. In the $n = 6$ case, we have

$$
\begin{bmatrix}
  \times & \times & \times & \times & \times & \times \\
  \times & \times & \times & \times & \times & \times \\
  \times & \times & \times & \times & \times & \times \\
  \times & \times & \times & \times & \times & \times \\
  \times & \times & \times & \times & \times & \times \\
  \times & \times & \times & \times & \times & \times \\
\end{bmatrix}
\quad P_1
\quad
\begin{bmatrix}
  \times & \times & \times & \times & \times & \times \\
  \times & \times & \times & \times & \times & \times \\
  0 & \times & \times & \times & \times & \times \\
  0 & 0 & \times & \times & \times & \times \\

\quad P_6
$$

In general, after $k - 1$ steps we have computed $k - 1$ Householder matrices $P_1, \ldots, P_{k-1}$ such that

$$(P_1 \cdots P_{k-1})^T A (P_1 \cdots P_{k-1}) = \begin{bmatrix} B_{11} & B_{12} & B_{13} \\ B_{21} & B_{22} & B_{23} \\ 0 & B_{32} & B_{33} \end{bmatrix} \begin{bmatrix} k - 1 \\ 1 \\ k - 1 \end{bmatrix}$$

$$= \begin{bmatrix} 1 & \cdots & 0 \\ 0 & \cdots & 1 \end{bmatrix}$$

is upper Hessenberg through its first $k - 1$ columns. Suppose $\bar{P}_k$ is an order $n - k$ Householder matrix such that $\bar{P}_k B_{32}$ is a multiple of $e_1^{(n-k)}$. If $P_k = \text{diag}(I_k, \bar{P}_k)$, then

$$(P_1 \cdots P_k)^T A (P_1 \cdots P_k) = \begin{bmatrix} B_{11} & B_{12} & B_{13} \bar{P}_k \\ B_{21} & B_{22} & B_{23} \bar{P}_k \\ 0 & \bar{P}_k B_{32} & \bar{P}_k B_{33} \bar{P}_k \end{bmatrix}$$
is upper Hessenberg through its first \( k \) columns. Repeating this for \( k = 1:n - 2 \) we obtain

Algorithm 7.4.2 (Householder Reduction to Hessenberg Form)
Given \( A \in \mathbb{R}^{n \times n} \), the following algorithm overwrites \( A \) with \( H = U_0^T A U_0 \) where \( H \) is upper Hessenberg and \( U_0 \) is product of Householder matrices.

\[
\begin{align*}
\text{for } k & = 1:n - 2 \\
& [v, \beta] = \text{house}(A(k + 1:n, k)) \\
& A(k + 1:n, k:n) = (I - \beta vv^T)A(k + 1:n, k:n) \\
& A(1:n, k + 1:n) = A(1:n, k + 1:n)(I - \beta vv^T)
\end{align*}
\]

end

This algorithm requires \( 10n^3/3 \) flops. If \( U_0 \) is explicitly formed, an additional \( 4n^3/3 \) flops are required. The \( k \)th Householder matrix can be represented in \( A(k + 2:n, k) \). See Martin and Wilkinson (1968d) for a detailed description.

The roundoff properties of this method for reducing \( A \) to Hessenberg form are very desirable. Wilkinson (1965, p.351) states that the computed Hessenberg matrix \( \tilde{H} \) satisfies \( \tilde{H} = Q^T(A + E)Q \), where \( Q \) is orthogonal and \( \| E \|_F \leq cn^2u\| A \|_F \) with \( c \) a small constant.

Example 7.4.2 If

\[
A = \begin{bmatrix} 1 & 5 & 7 \\ 3 & 0 & 6 \\ 4 & 3 & 1 \end{bmatrix} \quad \text{and} \quad U_0 = \begin{bmatrix} 1 & 0 & 0 \\ 0 & .6 & .8 \\ 0 & .8 & -.6 \end{bmatrix}
\]

then

\[
U_0^T A U_0 = H = \begin{bmatrix} 1.00 & 8.60 & -.20 \\ 5.00 & 4.96 & -.72 \\ 0.00 & 2.28 & -3.96 \end{bmatrix}
\]

7.4.4 Level-3 Aspects

The Hessenberg reduction (Algorithm 7.4.2) is rich in level-2 operations: half gaxpys and half outer product updates. We briefly discuss two methods for introducing level-3 computations into the process.

The first approach involves a block reduction to block Hessenberg form and is quite straightforward. Suppose (for clarity) that \( n = rN \) and write

\[
A = \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix} \begin{bmatrix} r \\ r \end{bmatrix} \quad n - r \quad n - r
\]

Suppose that we have computed the QR factorization \( A_{21} = \tilde{Q}_1 R_1 \) and that \( \tilde{Q}_1 \) is in WY form. That is, we have \( W_1, Y_1 \in \mathbb{R}^{(n-r) \times r} \) such that
\( \bar{Q}_1 = I - W_1 Y_1^T \). (See §5.2.2 for details.) If \( Q_1 = \text{diag}(I_r, \bar{Q}_1) \) then

\[
Q_1^T A Q_1 = \begin{bmatrix}
A_{11} & A_{12} \bar{Q}_1 \\
R_1 & \bar{Q}_1^T A_{22} \bar{Q}_1
\end{bmatrix}.
\]

Notice that the updates of the (1,2) and (2,2) blocks are rich in level-3 operations given that \( \bar{Q}_1 \) is in WY form. This fully illustrates the overall process as \( Q_1^T A Q_1 \) is block upper Hessenberg through its first block column. We next repeat the computations on the first \( r \) columns of \( \bar{Q}_1^T A_{22} \bar{Q}_1 \). After \( N - 2 \) such steps we obtain

\[
H = U_0^T A U_0 = \begin{bmatrix}
H_{11} & H_{12} & \cdots & \cdots & H_{1N} \\
H_{21} & H_{22} & \cdots & \cdots & H_{2N} \\
0 & \ddots & \ddots & \cdots & \vdots \\
\vdots & \ddots & \ddots & \ddots & \vdots \\
0 & 0 & \cdots & H_{N,N-1} & H_{NN}
\end{bmatrix}
\]

where each \( H_{ij} \) is \( r \)-by-\( r \) and \( U_0 = Q_1 \cdots Q_{N-2} \) with with each \( Q_i \) in WY form. The overall algorithm has a level-3 fraction of the form \( 1 - O(1/N) \).

Note that the subdiagonal blocks in \( H \) are upper triangular and so the matrix has lower bandwidth \( p \). It is possible to reduce \( H \) to actual Hessenberg form by using Givens rotations to zero all but the first subdiagonal.

Dongarra, Hammarling and Sorensen (1987) have shown how to proceed directly to Hessenberg form using a mixture of gaxpy's and level-3 updates. Their idea involves minimal updating after each Householder transformation is generated. For example, suppose the first Householder \( P_1 \) has been computed. To generate \( P_2 \) we need just the second column of \( P_1 A P_1 \), not the full outer product update. To generate \( P_3 \) we need just the 3rd column of \( P_2 P_1 A P_1 P_2 \), etc. In this way, the Householder matrices can be determined using only gaxpy operations. No outer product updates are involved. Once a suitable number of Householder matrices are known they can be aggregated and applied in a level-3 fashion.

### 7.4.5 Important Hessenberg Matrix Properties

The Hessenberg decomposition is not unique. If \( Z \) is any \( n \)-by-\( n \) orthogonal matrix and we apply Algorithm 7.4.2 to \( Z^T A Z \), then \( Q^T A Q = H \) is upper Hessenberg where \( Q = Z U_0 \). However, \( Q e_1 = Z(U_0 e_1) = Z e_1 \) suggesting that \( H \) is unique once the first column of \( Q \) is specified. This is essentially the case provided \( H \) has no zero subdiagonal entries. Hessenberg matrices with this property are said to be unreduced. Here is a very important theorem that clarifies the uniqueness of the Hessenberg reduction.

**Theorem 7.4.2 (Implicit Q Theorem)** Suppose \( Q = [q_1, \ldots, q_n] \) and \( V = [v_1, \ldots, v_n] \) are orthogonal matrices with the property that both \( Q^T A Q \)
7.4. THE HESSENBerg AND REAL SCHUR FORMS

$= H$ and $V^T A V = G$ are upper Hessenberg where $A \in \mathbb{R}^{n \times n}$. Let $k$ denote the smallest positive integer for which $h_{k+1,k} = 0$, with the convention that $k = n$ if $H$ is unreduced. If $q_i = v_1$, then $q_i = \pm v_i$ and $|h_{i,i-1}| = |g_{i,i-1}|$ for $i = 2:k$. Moreover, if $k < n$, then $g_{k+1,k} = 0$.

**Proof.** Define the orthogonal matrix $W = [w_1, \ldots, w_n] = V^T Q$ and observe that $GW = WH$. By comparing column $i - 1$ in this equation for $i = 2:k$ we see that

$$h_{i,i-1}w_i = Gw_{i-1} - \sum_{j=1}^{i-1} h_{j,i-1}w_j.$$ 

Since $w_1 = e_1$, it follows that $[w_1, \ldots, w_k]$ is upper triangular and thus $w_i = \pm I_n(:, i) = \pm e_i$ for $i = 2:k$. Since $w_i = V^T q_i$ and $h_{i,i-1} = w_i^T Gw_{i-1}$ it follows that $v_i = \pm q_i$ and

$$|h_{i,i-1}| = |q_i^T A q_{i-1}| = |v_i^T A v_{i-1}| = |g_{i,i-1}|$$

for $i = 2:k$. If $k < n$, then

$$g_{k+1,k} = e_{k+1}^T G e_k = e_{k+1}^T G W e_k = e_{k+1}^T W H e_k$$

$$= e_{k+1}^T \sum_{i=1}^{k} h_{ik} W e_i = \sum_{i=1}^{k} h_{ik} e_{k+1}^T e_i = 0.\Box$$

The gist of the implicit $Q$ theorem is that if $Q^T A Q = H$ and $Z^T A Z = G$ are each unreduced upper Hessenberg matrices and $Q$ and $Z$ have the same first column, then $G$ and $H$ are "essentially equal" in the sense that $G = D^{-1} H D$ where $D = \text{diag}(\pm 1, \ldots, \pm 1)$.

Our next theorem involves a new type of matrix called a Krylov matrix. If $A \in \mathbb{R}^{n \times n}$ and $v \in \mathbb{R}^n$, then the Krylov matrix $K(A, v, j) \in \mathbb{R}^{n \times j}$ is defined by

$$K(A, v, j) = [v, A v, \cdots, A^{j-1} v].$$

It turns out that there is a connection between the Hessenberg reduction $Q^T A Q = H$ and the QR factorization of the Krylov matrix $K(A, Q(:, 1), n)$.

**Theorem 7.4.3** Suppose $Q \in \mathbb{R}^{n \times n}$ is an orthogonal matrix and $A \in \mathbb{R}^{n \times n}$. Then $Q^T A Q = H$ is an unreduced upper Hessenberg matrix if and only if $Q^T K(A, Q(:, 1), n) = R$ is nonsingular and upper triangular.

**Proof.** Suppose $Q \in \mathbb{R}^{n \times n}$ is orthogonal and set $H = Q^T A Q$. Consider the identity

$$Q^T K(A, Q(:, 1), n) = [e_1, H e_1, \ldots, H^{n-1} e_1] \equiv R.$$ 

If $H$ is an unreduced upper Hessenberg matrix, then it is clear that $R$ is upper triangular with $r_{ii} = h_{21} h_{32} \cdots h_{i,i-1}$ for $i = 2:n$. Since $r_{11} = 1$ it follows that $R$ is nonsingular.
To prove the converse, suppose $R$ is upper triangular and nonsingular. Since $R(:, k + 1) = HR(:, k)$ it follows that $H(:, k) \in \text{span}\{ e_1, \ldots, e_{k+1} \}$. This implies that $H$ is upper Hessenberg. Since $r_{nn} = h_{21}h_{32} \cdots h_{n,n-1} \neq 0$ it follows that $H$ is also unreduced. □

Thus, there is more or less a correspondence between nonsingular Krylov matrices and orthogonal similarity reductions to unreduced Hessenberg form.

Our last result concerns eigenvalues of an unreduced upper Hessenberg matrix.

**Theorem 7.4.4** If $\lambda$ is an eigenvalue of an unreduced upper Hessenberg matrix $H \in \mathbb{R}^{n \times n}$, then its geometric multiplicity is one.

**Proof.** For any $\lambda \in \mathbb{C}$ we have rank$(A - \lambda I) \geq n - 1$ because the first $n - 1$ columns of $H - \lambda I$ are independent. □

### 7.4.6 Companion Matrix Form

Just as the Schur decomposition has a nonunitary analog in the Jordan decomposition, so does the Hessenberg decomposition have a nonunitary analog in the *companion matrix decomposition*. Let $x \in \mathbb{R}^n$ and suppose that the Krylov matrix $K = K(A, x, n)$ is nonsingular. If $c = c(0:n-1)$ solves the linear system $Kc = -A^nx$, then it follows that $AK = KC$ where $C$ has the form:

$$
C = \begin{bmatrix}
0 & 0 & \cdots & 0 & -c_0 \\
1 & 0 & \cdots & 0 & -c_1 \\
0 & 1 & \cdots & 0 & -c_2 \\
& \vdots & \vdots & \vdots & \vdots \\
0 & 0 & \cdots & 1 & -c_{n-1}
\end{bmatrix}.
$$

(7.4.4)

The matrix $C$ is said to be a *companion matrix*. Since

$$
\det(zI - C) = c_0 + c_1 z + \cdots + c_{n-1}z^{n-1} + z^n
$$

it follows that if $K$ is nonsingular, then the decomposition $K^{-1}AK = C$ displays $A$'s characteristic polynomial. This, coupled with the sparseness of $C$, has led to "companion matrix methods" in various application areas. These techniques typically involve:

- Computing the Hessenberg decomposition $U_0^T A U_0 = H$.
- Hoping $H$ is unreduced and setting $Y = [e_1, He_1, \ldots, H^{n-1}e_1]$.
- Solving $YC = HY$ for $C$. 
Unfortunately, this calculation can be highly unstable. \( A \) is similar to an unreduced Hessenberg matrix only if each eigenvalue has unit geometric multiplicity. Matrices that have this property are called nonderogatory. It follows that the matrix \( Y \) above can be very poorly conditioned if \( A \) is close to a derogatory matrix.

A full discussion of the dangers associated with companion matrix computation can be found in Wilkinson (1965, pp. 405 ff.).

### 7.4.7 Hessenberg Reduction Via Gauss Transforms

While we are on the subject of nonorthogonal reduction to Hessenberg form, we should mention that Gauss transformations can be used in lieu of Householder matrices in Algorithm 7.4.2. In particular, suppose permutations \( \Pi_1, \ldots, \Pi_{k-1} \) and Gauss transformations \( M_1, \ldots, M_{k-1} \) have been determined such that

\[
(M_{k-1} \Pi_{k-1} \cdots M_1 \Pi_1) A (M_{k-1} \Pi_{k-1} \cdots M_1 \Pi_1)^{-1} = B
\]

where

\[
B = \begin{bmatrix}
B_{11} & B_{12} & B_{13} \\
B_{21} & B_{22} & B_{23} \\
0 & B_{32} & B_{33}
\end{bmatrix}
\]

\[
= \begin{bmatrix}
k - 1 \\
1 \\
k - 1 & 1 & n - k
\end{bmatrix}
\]

is upper Hessenberg through its first \( k - 1 \) columns. A permutation \( \bar{\Pi}_k \) of order \( n - k \) is then determined such that the first element of \( \bar{\Pi}_k B_{32} \) is maximal in absolute value. This makes it possible to determine a stable Gauss transformation \( \bar{M}_k = I - z_k e_1^T \) also of order \( n - k \), such that all but the first component of \( \bar{M}_k (\bar{\Pi}_k B_{32}) \) is zero. Defining \( \Pi_k = \text{diag}(I_k, \bar{\Pi}_k) \) and \( M_k = \text{diag}(I_k, \bar{M}_k) \), we see that

\[
(M_k \Pi_k \cdots M_1 \Pi_1) A (M_k \Pi_k \cdots M_1 \Pi_1)^{-1} =
\begin{bmatrix}
B_{11} & B_{12} & B_{13} \bar{\Pi}_k^T \bar{M}_k^{-1} \\
B_{21} & B_{22} & B_{23} \bar{\Pi}_k^T \bar{M}_k^{-1} \\
0 & \bar{M}_k \bar{\Pi}_k B_{32} & \bar{M}_k \bar{\Pi}_k B_{33} \bar{\Pi}_k^T \bar{M}_k^{-1}
\end{bmatrix}
\]

is upper Hessenberg through its first \( k \) columns. Note that \( \bar{M}_k^{-1} = I + z_k e_1^T \) and so some very simple rank-one updates are involved in the reduction.

A careful operation count reveals that the Gauss reduction to Hessenberg form requires only half the number of flops of the Householder method. However, as in the case of Gaussian elimination with partial pivoting, there is a (fairly remote) chance of \( 2^n \) growth. See Businger (1969). Another difficulty associated with the Gauss approach is that the eigenvalue condition
numbers — the \( s(\lambda)^{-1} \) — are not preserved with nonorthogonal similarity transformations and this complicates the error estimation process.

Problems

P7.4.1 Suppose \( A \in \mathbb{R}^{n \times n} \) and \( z \in \mathbb{R}^n \). Give a detailed algorithm for computing an orthogonal \( Q \) such that \( Q^T AQ \) is upper Hessenberg and \( Q^T z \) is a multiple of \( e_1 \). (Hint: Reduce \( z \) first and then apply Algorithm 7.4.2.)

P7.4.2 Specify a complete reduction to Hessenberg form using Gauss transformations and verify that it only requires \( 5n^3/3 \) flops.

P7.4.3 In some situations, it is necessary to solve the linear system \( (A + zI)x = b \) for many different values of \( z \in \mathbb{R} \) and \( b \in \mathbb{R}^n \). Show how this problem can be efficiently and stably solved using the Hessenberg decomposition.

P7.4.4 Give a detailed algorithm for explicitly computing the matrix \( U_0 \) in Algorithm 7.4.2. Design your algorithm so that \( H \) is overwritten by \( U_0 \).

P7.4.5 Suppose \( H \in \mathbb{R}^{n \times n} \) is an unreduced upper Hessenberg matrix. Show that there exists a diagonal matrix \( D \) such that each subdiagonal element of \( D^{-1}HD \) is equal to one. What is \( \kappa_2(D) \)?

P7.4.6 Suppose \( W, Y \in \mathbb{R}^{n \times n} \) and define the matrices \( C \) and \( B \) by

\[
C = W + iY, \quad B = \begin{bmatrix} W & -Y \\ Y & W \end{bmatrix}
\]

Show that if \( \lambda \in \lambda(C) \) is real, then \( \lambda \in \lambda(B) \). Relate the corresponding eigenvectors.

P7.4.7 Suppose \( A = \begin{bmatrix} w & x \\ y & z \end{bmatrix} \) is a real matrix having eigenvalues \( \lambda \pm i\mu \), where \( \mu \) is nonzero. Give an algorithm that stably determines \( c = \cos(\theta) \) and \( s = \sin(\theta) \) such that

\[
\begin{bmatrix} c & s \\ -s & c \end{bmatrix}^T \begin{bmatrix} w & x \\ y & z \end{bmatrix} \begin{bmatrix} c & s \\ -s & c \end{bmatrix} = \begin{bmatrix} \lambda & \beta \\ \alpha & \lambda \end{bmatrix}
\]

where \( \alpha\beta = -\mu^2 \).

P7.4.8 Suppose \( (\lambda, x) \) is a known eigenvalue-eigenvector pair for the upper Hessenberg matrix \( H \in \mathbb{R}^{n \times n} \). Give an algorithm for computing an orthogonal matrix \( P \) such that

\[
P^T HP = \begin{bmatrix} \lambda & w^T \\ 0 & H_1 \end{bmatrix}
\]

where \( H_1 \in \mathbb{R}^{(n-1) \times (n-1)} \) is upper Hessenberg. Compute \( P \) as a product of Givens rotations.

P7.4.9 Suppose \( H \in \mathbb{R}^{n \times n} \) has lower bandwidth \( p \). Show how to compute \( Q \in \mathbb{R}^{n \times n} \), a product of Givens rotations, such that \( Q^T HQ \) is upper Hessenberg. How many flops are required?

P7.4.10 Show that if \( C \) is a companion matrix with distinct eigenvalues \( \lambda_1, \ldots, \lambda_n \), then

\[
VCV^{-1} = \text{diag}(\lambda_1, \ldots, \lambda_n)
\]

where

\[
V = \begin{bmatrix} 1 & \lambda_1 & \cdots & \lambda_1^{n-1} \\ 1 & \lambda_2 & \cdots & \lambda_2^{n-1} \\ \vdots & \vdots & \ddots & \vdots \\ 1 & \lambda_n & \cdots & \lambda_n^{n-1} \end{bmatrix}
\]

Notes and References for Sec. 7.4

The real Schur decomposition was originally presented in
7.4. THE HESSENBERG AND REAL SCHUR FORMS

A thorough treatment of the reduction to Hessenberg form is given in Wilkinson (1965, chapter 6), and Algol procedures for both the Householder and Gauss methods appear in

Fortran versions of the Algol procedures in the last reference are in Eispack.

Givens rotations can also be used to compute the Hessenberg decomposition. See

The high performance computation of the Hessenberg reduction is discussed in

The possibility of exponential growth in the Gauss transformation approach was first pointed out in

However, the algorithm should be regarded in the same light as Gaussian elimination with partial pivoting—stable for all practical purposes. See Eispack, pp. 56–58.

Aspects of the Hessenberg decomposition for sparse matrices are discussed in

Once an eigenvalue of an unreduced upper Hessenberg matrix is known, it is possible to zero the last subdiagonal entry using Givens similarity transformations. See

Some interesting mathematical properties of the Hessenberg form may be found in

Although the Hessenberg decomposition is largely appreciated as a "front end" decomposition for the QR iteration, it is increasingly popular as a cheap alternative to the more expensive Schur decomposition in certain problems. For a sampling of applications where it has proven to be very useful, consult

7.5 The Practical QR Algorithm

We return to the Hessenberg QR iteration which we write as follows:

\[ H = U_0^T A U_0 \quad \text{(Hessenberg Reduction)} \]

for \( k = 1, 2, \ldots \)

\[ H = UR \quad \text{(QR factorization)} \] \hspace{1cm} (7.5.1)

\[ H = RU \]

end

Our aim in this section is to describe how the \( H \)'s converge to upper quasi-triangular form and to show how the convergence rate can be accelerated by incorporating shifts.

7.5.1 Deflation

Without loss of generality we may assume that each Hessenberg matrix \( H \) in (7.5.1) is unreduced. If not, then at some stage we have

\[ H = \begin{bmatrix} H_{11} & H_{12} \\ 0 & H_{22} \end{bmatrix} \begin{bmatrix} p \\ n-p \end{bmatrix} \begin{bmatrix} n-p \\ p \end{bmatrix} \]

where \( 1 \leq p < n \) and the problem decouples into two smaller problems involving \( H_{11} \) and \( H_{22} \). The term deflation is also used in this context, usually when \( p = n - 1 \) or \( n - 2 \).

In practice, decoupling occurs whenever a subdiagonal entry in \( H \) is suitably small. For example, in Eispack if

\[ |h_{p+1,p}| \leq cu(|h_{pp}| + |h_{p+1,p+1}|) \] \hspace{1cm} (7.5.2)
for a small constant \(c\), then \(h_{p+1,p}\) is "declared" to be zero. This is justified
since rounding errors of order \(u\|H\|\) are already present throughout the
matrix.

### 7.5.2 The Shifted QR Iteration

Let \(\mu \in \mathbb{R}\) and consider the iteration:

\[
H = U_0^T A U_0 \quad \text{(Hessenberg Reduction)}
\]

for \(k = 1, 2, \ldots\)

Determine a scalar \(\mu\).

\[
H - \mu I = UR \quad \text{(QR factorization) \quad (7.5.3)}
\]

\[
H = RU + \mu I
\]

end

The scalar \(\mu\) is referred to as a shift. Each matrix \(H\) generated in (7.5.3)
is similar to \(A\), since \(RU + \mu I = U^T(UR + \mu I)U = U^THU\). If we order
the eigenvalues \(\lambda_i\) of \(A\) so that

\[
|\lambda_1 - \mu| \geq \cdots \geq |\lambda_n - \mu|,
\]

and \(\mu\) is fixed from iteration to iteration, then the theory of §7.3 says that
the \(p\)th subdiagonal entry in \(H\) converges to zero with rate

\[
\left| \frac{\lambda_{p+1} - \mu}{\lambda_p - \mu} \right|^k.
\]

Of course, if \(\lambda_p = \lambda_{p+1}\), then there is no convergence at all. But if, for
example, \(\mu\) is much closer to \(\lambda_n\) than to the other eigenvalues, then the
zeroing of the \((n,n-1)\) entry is rapid. In the extreme case we have the following:

**Theorem 7.5.1** Let \(\mu\) be an eigenvalue of an \(n\)-by-\(n\) unreduced Hessenberg
matrix \(H\). If \(\tilde{H} = RU + \mu I\), where \(H - \mu I = UR\) is the QR factorization
of \(H - \mu I\), then \(\tilde{h}_{n,n-1} = 0\) and \(\tilde{h}_{nn} = \mu\).

**Proof.** Since \(H\) is an unreduced Hessenberg matrix the first \(n-1\) columns
of \(H - \mu I\) are independent, regardless of \(\mu\). Thus, if \(UR = (H - \mu I)\) is the
QR factorization then \(r_{ii} \neq 0\) for \(i = 1:n-1\). But if \(H - \mu I\) is singular then
\(r_{11} \cdots r_{nn} = 0\). Thus, \(r_{nn} = 0\) and \(\tilde{H}(n,:) = [0, \ldots, 0, \mu]\).

The theorem says that if we shift by an exact eigenvalue, then in exact
arithmetic deflation occurs in one step.

**Example 7.5.1** If

\[
H = \begin{bmatrix}
9 & -1 & -2 \\
2 & 6 & -2 \\
0 & 1 & 5
\end{bmatrix},
\]
then $6 \in \lambda(H)$. If $UR = H - 6I$ is the QR factorization, then $\bar{H} = RU + 6I$ is given by

$$
\bar{H} = \begin{bmatrix}
8.5384 & -3.7313 & -1.0090 \\
0.6343 & 5.4615 & 1.3867 \\
0.0000 & 0.0000 & 6.0000
\end{bmatrix}.
$$

### 7.5.3 The Single Shift Strategy

Now let us consider varying $\mu$ from iteration to iteration incorporating new information about $\lambda(A)$ as the subdiagonal entries converge to zero. A good heuristic is to regard $h_{nn}$ as the best approximate eigenvalue along the diagonal. If we shift by this quantity during each iteration, we obtain the single-shift QR iteration:

```
for $k = 1, 2, \ldots$
    $\mu = H(n, n)$
    $H - \mu I = UR$ (QR Factorization)
    $H = RU + \mu I$
end
```

(7.5.4)

If the $(n, n-1)$ entry converges to zero, it is likely to do so at a quadratic rate. To see this, we borrow an example from Stewart (1973, p. 366). Suppose $H$ is an unreduced upper Hessenberg matrix of the form

$$
H = \begin{bmatrix}
\times & \times & \times & \times \\
\times & \times & \times & \times \\
0 & \times & \times & \times \\
0 & 0 & \times & \times \\
0 & 0 & 0 & \epsilon & h_{nn}
\end{bmatrix}
$$

and that we perform one step of the single-shift QR algorithm: $UR = H - h_{nn}I$, $\bar{H} = RU + h_{nn}I$. After $n-2$ steps in the reduction of $H - h_{nn}I$ to upper triangular form we obtain a matrix with the following structure:

$$
\bar{H} = \begin{bmatrix}
\times & \times & \times & \times \\
0 & \times & \times & \times \\
0 & 0 & \times & \times \\
0 & 0 & 0 & a & b \\
0 & 0 & 0 & \epsilon & 0
\end{bmatrix}
$$

It is not hard to show that the $(n, n-1)$ entry in $\bar{H} = RU + h_{nn}I$ is given by $-\epsilon^2 b / (\epsilon^2 + a^2)$. If we assume that $\epsilon \ll a$, then it is clear that
the new \((n, n - 1)\) entry has order \(e^2\), precisely what we would expect of a quadratically converging algorithm.

**Example 7.5.2** If

\[
H = \begin{bmatrix}
1 & 2 & 3 \\
4 & 5 & 6 \\
0 & 0.001 & 7
\end{bmatrix}
\]

and \(UR = H - 7I\) is the QR factorization, then \(\tilde{H} = RU + 7I\) is given by

\[
\tilde{H} \approx \begin{bmatrix}
-0.5384 & 1.6908 & 0.8351 \\
0.3076 & 6.5264 & -6.6555 \\
0.0000 & 2 \cdot 10^{-5} & 7.0119
\end{bmatrix}.
\]

Near-perfect shifts as above almost always ensure a small \(\tilde{h}_{n,n-1}\). However, this is just a heuristic. There are examples in which \(\tilde{h}_{n,n-1}\) is a relatively large matrix entry even though \(\sigma_{min}(H - \mu I) \approx u\).

### 7.5.4 The Double Shift Strategy

Unfortunately, difficulties with (7.5.4) can be expected if at some stage the eigenvalues \(a_1\) and \(a_2\) of

\[
G = \begin{bmatrix}
h_{mm} & h_{mn} \\
h_{nm} & h_{nn}
\end{bmatrix} \quad m = n - 1
\]

are complex for then \(h_{nn}\) would tend to be a poor approximate eigenvalue.

A way around this difficulty is to perform two single-shift QR steps in succession using \(a_1\) and \(a_2\) as shifts:

\[
\begin{align*}
H - a_1I &= U_1R_1 \\
H_1 &= R_1U_1 + a_1I \\
H_1 - a_2I &= U_2R_2 \\
H_2 &= R_2U_2 + a_2I
\end{align*}
\]

These equations can be manipulated to show that

\[
(U_1U_2)(R_2R_1) = M
\]

where \(M\) is defined by

\[
M = (H - a_1I)(H - a_2I).
\]

Note that \(M\) is a real matrix even if \(G\)'s eigenvalues are complex since

\[
M = H^2 - sH + tI
\]

where

\[
s = a_1 + a_2 = h_{mm} + h_{nn} = \text{trace}(G) \in \mathbb{R}
\]
and
\[ t = a_1a_2 = h_{mm}h_{nn} - h_{mn}h_{nm} = \det(G) \in \mathbb{R}. \]

Thus, (7.5.7) is the QR factorization of a real matrix and we may choose \( U_1 \) and \( U_2 \) so that \( Z = U_1U_2 \) is real orthogonal. It then follows that
\[ H_2 = U_2^H H_1 U_2 = U_2^H (U_1^H H U_1) U_2 = (U_1 U_2)^H H (U_1 U_2) = Z^T H Z. \]
is real.

Unfortunately, roundoff error almost always prevents an exact return to the real field. A real \( H_2 \) could be guaranteed if we

- explicitly form the real matrix \( M = H^2 - sH + tI \),
- compute the real QR factorization \( M = ZR \), and
- set \( H_2 = Z^T H Z \).

But since the first of these steps requires \( O(n^3) \) flops, this is not a practical course of action.

### 7.5.5 The Double Implicit Shift Strategy

Fortunately, it turns out that we can implement the double shift step with \( O(n^2) \) flops by appealing to the Implicit Q Theorem of §7.4.5. In particular we can effect the transition from \( H \) to \( H_2 \) in \( O(n^2) \) flops if we

- compute \( Me_1 \), the first column of \( M \);
- determine a Householder matrix \( P_0 \) such that \( P_0(Me_1) \) is a multiple of \( e_1 \);
- compute Householder matrices \( P_1, \ldots, P_{n-2} \) such that if \( Z_1 \) is the product \( Z_1 = P_0 P_1 \cdots P_{n-2} \), then \( Z_1^T H Z_1 \) is upper Hessenberg and the first columns of \( Z \) and \( Z_1 \) are the same.

Under these circumstances, the Implicit \( Q \) theorem permits us to conclude that if \( Z^T H Z \) and \( Z_1^T H Z_1 \) are both unreduced upper Hessenberg matrices, then they are essentially equal. Note that if these Hessenberg matrices are not unreduced, then we can effect a decoupling and proceed with smaller unreduced subproblems.

Let us work out the details. Observe first that \( P_0 \) can be determined in \( O(1) \) flops since \( Me_1 = [x, y, z, 0, \ldots, 0]^T \) where
\[
x = h_{11}^2 + h_{12} h_{21} - sh_{11} + t \\
y = h_{21} (h_{11} + h_{22} - s) \\
z = h_{21} h_{32}.
\]
Since a similarity transformation with $P_0$ only changes rows and columns 1, 2, and 3, we see that

$$P_0 H P_0 = \begin{bmatrix}
  * & * & * & * & * & * \\
  * & * & * & * & * & * \\
  * & * & * & * & * & * \\
  * & * & * & * & * & * \\
  0 & 0 & 0 & * & * & * \\
  0 & 0 & 0 & 0 & * & * \\
\end{bmatrix}$$

Now the mission of the Householder matrices $P_1, \ldots, P_{n-2}$ is to restore this matrix to upper Hessenberg form. The calculation proceeds as follows:

$$\begin{bmatrix}
  * & * & * & * & * & * \\
  * & * & * & * & * & * \\
  * & * & * & * & * & * \\
  * & * & * & * & * & * \\
  0 & 0 & 0 & * & * & * \\
  0 & 0 & 0 & 0 & * & * \\
\end{bmatrix} \rightarrow \begin{bmatrix}
  * & * & * & * & * & * \\
  * & * & * & * & * & * \\
  * & * & * & * & * & * \\
  * & * & * & * & * & * \\
  0 & 0 & 0 & * & * & * \\
  0 & 0 & 0 & 0 & * & * \\
\end{bmatrix} \rightarrow \begin{bmatrix}
  * & * & * & * & * & * \\
  * & * & * & * & * & * \\
  * & * & * & * & * & * \\
  * & * & * & * & * & * \\
  0 & 0 & 0 & * & * & * \\
  0 & 0 & 0 & 0 & * & * \\
\end{bmatrix} \rightarrow \begin{bmatrix}
  * & * & * & * & * & * \\
  * & * & * & * & * & * \\
  * & * & * & * & * & * \\
  * & * & * & * & * & * \\
  0 & 0 & 0 & * & * & * \\
  0 & 0 & 0 & 0 & * & * \\
\end{bmatrix} \rightarrow \begin{bmatrix}
  * & * & * & * & * & * \\
  * & * & * & * & * & * \\
  * & * & * & * & * & * \\
  * & * & * & * & * & * \\
  0 & 0 & 0 & * & * & * \\
  0 & 0 & 0 & 0 & * & * \\
\end{bmatrix}$$

Clearly, the general $P_k$ has the form $P_k = \text{diag}(I_k, \bar{P}_k, I_{n-k-3})$ where $\bar{P}_k$ is a 3-by-3 Householder matrix. For example,

$$P_2 = \begin{bmatrix}
  1 & 0 & 0 & 0 & 0 & 0 \\
  0 & 1 & 0 & 0 & 0 & 0 \\
  0 & 0 & * & * & * & 0 \\
  0 & 0 & * & * & * & 0 \\
  0 & 0 & * & * & * & 0 \\
  0 & 0 & 0 & 0 & 0 & 1 \\
\end{bmatrix}$$

Note that $P_{n-2}$ is an exception to this since $P_{n-2} = \text{diag}(I_{n-2}, \bar{P}_{n-2})$.

The applicability of Theorem 7.4.3 (the Implicit $Q$ theorem) follows from the observation that $P_k e_1 = e_1$ for $k = 1:n-2$ and that $P_0$ and $Z$
have the same first column. Hence, \( Z_1 e_1 = Z e_1 \), and we can assert that \( Z_1 \) essentially equals \( Z \) provided that the upper Hessenberg matrices \( Z^T H Z \) and \( Z_1^T H Z_1 \) are each unreduced.

The implicit determination of \( H_2 \) from \( H \) outlined above was first described by Francis (1961) and we refer to it as a Francis QR step. The complete Francis step is summarized as follows:

**Algorithm 7.5.1 (Francis QR Step)** Given the unreduced upper Hessenberg matrix \( H \in \mathbb{R}^{n \times n} \) whose trailing 2-by-2 principal submatrix has eigenvalues \( a_1 \) and \( a_2 \), this algorithm overwrites \( H \) with \( Z^T H Z \), where \( Z = P_1 \cdots P_{n-2} \) is a product of Householder matrices and \( Z^T (H - a_1 I)(H - a_2 I) \) is upper triangular.

\[
m = n - 1
\]

\{Compute first column of \((H - a_1 I)(H - a_2 I)\).\}

\[
s = H(m, m) + H(n, n)
\]

\[
t = H(m, m)H(n, n) - H(m, n)H(n, m)
\]

\[
x = H(1, 1)H(1, 1) + H(1, 2)H(2, 1) - s H(1, 1) + t
\]

\[
y = H(2, 1)(H(1, 1) + H(2, 2) - s)
\]

\[
z = H(2, 1)H(3, 2)
\]

\textbf{for} \( k = 0:n - 3 \)

\[
[v, \beta] = \text{house}([x \ y \ z]^T)
\]

\[
g = \max\{1, k\}.
\]

\[
H(k + 1:k + 3, g:n) = (I - \beta vv^T)H(k + 1:k + 3, g:n)
\]

\[
r = \min\{k + 4, n\}
\]

\[
H(1:r, k + 1:k + 3) = H(1:r, k + 1:k + 3)(I - \beta vv^T)
\]

\[
x = H(k + 2, k + 1)
\]

\[
y = H(k + 3, k + 1)
\]

\textbf{if} \( k < n - 3 \)

\[
z = H(k + 4, k + 1)
\]

\textbf{end}

\[
[v, \beta] = \text{house}([x \ y]^T)
\]

\[
H(n - 1:n, n - 2:n) = (I - \beta vv^T)H(n - 1:n, n - 2:n)
\]

\[
H(1:n, n - 1:n) = H(1:n, n - 1:n)(I - \beta vv^T)
\]

This algorithm requires \( 10n^2 \) flops. If \( Z \) is accumulated into a given orthogonal matrix, an additional \( 10n^2 \) flops are necessary.

### 7.5.6 The Overall Process

Reducing \( A \) to Hessenberg form using Algorithm 7.4.2 and then iterating with Algorithm 7.5.1 to produce the real Schur form is the standard means by which the dense unsymmetric eigenproblem is solved. During the iteration it is necessary to monitor the subdiagonal elements in \( H \) in order to
spot any possible decoupling. How this is done is illustrated in the following algorithm:

**Algorithm 7.5.2 (QR Algorithm)** Given \( A \in \mathbb{R}^{n \times n} \) and a tolerance \( tol \) greater than the unit roundoff, this algorithm computes the real Schur canonical form \( Q^T A Q = T \). \( A \) is overwritten with the Hessenberg decomposition. If \( Q \) and \( T \) are desired, then \( T \) is stored in \( H \). If only the eigenvalues are desired, then diagonal blocks in \( T \) are stored in the corresponding positions in \( H \).

Use Algorithm 7.4.2 to compute the Hessenberg reduction

\[
H = U_0^T A U_0 \quad \text{where} \quad U_0 = P_1 \cdots P_{n-2}.
\]

If \( Q \) is desired form \( Q = P_1 \cdots P_{n-2} \). See §5.1.6.

**until** \( q = n \)

Set to zero all subdiagonal elements that satisfy:

\[
|h_{i,i-1}| \leq tol(|h_{ii}| + |h_{i-1,i-1}|).
\]

Find the largest non-negative \( q \) and the smallest non-negative \( p \) such that

\[
H = \begin{bmatrix}
H_{11} & H_{12} & H_{13} \\
0 & H_{22} & H_{23} \\
0 & 0 & H_{33}
\end{bmatrix}
\begin{bmatrix}
p \\
n-p-q \\
q
\end{bmatrix}
\begin{bmatrix}
p \\
n-p-q \\
q
\end{bmatrix}
\]

where \( H_{33} \) is upper quasi-triangular and \( H_{22} \) is unreduced. (Note: either \( p \) or \( q \) may be zero.)

**if** \( q < n \)

Perform a Francis QR step on \( H_{22} \): \( H_{22} = Z^T H_{22} Z \)

**if** \( Q \) is desired

\[
Q = Q \text{diag}(I_p, Z, I_q)
\]

\[
H_{12} = H_{12} Z
\]

\[
H_{23} = Z^T H_{23}
\]

**end**

**end**

Upper triangularize all 2-by-2 diagonal blocks in \( H \) that have real eigenvalues and accumulate the transformations if necessary.

This algorithm requires \( 25n^3 \) flops if \( Q \) and \( T \) are computed. If only the eigenvalues are desired, then \( 10n^3 \) flops are necessary. These flops counts are very approximate and are based on the empirical observation that on average only two Francis iterations are required before the lower 1-by-1 or
2-by-2 decouples.

Example 7.5.3 If Algorithm 7.5.2 is applied to

\[
A = \begin{bmatrix}
2 & 3 & 4 & 5 & 6 \\
4 & 4 & 5 & 6 & 7 \\
0 & 3 & 6 & 7 & 8 \\
0 & 0 & 2 & 8 & 9 \\
0 & 0 & 0 & 1 & 10
\end{bmatrix},
\]

then the subdiagonal entries converge as follows

<table>

</table>

The roundoff properties of the QR algorithm are what one would expect of any orthogonal matrix technique. The computed real Schur form \(\hat{T}\) is orthogonally similar to a matrix near to \(A\), i.e.,

\[Q^T(A + E)Q = \hat{T}\]

where \(Q^TQ = I\) and \(\|E\|_2 \approx u\|A\|_2\). The computed \(\hat{Q}\) is almost orthogonal in the sense that \(\hat{Q}^T\hat{Q} = I + F\) where \(\|F\|_2 \approx u\).

The order of the eigenvalues along \(\hat{T}\) is somewhat arbitrary. But as we discuss in §7.6, any ordering can be achieved by using a simple procedure for swapping two adjacent diagonal entries.

### 7.5.7 Balancing

Finally, we mention that if the elements of \(A\) have widely varying magnitudes, then \(A\) should be balanced before applying the QR algorithm. This is an \(O(n^2)\) calculation in which a diagonal matrix \(D\) is computed so that if

\[D^{-1}AD = [c_1, \ldots, c_n] = \begin{bmatrix} r_1^T \\ \vdots \\ r_n^T \end{bmatrix}\]

then \(\|r_i\|_\infty \approx \|c_i\|_\infty\) for \(i = 1:n\). The diagonal matrix \(D\) is chosen to have the form \(D = \text{diag}(\beta^{i_1}, \ldots, \beta^{i_n})\) where \(\beta\) is the floating point base. Note
that $D^{-1}AD$ can be calculated without roundoff. When $A$ is balanced, the computed eigenvalues are often more accurate. See Parlett and Reinsch (1969).

**Problems**

P7.5.1 Show that if $\tilde{H} = Q^T HQ$ is obtained by performing a single-shift QR step with $H = \begin{bmatrix} w & x \\ y & z \end{bmatrix}$, then $|\tilde{h}_{21}| \leq |y^2 z|/((w-z)^2 + y^2)$.

P7.5.2 Give a formula for the 2-by-2 diagonal matrix $D$ that minimizes $\|D^{-1}AD\|_F$ where $A = \begin{bmatrix} w & x \\ y & z \end{bmatrix}$.

P7.5.3 Explain how the single-shift QR step $H - \mu I = UR$, $\tilde{H} = RU + \mu I$ can be carried out implicitly. That is, show how the transition from $\tilde{H}$ to $H$ can be carried out without subtracting the shift $\mu$ from the diagonal of $H$.

P7.5.4 Suppose $H$ is upper Hessenberg and that we compute the factorization $PH = LU$ via Gaussian elimination with partial pivoting. (See Algorithm 4.3.4.) Show that $H_1 = U(P^TL)$ is upper Hessenberg and similar to $H$. (This is the basis of the modified LR algorithm.)

P7.5.5 Show that if $H = H_0$ is given and we generate the matrices $H_k$ via $H_k - \mu_k I = U_k R_k$, $H_{k+1} = R_k U_k + \mu_k I$, then

$$(U_1 \cdots U_j)(R_j \cdots R_1) = (H - \mu_1 I) \cdots (H - \mu_j I).$$

**Notes and References for Sec. 7.5**

The development of the practical QR algorithm began with the important paper

The algorithm described here was then “orthogonalized” in

Descriptions of the practical QR algorithm may be found in Wilkinson (1965) and Stewart (1973), and Watkins (1991). See also

### 7.6 Invariant Subspace Computations

Several important invariant subspace problems can be solved once the real Schur decomposition $Q^TAQ = T$ has been computed. In this section we discuss how to

- compute the eigenvectors associated with some subset of $\lambda(A)$,
- compute an orthonormal basis for a given invariant subspace,
- block-diagonalize $A$ using well-conditioned similarity transformations,
- compute a basis of eigenvectors regardless of their condition, and
- compute an approximate Jordan canonical form of $A$.

Eigenvector/invariant subspace computation for sparse matrices is discussed elsewhere. See §7.3 as well as portions of Chapters 8 and 9.

#### 7.6.1 Selected Eigenvectors via Inverse Iteration

Let $q^{(0)} \in \mathbb{C}^n$ be a given unit 2-norm vector and assume that $A - \mu I \in \mathbb{R}^{n \times n}$ is nonsingular. The following is referred to as inverse iteration:

\[
\text{for } k = 1, 2, \ldots \n
\text{Solve } (A - \mu I)z^{(k)} = q^{(k-1)} \n
q^{(k)} = z^{(k)} / \| z^{(k)} \|_2 \n
\lambda^{(k)} = q^{(k)T} A q^{(k)} \tag{7.6.1} \n\text{end}
\]
Inverse iteration is just the power method applied to \((A - \mu I)^{-1}\).

To analyze the behavior of (7.6.1), assume that \(A\) has a basis of eigenvectors \(\{x_1, \ldots, x_n\}\) and that \(Ax_i = \lambda_i x_i\) for \(i = 1:n\). If

\[ q^{(0)} = \sum_{i=1}^{n} \beta_i x_i \]

then \(q^{(k)}\) is a unit vector in the direction of

\[ (A - \mu I)^{-k} q^{(0)} = \sum_{i=1}^{n} \frac{\beta_i}{(\lambda_i - \mu)^k} x_i. \]

Clearly, if \(\mu\) is much closer to an eigenvalue \(\lambda_j\) than to the other eigenvalues, then \(q^{(k)}\) is rich in the direction of \(x_j\) provided \(\beta_j \neq 0\).

A sample stopping criterion for (7.6.1) might be to quit as soon as the residual

\[ r^{(k)} = (A - \mu I)q^{(k)} \]

satisfies

\[ \| r^{(k)} \|_\infty \leq c u \| A \|_\infty \]  \hspace{1cm} (7.6.2)

where \(c\) is a constant of order unity. Since

\[ (A + E_k)q^{(k)} = \mu q^{(k)} \]

with \(E_k = -r^{(k)}q^{(k)T}\), it follows that (7.6.2) forces \(\mu\) and \(q^{(k)}\) to be an exact eigenpair for a nearby matrix.

Inverse iteration can be used in conjunction with the QR algorithm as follows:

- Compute the Hessenberg decomposition \(U_0^T A U_0 = H\).

- Apply the double implicit shift Francis iteration to \(H\) without accumulating transformations.

- For each computed eigenvalue \(\lambda\) whose corresponding eigenvector \(x\) is sought, apply (7.6.1) with \(A = H\) and \(\mu = \lambda\) to produce a vector \(z\) such that \(Hz \approx \mu z\).

- Set \(x = U_0 z\).

Inverse iteration with \(H\) is very economical because (1) we do not have to accumulate transformations during the double Francis iteration; (2) we can factor matrices of the form \(H - \lambda I\) in \(O(n^2)\) flops, and (3) only one iteration is typically required to produce an adequate approximate eigenvector.
This last point is perhaps the most interesting aspect of inverse iteration and requires some justification since \( \lambda \) can be comparatively inaccurate if it is ill-conditioned. Assume for simplicity that \( \lambda \) is real and let

\[
H - \lambda I = \sum_{i=1}^{n} \sigma_i u_i v_i^T = U \Sigma V^T
\]

be the SVD of \( H - \lambda I \). From what we said about the roundoff properties of the QR algorithm in \( \S 7.5.6 \), there exists a matrix \( E \in \mathbb{R}^{n \times n} \) such that \( H + E - \lambda I \) is singular and \( \| E \|_2 \approx u \| H \|_2 \). It follows that \( \sigma_n \approx u \sigma_1 \) and \( \| (H - \lambda I)v_n \|_2 \approx u \sigma_1 \), i.e., \( v_n \) is a good approximate eigenvector. Clearly if the starting vector \( q^{(0)} \) has the expansion

\[
q^{(0)} = \sum_{i=1}^{n} \gamma_i u_i
\]

then

\[
z^{(1)} = \sum_{i=1}^{n} \frac{\gamma_i}{\sigma_i} v_i
\]

is "rich" in the direction \( v_n \). Note that if \( s(\lambda) \approx |u_n^T v_n| \) is small, then \( z^{(1)} \) is rather deficient in the direction \( u_n \). This explains (heuristically) why another step of inverse iteration is not likely to produce an improved eigenvector approximate, especially if \( \lambda \) is ill-conditioned. For more details, see Peters and Wilkinson (1979).

Example 7.6.1 The matrix

\[
A = \begin{bmatrix}
1 & 1 \\
10^{-10} & 1
\end{bmatrix}
\]

has eigenvalues \( \lambda_1 = .99999 \) and \( \lambda_2 = 1.00001 \) and corresponding eigenvectors \( z_1 = [1, -10^{-5}]^T \) and \( z_2 = [1, 10^{-5}]^T \). The condition of both eigenvalues is of order \( 10^5 \). The approximate eigenvalue \( \mu = 1 \) is an exact eigenvalue of \( A + E \) where

\[
E = \begin{bmatrix}
0 & 0 \\
-10^{-10} & 0
\end{bmatrix}
\]

Thus, the quality of \( \mu \) is typical of the quality of an eigenvalue produced by the QR algorithm when executed in 10-digit floating point.

If (7.6.1) is applied with starting vector \( q^{(0)} = [0, 1]^T \), then \( q^{(1)} = [1, 0]^T \) and \( \| Aq^{(1)} - \mu q^{(1)} \|_2 = 10^{-10} \). However, one more step produces \( q^{(2)} = [0, 1]^T \) for which \( \| Aq^{(2)} - \mu q^{(2)} \|_2 = 1 \). This example is discussed in Peters and Wilkinson (1979).
7.6.2 Ordering Eigenvalues in the Real Schur Form

Recall that the real Schur decomposition provides information about invariant subspaces. If

\[ Q^T AQ = T = \begin{bmatrix} T_{11} & T_{12} \\ 0 & T_{22} \end{bmatrix} \begin{bmatrix} p \\ q \end{bmatrix} \]

and \( \lambda(T_{11}) \cap \lambda(T_{22}) = \emptyset \), then the first \( p \) columns of \( Q \) span the unique invariant subspace associated with \( \lambda(T_{11}) \). (See §7.1.4.) Unfortunately, the Francis iteration supplies us with a real Schur decomposition \( Q^T_F A Q_F = T_F \) in which the eigenvalues appear somewhat randomly along the diagonal of \( T_F \). This poses a problem if we want an orthonormal basis for an invariant subspace whose associated eigenvalues are not at the top of \( T_F \)'s diagonal. Clearly, we need a method for computing an orthogonal matrix \( Q_D \) such that \( Q^T_D T_F Q_D \) is upper quasi-triangular with appropriate eigenvalue ordering.

A look at the 2-by-2 case suggests how this can be accomplished. Suppose

\[ Q^T_F A Q_F = T_F = \begin{bmatrix} \lambda_1 & t_{12} \\ 0 & \lambda_2 \end{bmatrix} \quad \lambda_1 \neq \lambda_2 \]

and that we wish to reverse the order of the eigenvalues. Note that \( T_F x = \lambda_2 x \) where

\[ x = \begin{bmatrix} t_{12} \\ \lambda_2 - \lambda_1 \end{bmatrix}. \]

Let \( Q_D \) be a Givens rotation such that the second component of \( Q^T_D x \) is zero. If \( Q = Q_F Q_D \) then

\[ (Q^T A Q)e_1 = Q^T_D T_F (Q_D e_1) = \lambda_2 Q^T_D (Q_D e_1) = \lambda_2 e_1 \]

and so \( Q^T A Q \) must have the form

\[ Q^T A Q = \begin{bmatrix} \lambda_2 & \pm t_{12} \\ 0 & \lambda_1 \end{bmatrix}. \]

By systematically interchanging adjacent pairs of eigenvalues using this technique, we can move any subset of \( \lambda(A) \) to the top of \( T \)'s diagonal assuming that no 2-by-2 bumps are encountered along the way.

**Algorithm 7.6.1** Given an orthogonal matrix \( Q \in \mathbb{R}^{n \times n} \), an upper triangular matrix \( T = Q^T A Q \), and a subset \( \Delta = \{ \lambda_1, \ldots, \lambda_p \} \) of \( \lambda(A) \), the following algorithm computes an orthogonal matrix \( Q_D \) such that \( Q^T_D T Q_D = S \) is upper triangular and \( \{ s_{11}, \ldots, s_{pp} \} = \Delta \). The matrices \( Q \) and \( T \) are overwritten by \( Q Q_D \) and \( S \) respectively.
while \( \{ t_{11}, \ldots, t_{pp} \} \neq \Delta \)

for \( k = 1 : n - 1 \)

if \( t_{kk} \not\in \Delta \) and \( t_{k+1,k+1} \in \Delta \)

\[
\begin{bmatrix}
  c & s \\
  -s & c
\end{bmatrix}^T \begin{bmatrix}
  c & s \\
  -s & c
\end{bmatrix}^T = \mathsf{givens}(T(k,k+1), T(k+1,k+1) - T(k,k))
\]

\[
T(k:k+1, k:n) = \begin{bmatrix}
  c & s \\
  -s & c
\end{bmatrix}^T T(k:k+1, k:n)
\]

\[
T(1:k+1, k:k+1) = T(1:k+1, k:k+1) \begin{bmatrix}
  c & s \\
  -s & c
\end{bmatrix}
\]

\[
Q(1:n, k:k+1) = Q(1:n, k:k+1) \begin{bmatrix}
  c & s \\
  -s & c
\end{bmatrix}
\]

end

end

This algorithm requires \( k(12n) \) flops, where \( k \) is the total number of required swaps. The integer \( k \) is never greater than \( (n - p)p \).

The swapping gets a little more complicated when \( T \) has 2-by-2 blocks along its diagonal. See Ruhe (1970) and Stewart (1976) for details. Of course, these interchanging techniques can be used to sort the eigenvalues, say from maximum to minimum modulus.

Computing invariant subspaces by manipulating the real Schur decomposition is extremely stable. If \( \hat{Q} = [\hat{q}_1, \ldots, \hat{q}_n] \) denotes the computed orthogonal matrix \( Q \), then \( \| \hat{Q}^T \hat{Q} - I \|_2 \approx u \) and there exists a matrix \( E \) satisfying \( \| E \|_2 \approx u \| A \|_2 \) such that \( (A + E)\hat{q}_i \in \mathsf{span}\{\hat{q}_1, \ldots, \hat{q}_p\} \) for \( i = 1:p \).

### 7.6.3 Block Diagonalization

Let

\[
T = \begin{bmatrix}
  T_{11} & T_{12} & \cdots & T_{1q} \\
  0 & T_{22} & \cdots & T_{2q} \\
  \vdots & \vdots & \ddots & \vdots \\
  0 & 0 & \cdots & T_{qq}
\end{bmatrix}
\begin{bmatrix}
  n_1 \\
  n_2 \\
  \vdots \\
  n_q
\end{bmatrix}
\]

be a partitioning of some real Schur canonical form \( Q^T A Q = T \in \mathbb{R}^{n \times n} \) such that \( \lambda(T_{11}), \ldots, \lambda(T_{qq}) \) are disjoint. By Theorem 7.1.6 there exists a matrix \( Y \) such that \( Y^{-1}TY = \mathsf{diag}(T_{11}, \ldots, T_{qq}) \). A practical procedure for determining \( Y \) is now given together with an analysis of \( Y \)'s sensitivity as a function of the above partitioning.

Partition \( I_n = [E_1, \ldots, E_q] \) conformally with \( T \) and define the matrix
7.6. Invariant Subspace Computations

$Y_{ij} \in \mathbb{R}^{n \times n}$ as follows:

$$Y_{ij} = I_n + E_i Z_{ij} E_j^T. \quad i < j, \quad Z_{ij} \in \mathbb{R}^{n_i \times n_j}$$

In other words, $Y_{ij}$ looks just like the identity except that $Z_{ij}$ occupies the $(i, j)$ block position. It follows that if $Y_{ij}^{-1}TY_{ij} = \tilde{T} = (\tilde{T}_{ij})$ then $T$ and $\tilde{T}$ are identical except that

$$\tilde{T}_{ij} = T_{ii} Z_{ij} - Z_{ij} T_{jj} + T_{ij} \quad (k = j + 1 : q)$$
$$\tilde{T}_{ik} = T_{ik} - Z_{ij} T_{jk} \quad (k = 1 : i - 1)$$

Thus, $T_{ij}$ can be zeroed provided we have an algorithm for solving the Sylvester equation

$$FZ - ZG = C \quad (7.6.4)$$

where $F \in \mathbb{R}^{p \times p}$ and $G \in \mathbb{R}^{r \times r}$ are given upper quasi-triangular matrices and $C \in \mathbb{R}^{p \times r}$.

Bartels and Stewart (1972) have devised a method for doing this. Let $C = [c_1, \ldots, c_r]$ and $Z = [z_1, \ldots, z_r]$ be column partitionings. If $g_{k+1,k} = 0$, then by comparing columns in $(7.6.4)$ we find

$$F z_k - \sum_{i=1}^{k} g_{ik} z_i = c_k.$$ 

Thus, once we know $z_1, \ldots, z_{k-1}$ then we can solve the quasi-triangular system

$$(F - g_{kk} I) z_k = c_k + \sum_{i=1}^{k-1} g_{ik} z_i$$

for $z_k$. If $g_{k+1,k} \neq 0$, then $z_k$ and $z_{k+1}$ can be simultaneously found by solving the $2p$-by-$2p$ system

$$\begin{bmatrix} F - g_{kk} I & -g_{mk} I \\ -g_{km} I & F - g_{mm} I \end{bmatrix} \begin{bmatrix} z_k \\ z_m \end{bmatrix} = \begin{bmatrix} c_k \\ c_m \end{bmatrix} + \sum_{i=1}^{k-1} \begin{bmatrix} g_{ik} z_i \\ g_{im} z_i \end{bmatrix} \quad (7.6.5)$$

where $m = k + 1$. By reordering the equations according to the permutation $(1, p + 1, 2, p + 2, \ldots, p, 2p)$, a banded system is obtained that can be solved in $O(p^2)$ flops. The details may be found in Bartels and Stewart (1972). Here is the overall process for the case when $F$ and $G$ are each triangular.

Algorithm 7.6.2 (Bartels-Stewart Algorithm) Given $C \in \mathbb{R}^{p \times r}$ and upper triangular matrices $F \in \mathbb{R}^{p \times p}$ and $G \in \mathbb{R}^{r \times r}$ that satisfy $\lambda(F) \cap \lambda(G) = \emptyset$, the following algorithm overwrites $C$ with the solution to the equation $FZ - ZG = C$. 

for $k = 1:r$
\[ C(1:p, k) = C(1:p, k) + C(1:p, 1:k - 1)G(1:k - 1, k) \]
Solve $(F - G(k, k)I)z = C(1:p, k)$ for $z$.
\[ C(1:p, k) = z \]
end

This algorithm requires $pr(p + r)$ flops.

By zeroing the super diagonal blocks in $T$ in the appropriate order, the entire matrix can be reduced to block diagonal form.

**Algorithm 7.6.3** Given an orthogonal matrix $Q \in \mathbb{R}^{n \times n}$, an upper quasi-triangular matrix $T = Q^T AQ$, and the partitioning (7.6.3), the following algorithm overwrites $Q$ with $QY$ where $Y^{-1}TY = \text{diag}(T_{11}, \ldots, T_{qq})$.

for $j = 2:q$
for $i = 1:j - 1$
Solve $T_{ii}Z - ZT_{jj} = -T_{ij}$ for $Z$ using Algorithm 7.6.2.
for $k = j + 1:q$
\[ T_{ik} = T_{ik} - ZT_{jk} \]
end
for $k = 1:q$
\[ Q_{kj} = Q_{ki}Z + Q_{kj} \]
end
end

The number of flops required by this algorithm is a complicated function of the block sizes in (7.6.3).

The choice of the real Schur form $T$ and its partitioning in (7.6.3) determines the sensitivity of the Sylvester equations that must be solved in Algorithm 7.6.3. This in turn affects the condition of the matrix $Y$ and the overall usefulness of the block diagonalization. The reason for these dependencies is that the relative error of the computed solution $\hat{Z}$ to
\[ T_{ii}Z - ZT_{jj} = -T_{ij} \quad (7.6.6) \]
satisfies
\[
\frac{\| \hat{Z} - Z \|_F}{\| Z \|_F} \approx \frac{\| T \|_F}{\text{sep}(T_{ii}, T_{jj})} .
\]

For details, see Golub, Nash, and Van Loan (1979). Since
\[
\text{sep}(T_{ii}, T_{jj}) = \min_{X \neq 0} \frac{\| T_{ii}X - XT_{jj} \|_F}{\| X \|_F} \leq \min_{\lambda \in \lambda(T_{ii})} \frac{1}{\min_{\mu \in \lambda(T_{jj})} |\lambda - \mu|} ,
\]
there can be a substantial loss of accuracy whenever the subsets $\lambda(T_{ii})$ are insufficiently separated. Moreover, if $Z$ satisfies (7.6.6) then

$$
\| Z \|_F \leq \frac{\| T_{ij} \|_F}{\text{sep}(T_{ii}, T_{jj})}.
$$

Thus, large-norm solutions can be expected if $\text{sep}(T_{ii}, T_{jj})$ is small. This tends to make the matrix $Y$ in Algorithm 7.6.3 ill-conditioned since it is the product of the matrices

$$
Y_{ij} = \begin{bmatrix}
I & Z \\
0 & I
\end{bmatrix}.
$$

Note: $\kappa_F(Y_{ij}) = 2n + \| Z \|_F^2$.

Confronted with these difficulties, Bavelly and Stewart (1979) develop an algorithm for block diagonalizing that dynamically determines the eigenvalue ordering and partitioning in (7.6.3) so that all the $Z$ matrices in Algorithm 7.6.3 are bounded in norm by some user-supplied tolerance. They find that the condition of $Y$ can be controlled by controlling the condition of the $Y_{ij}$.

### 7.6.4 Eigenvector Bases

If the blocks in the partitioning (7.6.3) are all 1-by-1, then Algorithm 7.6.3 produces a basis of eigenvectors. As with the method of inverse iteration, the computed eigenvalue-eigenvector pairs are exact for some "nearby" matrix. A widely followed rule of thumb for deciding upon a suitable eigenvector method is to use inverse iteration whenever fewer than 25% of the eigenvectors are desired.

We point out, however, that the real Schur form can be used to determine selected eigenvectors. Suppose

$$
Q^T A Q = \begin{bmatrix}
T_{11} & u^T & T_{13} \\
0 & \lambda & v^T \\
0 & 0 & T_{33}
\end{bmatrix}
\begin{bmatrix}
k-1 \\
1 \\
n-k
\end{bmatrix}
$$

is upper quasi-triangular and that $\lambda \notin \lambda(T_{11}) \cup \lambda(T_{33})$. It follows that if we solve the linear systems $(T_{11} - \lambda I)w = -u$ and $(T_{33} - \lambda I)^T z = -v$ then

$$
x = Q \begin{bmatrix}
w \\
1 \\
0
\end{bmatrix} \quad \text{and} \quad y = Q \begin{bmatrix}
0 \\
1 \\
z
\end{bmatrix}
$$

are the associated right and left eigenvectors, respectively. Note that the condition of $\lambda$ is prescribed by $1/s(\lambda) = \sqrt{(1 + w^T w)(1 + z^T z)}$. 
7.6.5 Ascertaining Jordan Block Structures

Suppose that we have computed the real Schur decomposition $A = QTQ^T$, identified clusters of “equal” eigenvalues, and calculated the corresponding block diagonalization $T = Y \text{diag}(T_{i1}, \ldots, T_{iq})Y^{-1}$. As we have seen, this can be a formidable task. However, even greater numerical problems confront us if we attempt to ascertain the Jordan block structure of each $T_{ii}$. A brief examination of these difficulties will serve to highlight the limitations of the Jordan decomposition.

Assume for clarity that $\lambda(T_{ii})$ is real. The reduction of $T_{ii}$ to Jordan form begins by replacing it with a matrix of the form $C = \lambda I + N$, where $N$ is the strictly upper triangular portion of $T_{ii}$ and where $\lambda$, say, is the mean of its eigenvalues.

Recall that the dimension of a Jordan block $J(\lambda)$ is the smallest non-negative integer $k$ for which $[J(\lambda) - \lambda I]^k = 0$. Thus, if $p_i = \dim(\text{null}(N^i))$, for $i = 0:n$, then $p_i - p_{i-1}$ equals the number of blocks in $C$’s Jordan form that have dimension $i$ or greater. A concrete example helps to make this assertion clear and to illustrate the role of the SVD in Jordan form computations.

Assume that $C$ is 7-by-7. Suppose we compute the SVD $U_1^T NV_1 = \Sigma_1$ and “discover” that $N$ has rank 3. If we order the singular values from small to large then it follows that the matrix $N_1 = V_1^T NV_1$ has the form

$$N_1 = \begin{bmatrix} 0 & K \\ 0 & L \\ 4 & 3 \end{bmatrix}$$

At this point, we know that the geometric multiplicity of $\lambda$ is 4—i.e, $C$’s Jordan form has 4 blocks ($p_1 - p_0 = 4 - 0 = 4$).

Now suppose $\tilde{U}_2^T \tilde{L}\tilde{V}_2 = \Sigma_2$ is the SVD of $L$ and that we find that $L$ has unit rank. If we again order the singular values from small to large, then $L_2 = \tilde{V}_2^T L\tilde{V}_2$ clearly has the following structure:

$$L_2 = \begin{bmatrix} 0 & 0 & a \\ 0 & 0 & b \\ 0 & 0 & c \end{bmatrix}.$$ 

However $\lambda(L_2) = \lambda(L) = \{0, 0, 0\}$ and so $c = 0$. Thus, if

$$V_2 = \text{diag}(I_4, \tilde{V}_2)$$
then \( N_2 = V_2^T N_1 V_2 \) has the following form:

\[
N_2 = \begin{bmatrix}
0 & 0 & 0 & 0 & x & x & x \\
0 & 0 & 0 & 0 & x & x & x \\
0 & 0 & 0 & 0 & x & x & x \\
0 & 0 & 0 & 0 & 0 & 0 & a \\
0 & 0 & 0 & 0 & 0 & 0 & b \\
0 & 0 & 0 & 0 & 0 & 0 & 0
\end{bmatrix}.
\]

Besides allowing us to introduce more zeroes into the upper triangle, the SVD of \( L \) also enables us to deduce the dimension of the null space of \( N^2 \). Since

\[
N_1^2 = \begin{bmatrix} 0 & KL \\ 0 & L^2 \end{bmatrix} = \begin{bmatrix} 0 & K \\ 0 & L \end{bmatrix} \begin{bmatrix} 0 & K \\ 0 & L \end{bmatrix}
\]

and \( \begin{bmatrix} K \\ L \end{bmatrix} \) has full column rank,

\[
p_2 = \dim(\text{null}(N^2)) = \dim(\text{null}(N_1^2)) = 4 + \dim(\text{null}(L)) = p_1 + 2.
\]

Hence, we can conclude at this stage that the Jordan form of \( C \) has at least two blocks of dimension 2 or greater.

Finally, it is easy to see that \( N_1^3 = 0 \), from which we conclude that there is \( p_3 - p_2 = 7 - 6 = 1 \) block of dimension 3 or larger. If we define \( V = V_1 V_2 \) then it follows that the decomposition

\[
V^T C V = \begin{bmatrix}
\lambda & 0 & 0 & 0 & x & x & x \\
0 & \lambda & 0 & 0 & x & x & x \\
0 & 0 & \lambda & 0 & x & x & x \\
0 & 0 & 0 & \lambda & x & x & x \\
0 & 0 & 0 & 0 & \lambda & x & a \\
0 & 0 & 0 & 0 & 0 & \lambda & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & \lambda
\end{bmatrix}
\]

"displays" \( C \)'s Jordan block structure: 2 blocks of order 1 or larger, \( 4 \) blocks of order 1 or larger, and 1 block of order 3.

To compute the Jordan decomposition it is necessary to resort to non-orthogonal transformations. We refer the reader to either Golub and Wilkinson (1976) or Kågström and Ruhe (1980a, 1980b) for how to proceed with this phase of the reduction.

The above calculations with the SVD amply illustrate that difficult rank decisions must be made at each stage and that the final computed block structure depends critically on those decisions. Fortunately, the stable Schur decomposition can almost always be used in lieu of the Jordan decomposition in practical applications.
Problems

P7.6.1 Give a complete algorithm for solving a real, \( n \)-by-\( n \), upper quasi-triangular system \( Tx = b \).

P7.6.2 Suppose \( U^{-1}AU = \text{diag}(\alpha_1, \ldots, \alpha_m) \) and \( V^{-1}BV = \text{diag}(\beta_1, \ldots, \beta_n) \). Show that if \( \phi(X) = AX + XB \), then \( \lambda(\phi) = \{ \alpha_i + \beta_j : i = 1:m, j = 1:n \} \). What are the corresponding eigenvectors? How can these decompositions be used to solve \( AX + XB = C \)?

P7.6.3 Show that if \( Y = \begin{bmatrix} I & Z \\ 0 & I \end{bmatrix} \) then \( \kappa_2(Y) = [2 + \sigma^2 + \sqrt{4\sigma^4 + \sigma^4}] / 2 \) where \( \sigma = \|Z\|_2 \).

P7.6.4 Derive the system (7.6.5).

P7.6.5 Assume that \( T \in \mathbb{R}^{n \times n} \) is block upper triangular and partitioned as follows:

\[
T = \begin{bmatrix}
T_{11} & T_{12} & T_{13} \\
0 & T_{22} & T_{23} \\
0 & 0 & T_{33}
\end{bmatrix} \quad T \in \mathbb{R}^{n \times n}
\]

Suppose that the diagonal block \( T_{22} \) is 2-by-2 with complex eigenvalues that are disjoint from \( \lambda(T_{11}) \) and \( \lambda(T_{33}) \). Give an algorithm for computing the 2-dimensional real invariant subspace associated with \( T_{22} \)'s eigenvalues.

P7.6.6 Suppose \( H \in \mathbb{R}^{n \times n} \) is upper Hessenberg with a complex eigenvalue \( \lambda + i \cdot \mu \). How could inverse iteration be used to compute \( x, y \in \mathbb{R}^n \) so that \( H(x+iy) = \lambda + i\mu)(x+iy) \)? Hint: compare real and imaginary parts in this equation and obtain a 2n-by-2n real system.

P7.6.6 (a) Prove that if \( \mu_0 \in \mathbb{C} \) has nonzero real part, then the iteration

\[
\mu_{k+1} = \frac{1}{2} \left( \mu_k + \frac{1}{\mu_k} \right)
\]

converges to 1 if \( \text{Re}(\mu_0) > 0 \) and to -1 if \( \text{Re}(\mu_0) < 0 \). (b) Suppose \( A \in \mathbb{C}^{n \times n} \) is diagonalizable and that

\[
A = X \begin{bmatrix} D_+ & 0 \\ 0 & D_- \end{bmatrix} X^{-1}
\]

where \( D_+ \in \mathbb{C}^{p \times p} \) and \( D_- \in \mathbb{C}^{(n-p) \times (n-p)} \) are diagonal with eigenvalues in the open right half plane and open left half plane, respectively. Show that the iteration

\[
A_{k+1} = \frac{1}{2} \left( A_k + A_k^{-1} \right) \quad A_0 = A
\]

converges to

\[
\text{sign}(A) \equiv X \begin{bmatrix} I_p & 0 \\ 0 & -I_{n-p} \end{bmatrix} X^{-1}.
\]

(c) Suppose

\[
M = \begin{bmatrix} M_{11} & M_{12} \\ 0 & M_{22} \end{bmatrix}
\]

with the property that \( \lambda(M_{11}) \) is in the open right half plane and \( \lambda(M_{22}) \) is in the open left half plane. Show that

\[
\text{sign}(M) = \begin{bmatrix} I_p & Z \\ 0 & -I_{n-p} \end{bmatrix}
\]

and that \( -Z/2 \) solves \( M_{11}X - XM_{22} = -M_{12} \). Thus,

\[
U = \begin{bmatrix} I_p & -Z/2 \\ 0 & I_{n-p} \end{bmatrix} \Rightarrow U^{-1}MU = \begin{bmatrix} M_{11} & 0 \\ 0 & M_{22} \end{bmatrix}.
\]

7.7. The QZ Method for $Ax = \lambda Bx$

Hessenberg/QR iteration techniques are fast, but not very amenable to parallel computation. Because of this there is a hunger for radically new approaches to the eigenproblem. Here are some papers that focus on the matrix sign function and related ideas that have high performance potential:

7.7 The QZ Method for $Ax = \lambda Bx$

Let $A$ and $B$ be two $n$-by-$n$ matrices. The set of all matrices of the form $A - \lambda B$ with $\lambda \in \mathbb{C}$ is said to be a pencil. The eigenvalues of the pencil are elements of the set $\lambda(A,B)$ defined by

$$
\lambda(A,B) = \{ z \in \mathbb{C} : \det(A - zB) = 0 \}.
$$

If $\lambda \in \lambda(A,B)$ and

$$
Ax = \lambda Bx \quad x \neq 0
$$

(7.7.1)

then $x$ is referred to as an eigenvector of $A - \lambda B$.

In this section we briefly survey some of the mathematical properties of the generalized eigenproblem (7.7.1) and present a stable method for its solution. The important case when $A$ and $B$ are symmetric with the latter positive definite is discussed in §8.7.2.

7.7.1 Background

The first thing to observe about the generalized eigenvalue problem is that there are $n$ eigenvalues if and only if $\text{rank}(B) = n$. If $B$ is rank deficient
then $\lambda(A, B)$ may be finite, empty, or infinite:

$$A = \begin{bmatrix} 1 & 2 \\ 0 & 3 \end{bmatrix} \quad B = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \Rightarrow \lambda(A, B) = \{1\}$$

$$A = \begin{bmatrix} 1 & 2 \\ 0 & 3 \end{bmatrix} \quad B = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix} \Rightarrow \lambda(A, B) = \emptyset$$

$$A = \begin{bmatrix} 1 & 2 \\ 0 & 0 \end{bmatrix} \quad B = \begin{bmatrix} 1 & 0 \\ 0 & 0 \end{bmatrix} \Rightarrow \lambda(A, B) = \mathbb{C}$$

Note that if $0 \neq \lambda \in \lambda(A, B)$ then $(1/\lambda) \in \lambda(B, A)$. Moreover, if $B$ is nonsingular then $\lambda(A, B) = \lambda(B^{-1}A, I) = \lambda(B^{-1}A)$.

This last observation suggests one method for solving the $A - \lambda B$ problem when $B$ is nonsingular:

- Solve $BC = A$ for $C$ using (say) Gaussian elimination with pivoting.

- Use the QR algorithm to compute the eigenvalues of $C$.

Note that $C$ will be affected by roundoff errors of order $u\|A\|_2\|B^{-1}\|_2$. If $B$ is ill-conditioned, then this can rule out the possibility of computing any generalized eigenvalue accurately—even those eigenvalues that may be regarded as well-conditioned.

**Example 7.7.1** If

$$A = \begin{bmatrix} 1.746 & .940 \\ 1.246 & 1.898 \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} .780 & .563 \\ .913 & .659 \end{bmatrix}$$

then $\lambda(A, B) = \{2, 1.07 \times 10^6\}$. With 7-digit floating point arithmetic, we find $\lambda(fl(AB^{-1})) = \{1.562539, 1.01 \times 10^6\}$. The poor quality of the small eigenvalue is because $\kappa_2(B) \approx 2 \times 10^6$. On the other hand, we find that

$$\lambda(I, fl(A^{-1}B)) \approx \{2.000001, 1.06 \times 10^6\}.$$ 

The accuracy of the small eigenvalue is improved because $\kappa_2(A) \approx 4$.

Example 7.7.1 suggests that we seek an alternative approach to the $A - \lambda B$ problem. One idea is to compute well-conditioned $Q$ and $Z$ such that the matrices

$$A_1 = Q^{-1}AZ \quad B_1 = Q^{-1}BZ \quad (7.7.2)$$

are each in canonical form. Note that $\lambda(A, B) = \lambda(A_1, B_1)$ since

$$Ax = \lambda Bx \iff A_1y = \lambda B_1y \quad x = Zy$$

We say that the pencils $A - \lambda B$ and $A_1 - \lambda B_1$ are equivalent if (7.7.2) holds with nonsingular $Q$ and $Z$. 
7.7.2 The Generalized Schur Decomposition

As in the standard eigenproblem $A - \lambda I$ there is a choice between canonical forms. Analogous to the Jordan form is a decomposition of Kronecker in which both $A_1$ and $B_1$ are block diagonal. The blocks are similar to Jordan blocks. The Kronecker canonical form poses the same numerical difficulties as the Jordan form. However, this decomposition does provide insight into the mathematical properties of the pencil $A - \lambda B$. See Wilkinson (1978) and Demmel and Kågström (1987) for details.

More attractive from the numerical point of view is the following decomposition described in Moler and Stewart (1973).

Theorem 7.7.1 (Generalized Schur Decomposition) If $A$ and $B$ are in $\mathbb{C}^{n \times n}$, then there exist unitary $Q$ and $Z$ such that $Q^H AZ = T$ and $Q^H BZ = S$ are upper triangular. If for some $k$, $t_{kk}$ and $s_{kk}$ are both zero, then $\lambda(A, B) = \mathbb{C}$. Otherwise

$$\lambda(A, B) = \{t_{ii}/s_{ii} : s_{ii} \neq 0\}.$$

Proof. Let $\{B_k\}$ be a sequence of nonsingular matrices that converge to $B$. For each $k$, let $Q_k^H (AB_k^{-1})Q_k = R_k$ be a Schur decomposition of $AB_k^{-1}$. Let $Z_k$ be unitary such that $Z_k^H (B_k^{-1}Q_k) = S_k^{-1}$ is upper triangular. It follows that both $Q_k^H AZ_k = R_k S_k$ and $Q_k^H B_k Z_k = S_k$ are also upper triangular.

Using the Bolzano-Weierstrass theorem, we know that the bounded sequence $\{(Q_k, Z_k)\}$ has a converging subsequence, $\lim (Q_{k_i}, Z_{k_i}) = (Q, Z)$. It is easy to show that $Q$ and $Z$ are unitary and that $Q^H AZ$ and $Q^H BZ$ are upper triangular. The assertions about $\lambda(A, B)$ follow from the identity

$$\det(A - \lambda B) = \det(QZ^H) \prod_{i=1}^{n} (t_{ii} - \lambda s_{ii}). \Box$$

If $A$ and $B$ are real then the following decomposition, which corresponds to the real schur decomposition (Theorem 7.4.1), is of interest.

Theorem 7.7.2 (Generalized Real Schur Decomposition) If $A$ and $B$ are in $\mathbb{R}^{n \times n}$ then there exist orthogonal matrices $Q$ and $Z$ such that $Q^T AZ$ is upper quasi-triangular and $Q^T BZ$ is upper triangular.

Proof. See Stewart (1972). $\Box$

In the remainder of this section we are concerned with the computation of this decomposition and the mathematical insight that it provides.

7.7.3 Sensitivity Issues

The generalized Schur decomposition sheds light on the issue of eigenvalue sensitivity for the $A - \lambda B$ problem. Clearly, small changes in $A$ and $B$ can
induce large changes in the eigenvalue \( \lambda_i = t_{ii}/s_{ii} \) if \( s_{ii} \) is small. However, as Stewart (1978) argues, it may not be appropriate to regard such an eigenvalue as "ill-conditioned." The reason is that the reciprocal \( \mu_i = s_{ii}/t_{ii} \) might be a very well behaved eigenvalue for the pencil \( \mu A - B \). In the Stewart analysis, \( A \) and \( B \) are treated symmetrically and the eigenvalues are regarded more as ordered pairs \( (t_{ii}, s_{ii}) \) than as quotients. With this point of view it becomes appropriate to measure eigenvalue perturbations in the chordal metric chord \((a, b)\) defined by

\[
\text{chord}(a, b) = \frac{|a - b|}{\sqrt{1 + a^2}\sqrt{1 + b^2}}.
\]

Stewart shows that if \( \lambda \) is a distinct eigenvalue of \( A - \lambda B \) and \( \lambda_\epsilon \) is the corresponding eigenvalue of the perturbed pencil \( \tilde{A} - \lambda \tilde{B} \) with \( \| A - \tilde{A} \|_2 \approx \| B - \tilde{B} \|_2 \approx \epsilon \), then

\[
\text{chord}(\lambda, \lambda_\epsilon) \leq \frac{\epsilon}{(y^H A x)^2 + (y^H B x)^2} + O(\epsilon^2)
\]

where \( x \) and \( y \) have unit 2-norm and satisfy \( A x = \lambda B x \) and \( y^H = \lambda y^H B \). Note that the denominator in the upper bound is symmetric in \( A \) and \( B \). The "truly" ill-conditioned eigenvalues are those for which this denominator is small.

The extreme case when \( t_{kk} = s_{kk} = 0 \) for some \( k \) has been studied by Wilkinson (1979). He makes the interesting observation that when this occurs, the remaining quotients \( t_{ii}/s_{ii} \) can assume arbitrary values.

### 7.7.4 Hessenberg-Triangular Form

The first step in computing the generalized Schur decomposition of the pair \( (A, B) \) is to reduce \( A \) to upper Hessenberg form and \( B \) to upper triangular form via orthogonal transformations. We first determine an orthogonal \( U \) such that \( U^T B \) is upper triangular. Of course, to preserve eigenvalues, we must also update \( A \) in exactly the same way. Let's trace what happens in the \( n = 5 \) case.

\[
A = U^T A = \begin{bmatrix}
\bullet & x & x & x & x \\
x & x & x & x & x \\
x & x & x & x & x \\
x & x & x & x & x \\
x & x & x & x & x \\
\end{bmatrix},
B = U^T B = \begin{bmatrix}
x & x & x & x & x \\
0 & x & x & x & x \\
0 & 0 & x & x & x \\
0 & 0 & 0 & x & x \\
0 & 0 & 0 & 0 & x \\
\end{bmatrix}
\]
Next, we reduce $A$ to upper Hessenberg form while preserving $B$'s upper triangular form. First, a Givens rotation $Q_{45}$ is determined to zero $a_{51}$:

$$A = Q_{45}^T A = \begin{bmatrix} x & x & x & x & x \\ x & x & x & x & x \\ x & x & x & x & x \\ x & x & x & x & x \\ 0 & x & x & x & x \end{bmatrix}, B = Q_{45}^T B = \begin{bmatrix} x & x & x & x & x \\ 0 & x & x & x & x \\ 0 & x & x & x & x \\ 0 & 0 & 0 & x & x \\ 0 & 0 & 0 & 0 & x \end{bmatrix}$$

The nonzero entry arising in the (5,4) position in $B$ can be zeroed by postmultiplying with an appropriate Givens rotation $Z_{45}$:

$$A = A Z_{45} = \begin{bmatrix} x & x & x & x & x \\ x & x & x & x & x \\ x & x & x & x & x \\ x & x & x & x & x \\ 0 & x & x & x & x \end{bmatrix}, B = B Z_{45} = \begin{bmatrix} x & x & x & x & x \\ 0 & x & x & x & x \\ 0 & x & x & x & x \\ 0 & 0 & 0 & x & x \\ 0 & 0 & 0 & 0 & x \end{bmatrix}$$

Zeros are similarly introduced into the (4, 1) and (3, 1) positions in $A$:

$$A = Q_{34}^T A = \begin{bmatrix} x & x & x & x & x \\ x & x & x & x & x \\ x & x & x & x & x \\ x & x & x & x & x \\ 0 & x & x & x & x \\ 0 & x & x & x & x \end{bmatrix}, B = Q_{34}^T B = \begin{bmatrix} x & x & x & x & x \\ 0 & x & x & x & x \\ 0 & x & x & x & x \\ 0 & 0 & 0 & x & x \\ 0 & 0 & 0 & 0 & x \end{bmatrix}$$

$$A = A Z_{34} = \begin{bmatrix} x & x & x & x & x \\ x & x & x & x & x \\ x & x & x & x & x \\ x & x & x & x & x \\ 0 & x & x & x & x \\ 0 & x & x & x & x \end{bmatrix}, B = B Z_{34} = \begin{bmatrix} x & x & x & x & x \\ 0 & x & x & x & x \\ 0 & x & x & x & x \\ 0 & 0 & 0 & x & x \\ 0 & 0 & 0 & 0 & x \end{bmatrix}$$

$$A = Q_{23}^T A = \begin{bmatrix} x & x & x & x & x \\ x & x & x & x & x \\ x & x & x & x & x \\ x & x & x & x & x \\ 0 & x & x & x & x \\ 0 & x & x & x & x \end{bmatrix}, B = Q_{23}^T B = \begin{bmatrix} x & x & x & x & x \\ 0 & x & x & x & x \\ 0 & x & x & x & x \\ 0 & 0 & 0 & x & x \\ 0 & 0 & 0 & 0 & x \end{bmatrix}$$

$$A = A Z_{23} = \begin{bmatrix} x & x & x & x & x \\ x & x & x & x & x \\ x & x & x & x & x \\ x & x & x & x & x \\ 0 & x & x & x & x \\ 0 & x & x & x & x \end{bmatrix}, B = B Z_{23} = \begin{bmatrix} x & x & x & x & x \\ 0 & x & x & x & x \\ 0 & x & x & x & x \\ 0 & 0 & 0 & x & x \\ 0 & 0 & 0 & 0 & x \end{bmatrix}$$

$A$ is now upper Hessenberg through its first column. The reduction is completed by zeroing $a_{52}$, $a_{42}$, and $a_{53}$. As is evident above, two orthogonal transformations are required for each $a_{ij}$ that is zeroed—one to do the
zeroing and the other to restore $B$'s triangularity. Either Givens rotations or 2-by-2 modified Householder transformations can be used. Overall we have:

**Algorithm 7.7.1 (Hessenberg-Triangular Reduction)** Given $A$ and $B$ in $\mathbb{R}^{n \times n}$, the following algorithm overwrites $A$ with an upper Hessenberg matrix $Q^T AZ$ and $B$ with an upper triangular matrix $Q^T BZ$ where both $Q$ and $Z$ are orthogonal.

Using Algorithm 5.2.1, overwrite $B$ with $Q^T B = R$ where $Q$ is orthogonal and $R$ is upper triangular.

\[
A = Q^T A \\
\text{for } j = 1:n - 2 \\
\quad \text{for } i = n - 1:j + 2 \\
\quad \quad [c, s] = \text{givens}(A(i - 1,j), A(i, j)) \\
\quad \quad A(i - 1:i, j:n) = \begin{bmatrix} c & s \\ -s & c \end{bmatrix}^T A(i - 1:i, j:n) \\
\quad \quad B(i - 1:i, i - 1:n) = \begin{bmatrix} c & s \\ -s & c \end{bmatrix}^T B(i - 1:i, i - 1:n) \\
\quad \quad [c, s] = \text{givens}(-B(i,i), B(i, i - 1)) \\
\quad \quad B(1:i, i - 1:i) = B(1:i, i - 1:i) \begin{bmatrix} c & s \\ -s & c \end{bmatrix} \\
\quad \quad A(1:n, i - 1:i) = A(1:n, i - 1:i) \begin{bmatrix} c & s \\ -s & c \end{bmatrix} \\
\end{align*}

end

This algorithm requires about $8n^3$ flops. The accumulation of $Q$ and $Z$ requires about $4n^3$ and $3n^3$ flops, respectively.

The reduction of $A - \lambda B$ to Hessenberg-triangular form serves as a "front end" decomposition for a generalized QR iteration known as the QZ iteration which we describe next.

**Example 7.7.3** If
\[
A = \begin{bmatrix} 10 & 1 & 2 \\ 1 & 2 & -1 \\ 1 & 1 & 2 \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} 1 & 2 & 3 \\ 4 & 5 & 6 \\ 7 & 8 & 9 \end{bmatrix}
\]

and orthogonal matrices $Q$ and $Z$ are defined by
\[
Q = \begin{bmatrix} -.1231 & -.9917 & .0378 \\ -.4924 & .0279 & -.8699 \\ -.8616 & .1257 & .4917 \end{bmatrix} \quad \text{and} \quad Z = \begin{bmatrix} 1.0000 & 0.0000 & 0.0000 \\ 0.0000 & -.8944 & -.4472 \\ 0.0000 & .4472 & -.8944 \end{bmatrix}
\]

then $A_1 = Q^T AZ$ and $B_1 = Q^T BZ$ are given by
\[
A_1 = \begin{bmatrix} -2.5849 & 1.5413 & 2.4221 \\ -9.7631 & .0874 & 1.9239 \\ 0.0000 & 2.7233 & -.7612 \end{bmatrix} \quad \text{and} \quad B_1 = \begin{bmatrix} -8.1240 & 3.6332 & 14.2024 \\ 0.0000 & 0.0000 & 1.8739 \\ 0.0000 & 0.0000 & .7612 \end{bmatrix}
\]
7.7.5 Deflation

In describing the QZ iteration we may assume without loss of generality that $A$ is an unreduced upper Hessenberg matrix and that $B$ is a nonsingular upper triangular matrix. The first of these assertions is obvious, for if $a_{k+1,k} = 0$ then

$$A - \lambda B = \begin{bmatrix} A_{11} - \lambda B_{11} & A_{12} - \lambda B_{12} \\ 0 & A_{22} - \lambda B_{22} \end{bmatrix} = \begin{bmatrix} k \\ n-k \end{bmatrix}$$

and we may proceed to solve the two smaller problems $A_{11} - \lambda B_{11}$ and $A_{22} - \lambda B_{22}$. On the other hand, if $b_{kk} = 0$ for some $k$, then it is possible to introduce a zero in $A$’s $(n, n-1)$ position and thereby deflate. Illustrating by example, suppose $n = 5$ and $k = 3$:

$$A = \begin{bmatrix} x & x & x & x & x \\ x & x & x & x & x \\ 0 & x & x & x & x \\ 0 & 0 & x & x & x \\ 0 & 0 & 0 & x & x \end{bmatrix}, \quad B = \begin{bmatrix} x & x & x & x & x \\ 0 & x & x & x & x \\ 0 & 0 & 0 & x & x \\ 0 & 0 & 0 & 0 & x \\ 0 & 0 & 0 & 0 & x \end{bmatrix}$$

The zero on $B$’s diagonal can be “pushed down” to the $(5,5)$ position as follows using Givens rotations:

$$A = Q_{34}^T A = \begin{bmatrix} x & x & x & x & x \\ x & x & x & x & x \\ 0 & x & x & x & x \\ 0 & x & x & x & x \\ 0 & 0 & 0 & x & x \end{bmatrix}, \quad B = Q_{34}^T B = \begin{bmatrix} x & x & x & x & x \\ 0 & x & x & x & x \\ 0 & 0 & 0 & x & x \\ 0 & 0 & 0 & 0 & x \\ 0 & 0 & 0 & 0 & x \end{bmatrix}$$

$$A = A Z_{23} = \begin{bmatrix} x & x & x & x & x \\ x & x & x & x & x \\ 0 & x & x & x & x \\ 0 & 0 & x & x & x \\ 0 & 0 & 0 & x & x \end{bmatrix}, \quad B = B Z_{23} = \begin{bmatrix} x & x & x & x & x \\ 0 & x & x & x & x \\ 0 & 0 & 0 & x & x \\ 0 & 0 & 0 & 0 & x \\ 0 & 0 & 0 & 0 & x \end{bmatrix}$$

$$A = Q_{45}^T A = \begin{bmatrix} x & x & x & x & x \\ x & x & x & x & x \\ 0 & x & x & x & x \\ 0 & 0 & x & x & x \\ 0 & 0 & 0 & x & x \end{bmatrix}, \quad B = Q_{45}^T B = \begin{bmatrix} x & x & x & x & x \\ 0 & x & x & x & x \\ 0 & 0 & 0 & x & x \\ 0 & 0 & 0 & 0 & x \\ 0 & 0 & 0 & 0 & x \end{bmatrix}$$

$$A = A Z_{34} = \begin{bmatrix} x & x & x & x & x \\ x & x & x & x & x \\ 0 & x & x & x & x \\ 0 & 0 & x & x & x \\ 0 & 0 & 0 & x & x \end{bmatrix}, \quad B = B Z_{34}^T = \begin{bmatrix} x & x & x & x & x \\ 0 & x & x & x & x \\ 0 & 0 & 0 & x & x \\ 0 & 0 & 0 & 0 & x \\ 0 & 0 & 0 & 0 & x \end{bmatrix}$$
\[
A = AZ_{45} = \begin{bmatrix}
\times & \times & \times & \times & \times \\
\times & \times & \times & \times & \times \\
0 & \times & \times & \times & \times \\
0 & 0 & \times & \times & \times \\
0 & 0 & 0 & 0 & \times 
\end{bmatrix},
B = BZ_{45} = \begin{bmatrix}
\times & \times & \times & \times & \times \\
0 & \times & \times & \times & \times \\
0 & 0 & \times & \times & \times \\
0 & 0 & 0 & \times & \times \\
0 & 0 & 0 & 0 & 0 
\end{bmatrix}
\]

This zero-chasing technique is perfectly general and can be used to zero \(a_{n,n-1}\) regardless of where the zero appears along \(B\)'s diagonal.

### 7.7.6 The QZ Step

We are now in a position to describe a QZ step. The basic idea is to update \(A\) and \(B\) as follows

\[
(\tilde{A} - \lambda \tilde{B}) = \tilde{Q}^T (A - \lambda B) \tilde{Z},
\]

where \(\tilde{A}\) is upper Hessenberg, \(\tilde{B}\) is upper triangular, \(\tilde{Q}\) and \(\tilde{Z}\) are each orthogonal, and \(\tilde{A} \tilde{B}^{-1}\) is essentially the same matrix that would result if a Francis QR step (Algorithm 7.5.2) were explicitly applied to \(AB^{-1}\). This can be done with some clever zero-chasing and an appeal to the implicit \(Q\) theorem.

Let \(M = AB^{-1}\) (upper Hessenberg) and let \(v\) be the first column of the matrix \((M - aI)(M - bI)\), where \(a\) and \(b\) are the eigenvalues of \(M\)'s lower 2-by-2 submatrix. Note that \(v\) can be calculated in \(O(1)\) flops. If \(P_0\) is a Householder matrix such that \(P_0v\) is a multiple of \(e_1\), then

\[
A = P_0 A = \begin{bmatrix}
\times & \times & \times & \times & \times \\
\times & \times & \times & \times & \times \\
\times & \times & \times & \times & \times \\
0 & 0 & \times & \times & \times \\
0 & 0 & 0 & \times & \times \\
0 & 0 & 0 & 0 & \times 
\end{bmatrix}
\]

\[
B = P_0 B = \begin{bmatrix}
\times & \times & \times & \times & \times \\
\times & \times & \times & \times & \times \\
\times & \times & \times & \times & \times \\
0 & 0 & 0 & \times & \times \\
0 & 0 & 0 & 0 & \times \\
0 & 0 & 0 & 0 & 0 
\end{bmatrix}
\]

The idea now is to restore these matrices to Hessenberg-triangular form by chasing the unwanted nonzero elements down the diagonal.

To this end, we first determine a pair of Householder matrices \(Z_1\) and
$Z_2$ to zero $b_{31}$, $b_{32}$, and $b_{21}$:

$$A = AZ_1Z_2 = \begin{bmatrix}
\times & \times & \times & \times & \times & \times \\
\times & \times & \times & \times & \times & \times \\
\times & \times & \times & \times & \times & \times \\
\times & \times & \times & \times & \times & \times \\
0 & 0 & 0 & \times & \times & \times \\
0 & 0 & 0 & 0 & \times & \times 
\end{bmatrix}$$

$$B = BZ_1Z_2 = \begin{bmatrix}
\times & \times & \times & \times & \times & \times \\
0 & \times & \times & \times & \times & \times \\
0 & 0 & \times & \times & \times & \times \\
0 & 0 & 0 & \times & \times & \times \\
0 & 0 & 0 & 0 & \times & \times \\
0 & 0 & 0 & 0 & 0 & \times 
\end{bmatrix}$$

Then a Householder matrix $P_1$ is used to zero $a_{31}$ and $a_{41}$:

$$A = P_1A = \begin{bmatrix}
\times & \times & \times & \times & \times & \times \\
\times & \times & \times & \times & \times & \times \\
0 & \times & \times & \times & \times & \times \\
0 & 0 & \times & \times & \times & \times \\
0 & 0 & 0 & \times & \times & \times \\
0 & 0 & 0 & 0 & \times & \times 
\end{bmatrix}$$

$$B = P_1B = \begin{bmatrix}
\times & \times & \times & \times & \times & \times \\
0 & \times & \times & \times & \times & \times \\
0 & 0 & \times & \times & \times & \times \\
0 & 0 & 0 & \times & \times & \times \\
0 & 0 & 0 & 0 & \times & \times \\
0 & 0 & 0 & 0 & 0 & \times 
\end{bmatrix}$$

Notice that with this step the unwanted nonzero elements have been shifted down and to the right from their original position. This illustrates a typical step in the QZ iteration. Notice that $Q = Q_0Q_1 \cdots Q_{n-2}$ has the same first column as $Q_0$. By the way the initial Householder matrix was determined, we can apply the implicit $Q$ theorem and assert that $AB^{-1} = Q^T(AB^{-1})Q$ is indeed essentially the same matrix that we would obtain by applying the Francis iteration to $M = AB^{-1}$ directly. Overall we have:

**Algorithm 7.7.2 (The QZ Step)** Given an unreduced upper Hessenberg matrix $A \in \mathbb{R}^{n \times n}$ and a nonsingular upper triangular matrix $B \in \mathbb{R}^{n \times n}$, the following algorithm overwrites $A$ with the upper Hessenberg matrix $Q^T A Z$ and $B$ with the upper triangular matrix $Q^T B Z$ where $Q$ and $Z$ are orthogonal and $Q$ has the same first column as the orthogonal similarity transformation in Algorithm 7.5.1 when it is applied to $AB^{-1}$. 
Let $M = AB^{-1}$ and compute $(M - aI)(M - bI)e_1 = (x, y, z, 0, \ldots, 0)^T$ where $a$ and $b$ are the eigenvalues of $M$'s lower 2-by-2.

for $k = 1:n - 2$

Find Householder $Q_k$ so $Q_k[x y z]^T = [0 0 0]^T$.

$A = \text{diag}(I_{k-1}, Q_k, I_{n-k-2})A$

$B = \text{diag}(I_{k-1}, Q_k, I_{n-k-2})B$

Find Householder $Z_{k1}$ so

$[b_{k+1,k+2} b_{k+2,k+1} b_{k+2,k+2}]Z_{k1} = [0 0 \ast].$

$A = A\text{diag}(I_{k-1}, Z_{k1}, I_{n-k-2})$

$B = B\text{diag}(I_{k-1}, Z_{k1}, I_{n-k-2})$

Find Householder $Z_{k2}$ so

$[b_{k+1,k} b_{k+1,k+1}]Z_{k2} = [0 \ast].$

$A = A\text{diag}(I_{k-1}, Z_{k2}, I_{n-k-1})$

$B = B\text{diag}(I_{k-1}, Z_{k2}, I_{n-k-1})$

$x = a_{k+1,k}; y = a_{k+1,k}$

if $k < n - 2$

$z = a_{k+3,k}$

end

Find Householder $Q_{n-1}$ so $Q_{n-1}[x y]^T = [\ast 0]$

$A = \text{diag}(I_{n-2}, Q_{n-1})A$

$B = \text{diag}(I_{n-2}, Q_{n-1})B$

Find Householder $Z_{n-1}$ so

$[b_{n,n-1} b_{nn}]Z_{n-1} = [0 \ast].$

$A = A\text{diag}(I_{n-2}, Z_{n-1})$

$B = B\text{diag}(I_{n-2}, Z_{n-1})$

This algorithm requires $22n^2$ flops. $Q$ and $Z$ can be accumulated for an additional $8n^2$ flops and $13n^2$ flops, respectively.

### 7.7.7 The Overall QZ Process

By applying a sequence of QZ steps to the Hessenberg-triangular pencil $A - \lambda B$, it is possible to reduce $A$ to quasi-triangular form. In doing this it is necessary to monitor $A$'s subdiagonal and $B$'s diagonal in order to bring about decoupling whenever possible. The complete process, due to Moler and Stewart (1973), is as follows:

**Algorithm 7.7.3** Given $A \in \mathbb{R}^{n \times n}$ and $B \in \mathbb{R}^{n \times n}$, the following algorithm computes orthogonal $Q$ and $Z$ such that $Q^T A Z = T$ is upper quasi-triangular and $Q^T B Z = S$ is upper triangular. $A$ is overwritten by $T$ and $B$ by $S$. 
Using Algorithm 7.7.1, overwrite $A$ with $Q^TAZ$ (upper Hessenberg) and $B$ with $Q^TBZ$ (upper triangular).

until $q = n$

Set all subdiagonal elements in $A$ to zero that satisfy

$$|a_{i,i-1}| \leq \varepsilon (|a_{i-1,i-1}| + |a_{ii}|)$$

Find the largest nonnegative $q$ and the smallest nonnegative $p$ such that if

$$A = \begin{bmatrix} A_{11} & A_{12} & A_{13} \\ 0 & A_{22} & A_{23} \\ 0 & 0 & A_{33} \end{bmatrix} \begin{bmatrix} p \\ n-p-q \\ q \end{bmatrix}$$

then $A_{33}$ is upper quasi-triangular and $A_{22}$ is unreduced upper Hessenberg.

Partition $B$ conformably:

$$B = \begin{bmatrix} B_{11} & B_{12} & B_{13} \\ 0 & B_{22} & B_{23} \\ 0 & 0 & B_{33} \end{bmatrix} \begin{bmatrix} p \\ n-p-q \\ q \end{bmatrix}$$

if $q < n$

if $B_{22}$ is singular

Zero $a_{n-q,n-q-1}$

else

Apply Algorithm 7.7.2 to $A_{22}$ and $B_{22}$

$$A = \text{diag}(I_p, Q, I_q)^T A \text{diag}(I_p, Z, I_q)$$
$$B = \text{diag}(I_p, Q, I_q)^T B \text{diag}(I_p, Z, I_q)$$

end

end

This algorithm requires $30n^3$ flops. If $Q$ is desired, an additional $16n^3$ are necessary. If $Z$ is required, an additional $20n^3$ are needed. These estimates of work are based on the experience that about two QZ iterations per eigenvalue are necessary. Thus, the convergence properties of QZ are the same as for QR. The speed of the QZ algorithm is not affected by rank deficiency in $B$.

The computed $S$ and $T$ can be shown to satisfy

$$Q_0^T(A + E)Z_0 = T \quad Q_0^T(B + F)Z_0 = S$$
where \( Q_0 \) and \( Z_0 \) are exactly orthogonal and \( \|E\|_2 \approx u\|A\|_2 \) and \( \|F\|_2 \approx u\|B\|_2 \).

**Example 7.7.5** If the QZ algorithm is applied to

\[
A = \begin{bmatrix} 2 & 3 & 4 & 5 & 6 \\ 4 & 5 & 6 & 7 \\ 0 & 3 & 6 & 7 & 8 \\ 0 & 0 & 2 & 8 & 9 \\ 0 & 0 & 0 & 1 & 10 \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} 1 & -1 & -1 & -1 & -1 \\ 0 & 1 & -1 & -1 & -1 \\ 0 & 0 & 1 & -1 & -1 \\ 0 & 0 & 0 & 1 & -1 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix}
\]

then the subdiagonal elements of \( A \) converge as follows

### 7.7.8 Generalized Invariant Subspace Computations

Many of the invariant subspace computations discussed in §7.6 carry over to the generalized eigenvalue problem. For example, approximate eigenvectors can be found via inverse iteration:

\[ q^{(0)} \in \mathbb{C}^{n \times n} \text{ given.} \]

**for** \( k = 1, 2, \ldots \)

Solve \((A - \mu B)z^{(k)} = Bq^{(k-1)}\)

Normalize: \( q^{(k)} = z^{(k)} / \| z^{(k)} \|_2 \)

\( \chi^{(k)} = [q^{(k)}]^H A q^{(k)} / [q^{(k)}]^H A q^{(k)} \)

**end**

When \( B \) is nonsingular, this is equivalent to applying (7.6.1) with the matrix \( B^{-1}A \). Typically, only a single iteration is required if \( \mu \) is an approximate eigenvalue computed by the QZ algorithm. By inverse iterating with the Hessenberg-triangular pencil, costly accumulation of the Z-transformations during the QZ iteration can be avoided.

Corresponding to the notion of an invariant subspace for a single matrix, we have the notion of a deflating subspace for the pencil \( A - \lambda B \). In
7.7. The QZ Method for $A\mathbf{x} = \lambda B\mathbf{x}$

In particular, we say that a $k$-dimensional subspace $S \subseteq \mathbb{R}^n$ is "deflating" for the pencil $A - \lambda B$ if the subspace $\{Ax + By : x, y \in S\}$ has dimension $k$ or less. Note that the columns of the matrix $Z$ in the generalized Schur decomposition define a family of deflating subspaces, for if $Q = [q_1, \ldots, q_n]$ and $Z = [z_1, \ldots, z_n]$ then we have $\text{span}\{Az_1, \ldots, Az_k\} \subseteq \text{span}\{q_1, \ldots, q_k\}$ and $\text{span}\{Bz_1, \ldots, Bz_k\} \subseteq \text{span}\{q_1, \ldots, q_k\}$. Properties of deflating subspaces and their behavior under perturbation are described in Stewart (1972).

Problems

P7.7.1 Suppose $A$ and $B$ are in $\mathbb{R}^{m \times n}$ and that

$$U^T B V = \begin{bmatrix} D & 0 & \cdots & 0 \\ 0 & 0 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & 0 \end{bmatrix}_r \begin{bmatrix} U_1 & U_2 \\ \vdots & \vdots \\ U_r & U_{n-r} \end{bmatrix} \begin{bmatrix} V_1 & V_2 \\ \vdots & \vdots \\ V_r & V_{n-r} \end{bmatrix}$$

is the SVD of $B$, where $D$ is $r$-by-$r$ and $r = \text{rank}(B)$. Show that if $\lambda(A, B) = \mathbb{C}$ then $U_2^T AV_2$ is singular.

P7.7.2 Define $F : \mathbb{R}^n \rightarrow \mathbb{R}$ by

$$F(x) = \frac{1}{2} \left\| Ax - \frac{x^T B B x}{x^T B^T B x} \right\|^2$$

where $A$ and $B$ are in $\mathbb{R}^{m \times n}$. Show that if $\nabla F(x) = 0$, then $Ax$ is a multiple of $Bx$.

P7.7.3 Suppose $A$ and $B$ are in $\mathbb{R}^{m \times n}$. Give an algorithm for computing orthogonal $Q$ and $Z$ such that $Q^T AZ$ is upper Hessenberg and $Z^T BQ$ is upper triangular.

P7.7.4 Suppose

$$A = \begin{bmatrix} A_{11} & A_{12} \\ 0 & A_{22} \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} B_{11} & B_{12} \\ 0 & B_{22} \end{bmatrix}$$

with $A_{11}, B_{11} \in \mathbb{R}^{k \times k}$ and $A_{22}, B_{22} \in \mathbb{R}^{i \times i}$. Under what circumstances do there exist

$$X = \begin{bmatrix} I_k & X_{12} \\ 0 & I_j \end{bmatrix} \quad \text{and} \quad Y = \begin{bmatrix} I_k & Y_{12} \\ 0 & I_j \end{bmatrix}$$

so that $Y^{-1}AX$ and $Y^{-1}BX$ are both block diagonal? This is the generalized Sylvester equation problem. Specify an algorithm for the case when $A_{11}, A_{22}, B_{11},$ and $B_{22}$ are upper triangular. See Kågström (1994).

P7.7.5 Suppose $\mu \notin \lambda(A, B)$. Relate the eigenvalues and eigenvectors of $A_1 = (A - \mu B)^{-1}A$ and $B_1 = (A - \mu B)^{-1}B$ to the generalized eigenvalues and eigenvectors of $A - \lambda B$.

P7.7.6 Suppose $A, B, C, D \in \mathbb{R}^{m \times n}$. Show how to compute orthogonal matrices $Q, Z, U,$ and $V$ such that $Q^T AU$ is upper Hessenberg and $V^T CZ$, $Q^T BV$, and $V^T DZ$ are all upper triangular. Note that this converts the pencil $AC - \lambda BD$ to Hessenberg-triangular form. Your algorithm should not form the products $AC$ or $BD$ explicitly and not should not compute any matrix inverse. See Van Loan (1975).

The Symmetric Eigenvalue Problem

§8.1 Properties and Decompositions
§8.2 Power Iterations
§8.3 The Symmetric QR Algorithm
§8.4 Jacobi Methods
§8.5 Tridiagonal Methods
§8.6 Computing the SVD
§8.7 Some Generalized Eigenvalue Problems

The symmetric eigenvalue problem with its rich mathematical structure is one of the most aesthetically pleasing problems in numerical linear algebra. We begin our presentation with a brief discussion of the mathematical properties that underlie this computation. In §8.2 and §8.3 we develop various power iterations eventually focusing on the symmetric QR algorithm.

In §8.4 we discuss Jacobi's method, one of the earliest matrix algorithms to appear in the literature. This technique is of current interest because it is amenable to parallel computation and because under certain circumstances it has superior accuracy.

Various methods for the tridiagonal case are presented in §8.5. These include the method of bisection and a divide and conquer technique.

The computation of the singular value decomposition is detailed in §8.6. The central algorithm is a variant of the symmetric QR iteration that works on bidiagonal matrices.
In the final section we discuss the generalized eigenvalue problem $Ax = \lambda Bx$ for the important case when $A$ is symmetric and $B$ is symmetric positive definite. No suitable analog of the orthogonally-based QZ algorithm (see §7.7) exists for this specially structured, generalized eigenproblem. However, there are several successful methods that can be applied and these are presented along with a discussion of the generalized singular value decomposition.

Before You Begin

Chapter 1, §§2.1-2.5, and §2.7, Chapter 3, §§4.1-4.3, §§5.1-5.5 and §7.1.1 are assumed. Within this chapter there are the following dependencies:

\[
\begin{align*}
\Sect{8.4} & \uparrow \\
\Sect{8.1} & \rightarrow \Sect{8.2} \rightarrow \Sect{8.3} \rightarrow \Sect{8.6} \rightarrow \Sect{8.7} \\
\downarrow & \\
\Sect{8.5} &
\end{align*}
\]

Many of the algorithms and theorems in this chapter have unsymmetric counterparts in Chapter 7. However, except for a few concepts and definitions, our treatment of the symmetric eigenproblem can be studied before reading Chapter 7.

8.1 Properties and Decompositions

In this section we set down the mathematics that is required to develop and analyze algorithms for the symmetric eigenvalue problem.

8.1.1 Eigenvalues and Eigenvectors

Symmetry guarantees that all of A’s eigenvalues are real and that there is an orthonormal basis of eigenvectors.

Theorem 8.1.1 (Symmetric Schur Decomposition) If \( A \in \mathbb{R}^{n \times n} \) is symmetric, then there exists a real orthogonal \( Q \) such that

\[
Q^T A Q = \Lambda = \text{diag}(\lambda_1, \ldots, \lambda_n).
\]

Moreover, for \( k = 1:n, ~ A Q(:,k) = \lambda_k Q(:,k) \). See Theorem 7.1.3.

Proof. Suppose \( \lambda_1 \in \lambda(A) \) and that \( x \in \mathbb{C}^n \) is a unit 2-norm eigenvector with \( A x = \lambda_1 x \). Since \( \lambda_1 = x^H A x = x^H A^H x = x^H A x = \lambda_1 \) it follows that \( \lambda_1 \in \mathbb{R} \). Thus, we may assume that \( x \in \mathbb{R}^n \). Let \( P_1 \in \mathbb{R}^{n \times n} \) be a Householder matrix such that \( P_1^T x = e_1 = I_n(:,1) \). It follows from \( A x = \lambda_1 x \) that \( (P_1^T A P_1) e_1 = \lambda e_1 \). This says that the first column of \( P_1^T A P_1 \) is a multiple of \( e_1 \). But since \( P_1^T A P_1 \) is symmetric it must have the form

\[
P_1^T A P_1 = \begin{bmatrix}
\lambda_1 & 0 \\
0 & A_1
\end{bmatrix}
\]

where \( A_1 \in \mathbb{R}^{(n-1) \times (n-1)} \) is symmetric. By induction we may assume that there is an orthogonal \( Q_1 \in \mathbb{R}^{(n-1) \times (n-1)} \) such that \( Q_1^T A_1 Q_1 = \Lambda_1 \) is diagonal. The theorem follows by setting

\[
Q = P_1 \begin{bmatrix} 1 & 0 \\ 0 & Q_1 \end{bmatrix} \quad \text{and} \quad \Lambda = \begin{bmatrix} \lambda_1 & 0 \\ 0 & \Lambda_1 \end{bmatrix}
\]

and comparing columns in the matrix equation \( A Q = Q \Lambda \). \( \square \)

Example 8.1.1 If

\[
A = \begin{bmatrix}
6.8 & 2.4 \\
2.4 & 8.2
\end{bmatrix} \quad \text{and} \quad Q = \begin{bmatrix}
.6 & .8 \\
.8 & .6
\end{bmatrix},
\]
then $Q$ is orthogonal and $Q^T AQ = \text{diag}(10,5)$.

For a symmetric matrix $A$ we shall use the notation $\lambda_k(A)$ to designate the $k$th largest eigenvalue. Thus,

$$\lambda_n(A) \leq \cdots \leq \lambda_2(A) \leq \lambda_1(A).$$

It follows from the orthogonal invariance of the 2-norm that $A$ has singular values $\{ |\lambda_1(A)|, \ldots, |\lambda_n(A)| \}$ and so

$$\|A\|_2 = \max\{ |\lambda_1(A)|, |\lambda_n(A)| \}.$$ 

The eigenvalues of a symmetric matrix have a "minimax" characterization based on the values that can be assumed by the quadratic form ratio $x^T Ax/x^T x$.

**Theorem 8.1.2 (Courant-Fischer Minimax Theorem)** If $A \in \mathbb{R}^{n \times n}$ is symmetric, then

$$\lambda_k(A) = \max_{\dim(S) = k} \min_{0 \neq y \in S} \frac{y^T Ay}{y^T y}$$

for $k = 1:n$.

**Proof.** Let $Q^T AQ = \text{diag}(\lambda_i)$ be the Schur decomposition with $\lambda_k = \lambda_k(A)$ and $Q = [q_1, q_2, \ldots, q_n]$. Define

$$S_k = \text{span}\{q_1, \ldots, q_k\},$$

the invariant subspace associated with $\lambda_1, \ldots, \lambda_k$. It is easy to show that

$$\max_{\dim(S) = k} \min_{0 \neq y \in S} \frac{y^T Ay}{y^T y} \geq \min_{0 \neq y \in S_k} \frac{y^T Ay}{y^T y} = q_k^T A q_k = \lambda_k(A).$$

To establish the reverse inequality, let $S$ be any $k$-dimensional subspace and note that it must intersect $\text{span}\{q_k, \ldots, q_n\}$, a subspace that has dimension $n - k + 1$. If $y_* = \alpha_k q_k + \cdots + \alpha_n q_n$ is in this intersection, then

$$\min_{0 \neq y \in S} \frac{y^T Ay}{y^T y} \leq \frac{y_*^T Ay_*}{y_*^T y_*} \leq \lambda_k(A).$$

Since this inequality holds for all $k$-dimensional subspaces,

$$\max_{\dim(S) = k} \min_{0 \neq y \in S} \frac{y^T Ay}{y^T y} \leq \lambda_k(A)$$

thereby completing the proof of the theorem. \(\Box\)

If $A \in \mathbb{R}^{n \times n}$ is symmetric positive definite, then $\lambda_n(A) > 0$. 
8.1.2 Eigenvalue Sensitivity

An important solution framework for the symmetric eigenproblem involves the production of a sequence of orthogonal transformations \( \{Q_k\} \) with the property that the matrices \( Q_k^T A Q_k \) are progressively "more diagonal." The question naturally arises, how well do the diagonal elements of a matrix approximate its eigenvalues?

**Theorem 8.1.3 (Gershgorin)** Suppose \( A \in \mathbb{R}^{n \times n} \) is symmetric and that \( Q \in \mathbb{R}^{n \times n} \) is orthogonal. If \( Q^T A Q = D + F \) where \( D = \text{diag}(d_1, \ldots, d_n) \) and \( F \) has zero diagonal entries, then

\[
\lambda(A) \subseteq \bigcup_{i=1}^{n} [d_i - r_i, d_i + r_i]
\]

where \( r_i = \sum_{j=1}^{n} |f_{ij}| \) for \( i = 1:n \). See Theorem 7.2.1.

**Proof.** Suppose \( \lambda \in \lambda(A) \) and assume without loss of generality that \( \lambda \neq d_i \) for \( i = 1:n \). Since \( (D - \lambda I) + F \) is singular, it follows from Lemma 2.3.3 that

\[
1 \leq \|(D - \lambda I)^{-1} F\|_{\infty} = \sum_{j=1}^{n} \frac{|f_{kj}|}{|d_k - \lambda|} = \frac{r_k}{|d_k - \lambda|}
\]

for some \( k, 1 \leq k \leq n \). But this implies that \( \lambda \in [d_k - r_k, d_k + r_k] \).

**Example 8.1.2** The matrix

\[
A = \begin{bmatrix}
2.0000 & 0.1000 & 0.2000 \\
0.2000 & 5.0000 & 0.3000 \\
0.1000 & 0.3000 & -1.0000
\end{bmatrix}
\]

has Gershgorin intervals \([1.7, 2.3], [4.5, 5.5], \) and \([-1.4, -0.6]\) and eigenvalues 1.9984, 5.0224, and -1.0208.

The next results show that if \( A \) is perturbed by a symmetric matrix \( E \), then its eigenvalues do not move by more than \( \| E \| \).

**Theorem 8.1.4 (Wielandt-Hoffman)** If \( A \) and \( A + E \) are \( n \times n \) symmetric matrices, then

\[
\sum_{i=1}^{n} (\lambda_i(A + E) - \lambda_i(A))^2 \leq \| E \|_F^2.
\]

Example 8.1.3 If
\[ A = \begin{bmatrix} 6.8 & 2.4 \\ 2.4 & 8.2 \end{bmatrix} \quad \text{and} \quad E = \begin{bmatrix} 0.002 & 0.003 \\ 0.003 & 0.001 \end{bmatrix}, \]
then \( \lambda(A) = \{5, 10\} \) and \( \lambda(A + E) = \{4.9988, 10.004\} \) confirming that
\[ 1.95 \times 10^{-5} = |4.9988 - 5|^2 + |10.004 - 10|^2 \leq \| E \|^2_F = 2.3 \times 10^{-5}. \]

Theorem 8.1.5 If \( A \) and \( A + E \) are \( n \)-by-\( n \) symmetric matrices, then
\[ \lambda_k(A) + \lambda_n(E) \leq \lambda_k(A + E) \leq \lambda_k(A) + \lambda_1(E) \quad k = 1:n. \]

Proof. This follows from the minimax characterization. See Wilkinson (1965, pp.101–2) or Stewart and Sun (1990, p.203). □

Example 8.1.4 If
\[ A = \begin{bmatrix} 6.8 & 2.4 \\ 2.4 & 8.2 \end{bmatrix} \quad \text{and} \quad E = \begin{bmatrix} 0.002 & 0.003 \\ 0.003 & 0.001 \end{bmatrix}, \]
then \( \lambda(A) = \{5, 10\} \), \( \lambda(E) = \{-0.0015, 0.0045\} \), and \( \lambda(A + E) = \{4.9988, 10.0042\} \), confirming that
\[ 5 - 0.0015 \leq 4.9988 \leq 5 + 0.0045 \]
\[ 10 - 0.0015 \leq 10.0042 \leq 10 + 0.0045. \]

Corollary 8.1.6 If \( A \) and \( A + E \) are \( n \)-by-\( n \) symmetric matrices, then
\[ |\lambda_k(A + E) - \lambda_k(A)| \leq \| E \|_2 \]
for \( k = 1:n. \)

Proof.
\[ |\lambda_k(A + E) - \lambda_k(A)| \leq \max\{|\lambda_n(E)|, |\lambda_1(E)|\} = \| E \|_2. \]

Several more useful perturbation results follow from the minimax property.

Theorem 8.1.7 (Interlacing Property) If \( A \in \mathbb{R}^{n \times n} \) is symmetric and \( A_r = A(1:r, 1:r) \), then
\[ \lambda_{r+1}(A_{r+1}) \leq \lambda_r(A_r) \leq \lambda_r(A_{r+1}) \leq \cdots \leq \lambda_2(A_{r+1}) \leq \lambda_1(A_r) \leq \lambda_1(A_{r+1}) \]
for \( r = 1:n - 1. \)
8.1. Properties and Decompositions

Example 8.1.5 If

$$A = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & 2 & 3 & 4 \\ 1 & 3 & 6 & 10 \\ 1 & 4 & 10 & 20 \end{bmatrix}$$

then \( \lambda(A_1) = \{1\} \), \( \lambda(A_2) = \{.3820, \ 2.6180\} \), \( \lambda(A_3) = \{.1270, \ 1.0000, \ 7.873\} \), and \( \lambda(A_4) = \{.0380, \ .4538, \ 2.2034, 2.63047\} \).

Theorem 8.1.8 Suppose \( B = A + rcc^T \) where \( A \in \mathbb{R}^{n \times n} \) is symmetric, \( c \in \mathbb{R}^n \) has unit 2-norm and \( r \in \mathbb{R} \). If \( r \geq 0 \), then

$$\lambda_i(B) \in [\lambda_i(A), \lambda_{i-1}(A)] \quad i = 2:n$$

while if \( r \leq 0 \) then

$$\lambda_i(B) \in [\lambda_{i+1}(A), \lambda_i(A)], \quad i = 1:n - 1.$$

In either case, there exist nonnegative \( m_1, \ldots, m_n \) such that

$$\lambda_i(B) = \lambda_i(A) + m_i r, \quad i = 1:n$$

with \( m_1 + \cdots + m_n = 1 \).

8.1.3 Invariant Subspaces

Many eigenvalue computations proceed by breaking the original problem into a collection of smaller subproblems. The following result is the basis for this solution framework.

Theorem 8.1.9 Suppose \( A \in \mathbb{R}^{n \times n} \) is symmetric and that

$$Q = \begin{bmatrix} Q_1 & Q_2 \\ r & n-r \end{bmatrix}$$

is orthogonal. If \( \text{ran}(Q_1) \) is an invariant subspace, then

$$Q^T AQ = D = \begin{bmatrix} D_1 & 0 \\ 0 & D_2 \end{bmatrix} \begin{bmatrix} r \\ r \\ n-r \end{bmatrix} \quad (8.1.1)$$

and \( \lambda(A) = \lambda(D_1) \cup \lambda(D_2) \). See also Lemma 7.1.2.
Proof. If
\[ Q^T AQ = \begin{bmatrix} D_1 & E_{21}^T \\ E_{21} & D_2 \end{bmatrix}, \]
then from \( AQ = QD \) we have \( AQ_1 - Q_1D_1 = Q_2E_{21} \). Since \( \text{ran}(Q_1) \) is invariant, the columns of \( Q_2E_{21} \) are also in \( \text{ran}(Q_1) \) and therefore perpendicular to the columns of \( Q_2 \). Thus,
\[ 0 = Q_2^T (AQ_1 - Q_1D_1) = Q_2^T Q_2E_{21} = E_{21}. \]
and so (8.1.1) holds. It is easy to show
\[ \det(A - \lambda I_n) = \det(Q^T AQ - \lambda I_n) = \det(D_1 - \lambda I_r)\det(D_2 - \lambda I_{n-r}) \]
confirming that \( \lambda(A) = \lambda(D_1) \cup \lambda(D_2) \). \( \square \)

The sensitivity to perturbation of an invariant subspace depends upon the separation of the associated eigenvalues from the rest of the spectrum. The appropriate measure of separation between the eigenvalues of two symmetric matrices \( B \) and \( C \) is given by
\[ \text{sep}(B, C) = \min_{\lambda \in \lambda(B)} \min_{\mu \in \lambda(C)} |\lambda - \mu|. \]  
(8.1.2)

With this definition we have

Theorem 8.1.10 Suppose \( A \) and \( A + E \) are \( n \times n \) symmetric matrices and that
\[ Q = \begin{bmatrix} Q_1 & Q_2 \\ r & n-r \end{bmatrix} \]
is an orthogonal matrix such that \( \text{ran}(Q_1) \) is an invariant subspace for \( A \). Partition the matrices \( Q^T AQ \) and \( Q^T EQ \) as follows:
\[ Q^T AQ = \begin{bmatrix} D_1 & 0 \\ 0 & D_2 \end{bmatrix} \begin{bmatrix} r & n-r \end{bmatrix} \quad Q^T EQ = \begin{bmatrix} E_{11} & E_{21}^T \\ E_{21} & E_{22} \end{bmatrix} \begin{bmatrix} r & n-r \end{bmatrix}. \]
If \( \text{sep}(D_1, D_2) > 0 \) and
\[ \| E \|_2 \leq \frac{\text{sep}(D_1, D_2)}{5}, \]
then there exists a matrix \( P \in \mathbb{R}^{(n-r) \times r} \) with
\[ \| P \|_2 \leq \frac{4}{\text{sep}(D_1, D_2)} \| E_{21} \|_2 \]
such that the columns of \( \tilde{Q}_1 = (Q_1 + Q_2P)(I + P^TP)^{-1/2} \) define an orthonormal basis for a subspace that is invariant for \( A + E \). See also Theorem 7.2.4.
8.1. Properties and Decompositions

Proof. This result is a slight adaptation of of Theorem 4.11 in Stewart (1973). The matrix \((I + P^T P)^{-1/2}\) is the inverse of the square root of \(I + P^T P\). See §4.2.10. □

Corollary 8.1.11 If the conditions of the theorem hold, then

\[
\text{dist}(\text{ran}(Q_1), \text{ran}({\hat{Q}_1})) \leq \frac{4}{\text{sep}(D_1, D_2)} \| E_{21} \|_2.
\]

See also Corollary 7.2.5.

Proof. It can be shown using the SVD that

\[
\| P(I + P^T P)^{-1/2} \|_2 \leq \| P \|_2. \tag{8.1.3}
\]

Since \(Q_2^T {\hat{Q}_1} = P(I + P^H P)^{-1/2}\) it follows that

\[
\text{dist}(\text{ran}(Q_1), \text{ran}({\hat{Q}_1})) = \| Q_2^T {\hat{Q}_1} \|_2 = \| P(I + P^H P)^{-1/2} \|_2 \leq \| P \|_2 \leq \| E_{21} \|_2/\text{sep}(D_1, D_2). \quad □
\]

Thus, the reciprocal of \(\text{sep}(D_1, D_2)\) can be thought of as a condition number that measures the sensitivity of \(\text{ran}(Q_1)\) as an invariant subspace.

The effect of perturbations on a single eigenvector is sufficiently important that we specialize the above results to this important case.

Theorem 8.1.12 Suppose \(A\) and \(A + E\) are \(n\)-by-\(n\) symmetric matrices and that

\[
Q = \begin{bmatrix} q_1 & Q_2 \\ 1 & n-1 \end{bmatrix}
\]

is an orthogonal matrix such that \(q_1\) is an eigenvector for \(A\). Partition the matrices \(Q^T AQ\) and \(Q^T EQ\) as follows:

\[
Q^T AQ = \begin{bmatrix} \lambda & 0 \\ 0 & D_2 \end{bmatrix} \begin{bmatrix} 1 \\ n-1 \end{bmatrix} \quad \text{and} \quad Q^T EQ = \begin{bmatrix} \epsilon & e^T \\ e & E_{22} \end{bmatrix} \begin{bmatrix} 1 \\ n-1 \end{bmatrix}.
\]

If \(d = \min_{\mu \in \lambda(D_2)} |\lambda - \mu| > 0\) and

\[
\| E \|_2 \leq \frac{d}{4},
\]

then there exists \(p \in \mathbb{R}^{n-1}\) satisfying

\[
\| p \|_2 \leq \frac{4}{d} \| e \|_2.
\]
such that $\hat{q}_1 = (q_1 + Q_2 p)/\sqrt{1 + p^T p}$ is a unit 2-norm eigenvector for $A + E$. Moreover,

$$\text{dist}(\text{span}\{q_1\}, \text{span}\{\hat{q}_1\}) = \sqrt{1 - (q_1^T \hat{q}_1)^2} \leq \frac{4}{d} \|e\|_2.$$

See also Corollary 7.2.6.

**Proof.** Apply Theorem 8.1.10 and Corollary 8.1.11 with $r = 1$ and observe that if $D_1 = (\lambda)$, then $d = \text{sep}(D_1, D_2)$. $\Box$

**Example 8.1.6** If $A = \text{diag}(.999, 1.001, 2.)$, and

$$E = \begin{bmatrix}
0.00 & 0.01 & 0.01 \\
0.01 & 0.00 & 0.01 \\
0.01 & 0.01 & 0.00
\end{bmatrix},$$

then $\hat{Q}^T(A + E)\hat{Q} = \text{diag}(.9899, 1.0098, 2.0002)$ where

$$\hat{Q} = \begin{bmatrix}
-.7418 & .6706 & .0101 \\
.6708 & .7417 & .0101 \\
.0007 & -.0143 & .9999
\end{bmatrix}$$

is orthogonal. Let $\hat{q}_i = \hat{Q}e_i$, $i = 1, 2, 3$. Thus, $\hat{q}_i$ is the perturbation of $A$'s eigenvector $q_i = e_i$. A calculation shows that

$$\text{dist}(\text{span}\{q_1\}, \text{span}\{\hat{q}_1\}) = \text{dist}(\text{span}\{q_2\}, \text{span}\{\hat{q}_2\}) = .67$$

Thus, because they are associated with nearby eigenvalues, the eigenvectors $q_1$ and $q_2$ cannot be computed accurately. On the other hand, since $\lambda_1$ and $\lambda_2$ are well separated from $\lambda_3$, they define a two-dimensional subspace that is not particularly sensitive as $\text{dist}(\text{span}\{q_1, q_2\}, \text{span}\{\hat{q}_1, \hat{q}_2\}) = .01$.

### 8.1.4 Approximate Invariant Subspaces

If the columns of $Q_1 \in \mathbb{R}^{n \times r}$ are independent and the residual matrix $R = AQ_1 - Q_1S$ is small for some $S \in \mathbb{R}^{r \times r}$, then the columns of $Q_1$ define an approximate invariant subspace. Let us discover what we can say about the eigensystem of $A$ when in the possession of such a matrix.

**Theorem 8.1.13** Suppose $A \in \mathbb{R}^{n \times n}$ and $S \in \mathbb{R}^{r \times r}$ are symmetric and that

$$AQ_1 - Q_1 S = E_1$$

where $Q_1 \in \mathbb{R}^{n \times r}$ satisfies $Q_1^T Q_1 = I_r$. Then there exist $\mu_1, \ldots, \mu_r \in \lambda(A)$ such that

$$|\mu_k - \lambda_k(S)| \leq \sqrt{2} \|E_1\|_2$$

for $k = 1:r$. 
8.1. Properties and Decompositions

Proof. Let \( Q_2 \in \mathbb{R}^{n \times (n-r)} \) be any matrix such that \( Q = [ Q_1, Q_2 ] \) is orthogonal. It follows that

\[
Q^T AQ = \begin{bmatrix}
S & 0 \\
0 & Q_2^T AQ_2
\end{bmatrix} + \begin{bmatrix}
Q_1^T E_1 & E_1^T Q_2 \\
Q_2^T E_1 & 0
\end{bmatrix} = B + E
\]

and so by using Corollary 8.1.6 we have \( |\lambda_k(A) - \lambda_k(B)| \leq \| E \|_2 \) for \( k = 1:n \). Since \( \lambda(S) \subseteq \lambda(B) \), there exist \( \mu_1, \ldots, \mu_r \in \lambda(A) \) such that

\[
|\mu_k - \lambda_k(S)| \leq \| E \|_2
\]

for \( k = 1:r \). The theorem follows by noting that for any \( x \in \mathbb{R}^r \) and \( y \in \mathbb{R}^{n-r} \) we have

\[
\| E \begin{bmatrix} x \\ y \end{bmatrix} \|_2 \leq \| E_1 x \|_2 + \| E_1^T Q_2 y \|_2 \leq \| E_1 \|_2 \| x \|_2 + \| E_1 \|_2 \| y \|_2
\]

from which we readily conclude that \( \| E \|_2 \leq \sqrt{2} \| E_1 \|_2 \). \( \square \)

Example 8.1.7 If

\[
A = \begin{bmatrix}
6.8 & 2.4 \\
2.4 & 8.2
\end{bmatrix}, \quad Q_1 = \begin{bmatrix}
.7994 \\
.6007
\end{bmatrix}, \quad \text{and} \quad S = (5.1) \in \mathbb{R}
\]

then

\[
AQ_1 - Q_1 S = \begin{bmatrix}
-0.0828 \\
-0.0562
\end{bmatrix} = E_1.
\]

The theorem predicts that \( A \) has an eigenvalue within \( \sqrt{2} \| E_1 \|_2 \approx 1.415 \) of 5.1. This is true since \( \lambda(A) = \{5, 10\} \).

The eigenvalue bounds in Theorem 8.1.13 depend on \( \| AQ_1 - Q_1 S \|_2 \). Given \( A \) and \( Q_1 \), the following theorem indicates how to choose \( S \) so that this quantity is minimized in the Frobenius norm.

Theorem 8.1.14 If \( A \in \mathbb{R}^{n \times n} \) is symmetric and \( Q_1 \in \mathbb{R}^{n \times r} \) has orthonormal columns, then

\[
\min_{S \in \mathbb{R}^{r \times r}} \| AQ_1 - Q_1 S \|_F = \| (I - Q_1 Q_1^T) AQ_1 \|_F
\]

and \( S = Q_1^T AQ_1 \) is the minimizer.

Proof. Let \( Q_2 \in \mathbb{R}^{n \times (n-r)} \) be such that \( Q = [ Q_1, Q_2 ] \) is orthogonal. For any \( S \in \mathbb{R}^{r \times r} \) we have

\[
\| AQ_1 - Q_1 S \|_F^2 = \| Q^T AQ_1 - Q^T Q_1 S \|_F^2 \\
= \| Q_1^T AQ_1 - S \|_F^2 + \| Q_2^T AQ_1 \|_F^2.
\]
Clearly, the minimizing $S$ is given by $S = Q_1^T A Q_1$. □

This result enables us to associate any $r$-dimensional subspace $\text{ran}(Q_1)$, with a set of $r$ "optimal" eigenvalue-eigenvector approximates.

**Theorem 8.1.15** Suppose $A \in \mathbb{R}^{n \times n}$ is symmetric and that $Q_1 \in \mathbb{R}^{n \times r}$ satisfies $Q_1^T Q_1 = I_r$. If

$$Z^T (Q_1^T A Q_1) Z = \text{diag}(\theta_1, \ldots, \theta_r) = D$$

is the Schur decomposition of $Q_1^T A Q_1$ and $Q_1 Z = [y_1, \ldots, y_r]$, then

$$\| A y_k - \theta_k y_k \|_2 = \| (I - Q_1 Q_1^T) A Q_1 Z e_k \|_2 \leq \| (I - Q_1 Q_1^T) A Q_1 \|_2$$

for $k = 1: r$.

**Proof.**

$$A y_k - \theta_k y_k = A Q_1 Z e_k = Q_1 Z D e_k = (A Q_1 - Q_1 (Q_1^T A Q_1)) Z e_k.$$

The theorem follows by taking norms. □

In Theorem 8.1.15, the $\theta_k$ are called Ritz values, the $y_k$ are called Ritz vectors, and the $(\theta_k, y_k)$ are called Ritz pairs.

The usefulness of Theorem 8.1.13 is enhanced if we weaken the assumption that the columns of $Q_1$ are orthonormal. As can be expected, the bounds deteriorate with the loss of orthogonality.

**Theorem 8.1.16** Suppose $A \in \mathbb{R}^{n \times n}$ is symmetric and that

$$AX_1 - X_1 S = F_1,$$

where $X_1 \in \mathbb{R}^{n \times r}$ and $S = X_1^T A X_1$. If

$$\| X_1^T X_1 - I_r \|_2 = \tau < 1,$$  \hspace{1cm} (8.1.4)

then there exist $\mu_1, \ldots, \mu_r \in \lambda(A)$ such that

$$|\mu_k - \lambda_k(S)| \leq \sqrt{2} (\| F_1 \|_2 + \tau (2 + \tau) \| A \|_2)$$

for $k = 1: r$.

**Proof.** Let $X_1 = Z P$ be the polar decomposition of $X_1$. Recall from §4.2.10 that this means $Z \in \mathbb{R}^{n \times r}$ has orthonormal columns and $P \in \mathbb{R}^{k \times k}$ is a symmetric positive semidefinite matrix that satisfies $P^2 = X_1^T X_1$.

Taking norms in the equation

$$E_1 = AZ - ZS = (AX_1 - X_1 S) + A(Z - X_1) - (Z - X_1)S$$

$$= F_1 + AZ(I - P) - Z(I - P)X_1^T A X_1$$
gives
\[ \| E_1 \|_2 \leq \| F_1 \|_2 + \| A \|_2 \| I - P \|_2 (1 + \| X_1 \|_2^2) . \] (8.1.5)

Equation (8.1.4) implies that
\[ \| X_1 \|_2^2 \leq 1 + \tau. \] (8.1.6)

Since \( P \) is positive semidefinite, \((I + P)\) is nonsingular and so
\[ I - P = (I + P)^{-1}(I - P^2) = (I + P)^{-1}(I - X_1^T X_1) \]
which implies \( \| I - P \|_2 \leq \tau \). By substituting this inequality and (8.1.6) into (8.1.5) we have \( \| E_1 \|_2 \leq \| F_1 \|_2 + \tau(2 + \tau)\| A \|_2 \). The proof is completed by noting that we can use Theorem 8.1.13 with \( Q_1 = Z \) to relate the eigenvalues of \( A \) and \( S \) via the residual \( E_1 \).

### 8.1.5 The Law of Inertia

The inertia of a symmetric matrix \( A \) is a triplet of nonnegative integers \((m, z, p)\) where \( m, z, \) and \( p \) are respectively the number of negative, zero, and positive elements of \( \lambda(A) \).

**Theorem 8.1.17 (Sylvester Law of Inertia)** If \( A \in \mathbb{R}^{n \times n} \) is symmetric and \( X \in \mathbb{R}^{n \times n} \) is nonsingular, then \( A \) and \( X^T A X \) have the same inertia.

**Proof.** Suppose for some \( r \) that \( \lambda_r(A) > 0 \) and define the subspace \( S_0 \subseteq \mathbb{R}^n \) by
\[ S_0 = \text{span}\{X^{-1}q_1, \ldots, X^{-1}q_r\}, \quad q_i \neq 0 \]
where \( Aq_i = \lambda_i(A)q_i \) and \( i = 1:r \). From the minimax characterization of \( \lambda_r(X^T A X) \) we have
\[ \lambda_r(X^T A X) = \max_{\dim(S) = r} \min_{y \in S} \frac{y^T(X^T A X)y}{y^T y} \geq \min_{y \in S_0} \frac{y^T(X^T A X)y}{y^T y}. \]

Since
\[ y \in \mathbb{R}^n \Rightarrow \frac{y^T(X^T X)y}{y^T y} \geq \sigma_n(X)^2 \]
\[ y \in S_0 \Rightarrow \frac{y^T(X^T A X)y}{y^T y} \geq \lambda_r(A) \]
it follows that
\[ \lambda_r(X^T A X) \geq \min_{y \in S_0} \left\{ \frac{y^T(X^T A X)y}{y^T(X^T X)y} \frac{y^T(X^T X)y}{y^T y} \right\} \geq \lambda_r(A)\sigma_n(X)^2. \]
An analogous argument with the roles of $A$ and $X^TAX$ reversed shows that

$$\lambda_r(A) \geq \lambda_r(X^TAX)\sigma_n(X^{-1})^2 = \frac{\lambda_r(X^TAX)}{\sigma_1(X)^2}.$$  

Thus, $\lambda_r(A)$ and $\lambda_r(X^TAX)$ have the same sign and so we have shown that $A$ and $X^TAX$ have the same number of positive eigenvalues. If we apply this result to $-A$, we conclude that $A$ and $X^TAX$ have the same number of negative eigenvalues. Obviously, the number of zero eigenvalues possessed by each matrix is also the same. □

Example 8.1.8 If $A = \text{diag}(3, 2, -1)$ and

$$X = \begin{bmatrix}
1 & 4 & 5 \\
0 & 1 & 2 \\
0 & 0 & 1
\end{bmatrix},$$

then

$$X^TAX = \begin{bmatrix}
3 & 12 & 15 \\
12 & 50 & 64 \\
15 & 64 & 82
\end{bmatrix}$$

and $\lambda(X^TAX) = \{134.769, .3555, -.1252\}$.

Problems

P8.1.1 Without using any of the results in this section, show that the eigenvalues of a 2-by-2 symmetric matrix must be real.

P8.1.2 Compute the Schur decomposition of $A = \begin{bmatrix} 1 & 2 \\ 2 & 3 \end{bmatrix}$.

P8.1.3 Show that the eigenvalues of a Hermitian matrix ($A^H = A$) are real. For each theorem and corollary in this section, state and prove the corresponding result for Hermitian matrices. Which results have analogs when $A$ is skew-symmetric? (Hint: If $A^T = -A$, then $iA$ is Hermitian.)

P8.1.4 Show that if $X \in \mathbb{R}^{n \times r}$, $r \leq n$, and $\|X^TX - I\| = \tau < 1$, then $\sigma_{\min}(X) \geq 1 - \tau$.

P8.1.5 Suppose $A, E \in \mathbb{R}^{n \times n}$ are symmetric and consider the Schur decomposition $A+tE = QDQ^T$ where we assume that $Q = Q(t)$ and $D = D(t)$ are continuously differentiable functions of $t \in \mathbb{R}$. Show that $D(t) = \text{diag}(Q(t)^TEQ(t))$ where the matrix on the right is the diagonal part of $Q(t)^TEQ(t)$. Establish the Wielandt-Hoffman theorem by integrating both sides of this equation from 0 to 1 and taking Frobenius norms to show that

$$\|D(1) - D(0)\|_F \leq \int_0^1 \|\text{diag}(Q(t)^TEQ(t))\|_F dt \leq \|E\|_F.$$  

P8.1.6 Prove Theorem 8.1.5.

P8.1.7 Prove Theorem 8.1.7.

P8.1.8 If $C \in \mathbb{R}^{n \times n}$ then the trace function $\text{tr}(C) = c_{11} + \cdots + c_{nn}$ equals the sum of $C$'s eigenvalues. Use this to prove Theorem 8.1.8.

P8.1.9 Show that if $B \in \mathbb{R}^{m \times m}$ and $C \in \mathbb{R}^{n \times n}$ are symmetric, then $\text{sep}(B, C) = \min$
\[ \|BX - XC\| F \text{ where the min is taken over all matrices in } \mathbb{R}^{m \times n}. \]

**P8.1.10** Prove the inequality (8.1.3).

**P8.1.11** Suppose \( A \in \mathbb{R}^{n \times n} \) is symmetric and \( C \in \mathbb{R}^{n \times r} \) has full column rank and assume that \( r \ll n \). By using Theorem 8.1.8 relate the eigenvalues of \( A + CC^T \) to the eigenvalues of \( A \).

**Notes and References for Sec. 8.1**

The perturbation theory for the symmetric eigenvalue problem is surveyed in Wilkinson (1965, chapter 2), Parlett (1980, chapters 10 and 11), and Stewart and Sun (1990, chapters 4 and 5). Some representative papers in this well-researched area include

### 8.2 Power Iterations

Assume that \( A \in \mathbb{R}^{n \times n} \) is symmetric and that \( U_0 \in \mathbb{R}^{n \times n} \) is orthogonal. Consider the following *QR iteration*:

\[
T_0 = U_0^T A U_0 \\
\text{for } k = 1, 2, \ldots \\
T_{k-1} = U_k R_k \quad \text{(QR factorization)} \tag{8.2.1} \\
T_k = R_k U_k
\]

end

Since \( T_k = R_k U_k = U_k^T (U_k R_k) U_k = U_k^T T_{k-1} U_k \) it follows by induction that

\[
T_k = (U_0 U_1 \cdots U_k)^T A (U_0 U_1 \cdots U_k). \tag{8.2.2}
\]
Thus, each $T_k$ is orthogonally similar to $A$. Moreover, the $T_k$ almost always converge to diagonal form and so it can be said that (8.2.1) almost always "converges" to a Schur decomposition of $A$. In order to establish this remarkable result we first consider the power method and the method of orthogonal iteration.

### 8.2.1 The Power Method

Given a unit 2-norm $q^{(0)} \in \mathbb{R}^n$, the power method produces a sequence of vectors $q^{(k)}$ as follows:

```latex
\text{for } k = 1, 2, \ldots \\
\hspace{1cm} z^{(k)} = Aq^{(k-1)} \\
\hspace{1cm} q^{(k)} = z^{(k)} / \| z^{(k)} \|_2 \\
\hspace{1cm} \lambda^{(k)} = [q^{(k)}]^T Aq^{(k)} \\
\text{end}
```

(8.2.3)

If $q^{(0)}$ is not "deficient" and $A$'s eigenvalue of maximum modulus is unique, then the $q^{(k)}$ converge to an eigenvector.

**Theorem 8.2.1** Suppose $A \in \mathbb{R}^{n \times n}$ is symmetric and that

$$Q^T A Q = \text{diag}(\lambda_1, \ldots, \lambda_n)$$

where $Q = [q_1, \ldots, q_n]$ is orthogonal and $|\lambda_1| > |\lambda_2| \geq \cdots \geq |\lambda_n|$. Let the vectors $q_k$ be specified by (8.2.3) and define $\theta_k \in [0, \pi/2]$ by

$$\cos(\theta_k) = \left| q_1^T q^{(k)} \right|.$$ 

If $\cos(\theta_0) \neq 0$, then

$$|\sin(\theta_k)| \leq \tan(\theta_0) \left| \frac{\lambda_2}{\lambda_1} \right|^k$$

(8.2.4)

$$|\lambda^{(k)} - \lambda| \leq |\lambda_1 - \lambda_n| \tan(\theta_0)^2 \left| \frac{\lambda_2}{\lambda_1} \right|^{2k}.$$ 

(8.2.5)

**Proof.** From the definition of the iteration, it follows that $q^{(k)}$ is a multiple of $A^k q^{(0)}$ and so

$$|\sin(\theta_k)|^2 = 1 - \left( q_1^T q^{(k)} \right)^2 = 1 - \left( \frac{q_1^T A^k q^{(0)}}{\| A^k q^{(0)} \|_2} \right)^2.$$ 

If $q^{(0)}$ has the eigenvector expansion $q^{(0)} = a_1 q_1 + \cdots + a_n q_n$, then

$$|a_1| = |q_1^T q^{(0)}| = \cos(\theta_0) \neq 0,$$
8.2. Power Iterations

\[ a_1^2 + \cdots + a_n^2 = 1, \]

and

\[ A^k q^{(0)} = a_1 \lambda_1^k q_1 + a_2 \lambda_2^k q_2 + \cdots + a_n \lambda_n^k q_n. \]

Thus,

\[
|\sin(\theta_k)|^2 = 1 - \frac{\sum_{i=1}^{n} a_i^2 \lambda_i^{2k}}{\sum_{i=1}^{n} a_i^2 \lambda_i^{2k}} = \frac{\sum_{i=2}^{n} a_i^2 \lambda_i^{2k}}{\sum_{i=1}^{n} a_i^2 \lambda_i^{2k}}
\]

\[
\leq \frac{\sum_{i=2}^{n} a_i^2 \lambda_i^{2k}}{a_1^2 \lambda_1^{2k}} = \frac{1}{a_1^2} \sum_{i=2}^{n} a_i^2 \left( \frac{\lambda_i}{\lambda_1} \right)^{2k}
\]

\[
\leq \frac{1}{a_1^2} \left( \sum_{i=2}^{n} a_i^2 \right) \left( \frac{\lambda_2}{\lambda_1} \right)^{2k} = \frac{1 - a_1^2}{a_1^2} \left( \frac{\lambda_2}{\lambda_1} \right)^{2k}
\]

\[
= \tan(\theta_0)^2 \left( \frac{\lambda_2}{\lambda_1} \right)^{2k}.
\]

This proves (8.2.4). Likewise,

\[
\lambda^{(k)} = \left[ q^{(k)} \right]^T A q^{(k)} = \frac{\left[ q^{(0)} \right]^T A^{2k+1} q^{(0)}}{\left[ q^{(0)} \right]^T A^{2k} q^{(0)}} = \frac{\sum_{i=1}^{n} a_i^2 \lambda_i^{2k+1}}{\sum_{i=1}^{n} a_i^2 \lambda_i^{2k}}
\]

and so

\[
|\lambda^{(k)} - \lambda_1| = \left| \frac{\sum_{i=2}^{n} a_i^2 \lambda_i^{2k} (\lambda_i - \lambda_1)}{\sum_{i=1}^{n} a_i^2 \lambda_i^{2k}} \right| \leq |\lambda_1 - \lambda_n| \frac{1}{a_1^2} \sum_{i=2}^{n} a_i^2 \left( \frac{\lambda_i}{\lambda_1} \right)^{2k}
\]

\[
\leq |\lambda_1 - \lambda_n| \tan(\theta_0)^2 \left( \frac{\lambda_2}{\lambda_1} \right)^{2k}. \square
\]

**Example 8.2.1** The eigenvalues of

\[
A = \begin{bmatrix}
-1.6407 & 1.0814 & 1.2014 & 1.1539 \\
1.0814 & 4.1573 & 7.4035 & -1.0463 \\
1.2014 & 7.4035 & 2.7890 & -1.5737 \\
1.1539 & -1.0463 & -1.5737 & 8.6944
\end{bmatrix}
\]
are given by \( \lambda(A) = \{12, 8, -4, -2\} \). If (8.2.3) is applied to this matrix with \( q^{(0)} = [1 \ 0 \ 0 \ 0]^T \), then

\[
\begin{array}{c|c}
 k & \lambda^{(k)} \\
 1 & 2.3156 \\
 2 & 8.6802 \\
 3 & 10.3163 \\
 4 & 11.0663 \\
 5 & 11.5259 \\
 6 & 11.7747 \\
 7 & 11.8967 \\
 8 & 11.9534 \\
 9 & 11.9792 \\
 10 & 11.9907 \\
\end{array}
\]

Observe the convergence to \( \lambda_1 = 12 \) with rate \( |\lambda_2 / \lambda_1|^{2k} = (8/12)^{2k} = (4/9)^k \).

Computable error bounds for the power method can be obtained by using Theorem 8.1.13. If

\[
\| Aq^{(k)} - \lambda^{(k)}q^{(k)} \|_2 = \delta,
\]

then there exists \( \lambda \in \lambda(A) \) such that \( |\lambda^{(k)} - \lambda| \leq \sqrt{2}\delta \).

### 8.2.2 Inverse Iteration

Suppose the power method is applied with \( A \) replaced by \( (A - \lambda I)^{-1} \). If \( \lambda \) is very close to a distinct eigenvalue of \( A \), then the next iterate vector will be very rich in the corresponding eigendirection:

\[
x = \sum_{i=1}^{n} a_i q_i \quad \Rightarrow \quad (A - \lambda I)^{-1} x = \sum_{i=1}^{n} \frac{a_i}{\lambda_i - \lambda} q_i.
\]

Thus, if \( \lambda \approx \lambda_j \) and \( a_j \) is not too small, then this vector has a strong component in the direction of \( q_j \). This process is called inverse iteration and it requires the solution of a linear system with matrix of coefficients \( A - \lambda I \).

### 8.2.3 Rayleigh Quotient Iteration

Suppose \( A \in \mathbb{R}^{n \times n} \) is symmetric and that \( x \) is a given nonzero \( n \)-vector. A simple differentiation reveals that

\[
\lambda = r(x) \equiv \frac{x^T A x}{x^T x}
\]

minimizes \( \| (A - \lambda I)x \|_2 \). (See also Theorem 8.1.14.) The scalar \( r(x) \) is called the Rayleigh quotient of \( x \). Clearly, if \( x \) is an approximate eigenvector, then \( r(x) \) is a reasonable choice for the corresponding eigenvalue.
Combining this idea with inverse iteration gives rise to the Rayleigh quotient iteration:

\[ x_0 \text{ given, } \| x_0 \|_2 = 1 \]

\[ \text{for } k = 0, 1, \ldots \]

\[ \mu_k = r(x_k) \quad (8.2.6) \]

Solve \( (A - \mu_k I) z_{k+1} = x_k \) for \( z_{k+1} \)

\[ x_{k+1} = z_{k+1} / \| z_{k+1} \|_2 \]

end

Example 8.2.2 If (8.2.6) is applied to

\[ A = \begin{bmatrix}
  1 & 1 & 1 & 1 & 1 \\
  1 & 2 & 3 & 4 & 5 \\
  1 & 3 & 6 & 10 & 15 \\
  1 & 4 & 10 & 20 & 35 \\
  1 & 5 & 15 & 35 & 70 \\
  1 & 6 & 21 & 56 & 126 \\
\end{bmatrix} \]

with \( x_0 = [1, 1, 1, 1, 1]^T / 6 \), then

\[
\begin{array}{c|c}
 k & \mu_k \\
\hline
 0 & 153.8333 \\
 1 & 120.0571 \\
 2 & 49.5011 \\
 3 & 13.8687 \\
 4 & 15.4959 \\
 5 & 15.5534 \\
\end{array}
\]

The iteration is converging to the eigenvalue \( \lambda = 15.5534732737 \).

The Rayleigh quotient iteration almost always converges and when it does, the rate of convergence is cubic. We demonstrate this for the case \( n = 2 \). Without loss of generality, we may assume that \( A = \text{diag}(\lambda_1, \lambda_2) \), with \( \lambda_1 > \lambda_2 \). Denoting \( x_k \) by

\[ x_k = \begin{bmatrix} c_k \\ s_k \end{bmatrix} \quad c_k^2 + s_k^2 = 1 \]

it follows that \( \mu_k = \lambda_1 c_k^2 + \lambda_2 s_k^2 \) in (8.2.6) and

\[ z_{k+1} = \frac{1}{\lambda_1 - \lambda_2} \begin{bmatrix} c_k / s_k^2 \\ -s_k / c_k^2 \end{bmatrix} . \]

A calculation shows that

\[ c_{k+1} = \frac{c_k^3}{\sqrt{c_k^8 + s_k^8}} \quad s_{k+1} = \frac{-s_k^3}{\sqrt{c_k^8 + s_k^8}} . \quad (8.2.7) \]

From these equations it is clear that the \( x_k \) converge cubically to either span\{e_1\} or span\{e_2\} provided \( |c_k| \neq |s_k| \).

Details associated with the practical implementation of the Rayleigh quotient iteration may be found in Parlett (1974).
8.2.4 Orthogonal Iteration

A straightforward generalization of the power method can be used to compute higher-dimensional invariant subspaces. Let \( r \) be a chosen integer satisfying \( 1 \leq r \leq n \). Given an \( n \times n \) matrix \( Q_0 \) with orthonormal columns, the method of orthogonal iteration generates a sequence of matrices \( \{Q_k\} \subseteq \mathbb{R}^{n \times r} \) as follows:

\[
\begin{align*}
& \text{for } k = 1, 2, \ldots \\
& Z_k = AQ_{k-1} \\
& Q_k R_k = Z_k \quad \text{(QR factorization)} \\
& \text{end}
\end{align*}
\]  

(8.2.8)

Note that if \( r = 1 \), then this is just the power method. Moreover, the sequence \( \{Q_k e_1\} \) is precisely the sequence of vectors produced by the power iteration with starting vector \( q^{(0)} = Q_0 e_1 \).

In order to analyze the behavior of (8.2.8), assume that

\[
Q^T A Q = D = \text{diag}(\lambda_1, \ldots, \lambda_n) \quad |\lambda_1| \geq |\lambda_2| \geq \cdots \geq |\lambda_n|  
\]

(8.2.9)

is a Schur decomposition of \( A \in \mathbb{R}^{n \times n} \). Partition \( Q \) and \( D \) as follows:

\[
Q = \begin{bmatrix} Q_\alpha & Q_\beta \\ r & n-r \end{bmatrix} \quad D = \begin{bmatrix} D_1 & 0 \\ 0 & D_2 \end{bmatrix}^{r \times n-r}
\]

(8.2.10)

If \( |\lambda_r| > |\lambda_{r+1}| \), then

\[
D_r(A) = \text{ran}(Q_\alpha)
\]

is the dominant invariant subspace of dimension \( r \). It is the unique invariant subspace associated with the eigenvalues \( \lambda_1, \ldots, \lambda_r \).

The following theorem shows that with reasonable assumptions, the subspaces \( \text{ran}(Q_k) \) generated by (8.2.8) converge to \( D_r(A) \) at a rate proportional to \( |\lambda_{r+1}/\lambda_r|^k \).

**Theorem 8.2.2** Let the Schur decomposition of \( A \in \mathbb{R}^{n \times n} \) be given by (8.2.9) and (8.2.10) with \( n \geq 2 \). Assume that \( |\lambda_r| > |\lambda_{r+1}| \) and that the \( n \times r \) matrices \( \{Q_k\} \) are defined by (8.2.8). If \( \theta \in [0, \pi/2] \) is specified by

\[
\cos(\theta) = \min_{u \in D_r(A)} \min_{v \in \text{ran}(Q_\alpha)} \frac{|u^T v|}{\|u\|_2 \|v\|_2} > 0,
\]

then

\[
\text{dist}(D_r(A), \text{ran}(Q_k)) \leq \tan(\theta) \left| \frac{\lambda_{r+1}}{\lambda_r} \right|^k.
\]

See also Theorem 7.3.1.
Proof. By induction it can be shown that

\[ A^k Q_0 = Q_k (R_k \cdots R_1) \]

and so with the partitionings (8.2.10) we have

\[
\begin{bmatrix}
  D_1^k & 0 \\
  0 & D_2^k
\end{bmatrix}
\begin{bmatrix}
  Q_{\alpha}^T Q_0 \\
  Q_{\beta}^T Q_0
\end{bmatrix}
= \begin{bmatrix}
  Q_{\alpha}^T Q_k \\
  Q_{\beta}^T Q_k
\end{bmatrix}
= (R_k \cdots R_1).
\]

If

\[ Q^T Q_k = [Q_{\alpha}, Q_{\beta}]^T Q_k = \begin{bmatrix}
  Q_{\alpha}^T Q_k \\
  Q_{\beta}^T Q_k
\end{bmatrix} = \begin{bmatrix}
  V_k \\
  W_k
\end{bmatrix}, \]

then

\[
\cos(\theta_{\text{min}}) = \sigma_r(V_0) = \sqrt{1 - \|W_0\|_2^2}
\]

\[
\text{dist}(D_r(A), \text{ran}(Q_k)) = \|W_k\|_2
\]

\[ D_1^k V_0 = V_k (R_k \cdots R_1) \]

\[ D_2^k W_0 = W_k (R_k \cdots R_1) \]

It follows that \( V_0 \) is nonsingular which in turn implies that \( V_k \) and \((R_k \cdots R_1)\) are also nonsingular. Thus,

\[
W_k = D_2^k W_0 (R_k \cdots R_1)^{-1} = D_2^k W_0 (V_k^{-1} D_1^k V_0)^{-1}
\]

\[ = D_2^k W_0 V_0^{-1} D_1^{-k} V_k \]

and so

\[
\|W_k\|_2 \leq \|D_2^k\|_2 \|W_0\|_2 \|V_0^{-1}\|_2 \|D_1^{-k}\|_2 \|V_k\|_2
\]

\[ \leq |\lambda_{r+1}|^k \sin(\theta) \frac{1}{\cos(\theta)} \frac{1}{|\lambda_r|^k} = \tan(\theta) \frac{|\lambda_{r+1}|}{|\lambda_r|} \]

\[ \square \]

Example 8.2.3 If (8.2.8) is applied to the matrix of Example 8.2.1 with \( r = 2 \) and \( Q_0 = I_4(:,1:2) \), then

8.2.5 The QR Iteration

Consider what happens when we apply the method of orthogonal iteration (8.2.8) with \( r = n \). Let \( Q^T A Q = \text{diag}(\lambda_1, \ldots, \lambda_n) \) be the Schur decomposition and assume

\[
|\lambda_1| > |\lambda_2| > \cdots > |\lambda_n|.
\]

If \( Q = [q_1, \ldots, q_n] \) and \( Q_k = \begin{bmatrix} q_1^{(k)} \\ \vdots \\ q_n^{(k)} \end{bmatrix} \) and

\[
\text{dist}(D_i(A), \text{span}\{q_i^{(0)}, \ldots, q_i^{(0)}\}) < 1 \tag{8.2.11}
\]

for \( i = 1:n - 1 \), then it follows from Theorem 8.2.2 that

\[
\text{dist}(\text{span}\{q_i^{(k)}, \ldots, q_i^{(k)}\}, \text{span}\{q_1, \ldots, q_i\}) = 0 \left( \frac{1}{|\lambda_{i+1}|} \right). 
\]

for \( i = 1:n - 1 \). This implies that the matrices \( T_k \) defined by

\[
T_k = Q_k^T A Q_k
\]

are converging to diagonal form. Thus, it can be said that the method of orthogonal iteration computes a Schur decomposition if \( r = n \) and the original iterate \( Q_0 \in \mathbb{R}^{n \times n} \) is not deficient in the sense of (8.2.11).

The QR iteration arises by considering how to compute the matrix \( T_k \) directly from its predecessor \( T_{k-1} \). On the one hand, we have from (8.2.1) and the definition of \( T_{k-1} \) that

\[
T_{k-1} = Q_{k-1}^T A Q_{k-1} = Q_{k-1}^T (AQ_{k-1}) = (Q_{k-1}^T Q_k) R_k.
\]

On the other hand,

\[
T_k = Q_k^T A Q_k = (Q_k^T AQ_{k-1})(Q_{k-1}^T Q_k) = R_k(Q_{k-1}^T Q_k).
\]

Thus, \( T_k \) is determined by computing the QR factorization of \( T_{k-1} \) and then multiplying the factors together in reverse order. This is precisely what is done in (8.2.1).

**Example 8.2.4** If the QR iteration (8.2.1) is applied to the matrix in Example 8.2.1, then after 10 iterations

\[
T_{10} = \begin{bmatrix}
11.9907 & -0.1926 & -0.0004 & 0.0000 \\
-0.1926 & 8.0093 & -0.0029 & 0.0001 \\
-0.0004 & -0.0029 & 4.0000 & 0.0007 \\
0.0000 & 0.0001 & 0.0007 & -2.0000
\end{bmatrix}.
\]

The off-diagonal entries of the \( T_k \) matrices go to zero as follows:
8.2. Power Iterations

| $k$ | $|T_k(2,1)|$ | $|T_k(3,1)|$ | $|T_k(4,1)|$ | $|T_k(3,2)|$ | $|T_k(4,2)|$ | $|T_k(4,3)|$ |
|-----|-------------|-------------|-------------|-------------|-------------|-------------|
| 1   | 3.9254      | 1.8122      | 3.3892      | 4.2492      | 2.8367      | 1.1679      |
| 2   | 2.6491      | 1.2841      | 2.1908      | 1.1587      | 3.1473      | 0.2294      |
| 3   | 2.0147      | 0.6154      | 0.5082      | 0.0997      | 0.9859      | 0.0748      |
| 4   | 1.6930      | 0.2408      | 0.0970      | 0.0723      | 0.2596      | 0.0440      |
| 5   | 1.2928      | 0.0866      | 0.0173      | 0.0665      | 0.0667      | 0.0233      |
| 6   | 0.9222      | 0.0299      | 0.0030      | 0.0405      | 0.0169      | 0.0118      |
| 7   | 0.6346      | 0.0101      | 0.0005      | 0.0219      | 0.0043      | 0.0059      |
| 8   | 0.4292      | 0.0034      | 0.0001      | 0.0113      | 0.0011      | 0.0030      |
| 9   | 0.2880      | 0.0011      | 0.0000      | 0.0057      | 0.0003      | 0.0015      |
| 10  | 0.1926      | 0.0004      | 0.0000      | 0.0029      | 0.0001      | 0.0007      |

Note that a single QR iteration involves $O(n^3)$ flops. Moreover, since convergence is only linear (when it exists), it is clear that the method is a prohibitively expensive way to compute Schur decompositions. Fortunately, these practical difficulties can be overcome as we show in the next section.

Problems

P8.2.1 Suppose $A_0 \in \mathbb{R}^{n \times n}$ is symmetric and positive definite and consider the following iteration:

$$
\begin{align*}
for \; k = 1, 2, \ldots \\
A_{k-1} &= G_k G_k^T \\
A_k &= G_k^T G_k \\
\end{align*}
$$

(Cholesky)

(a) Show that this iteration is defined. (b) Show that if $A_0 = \begin{bmatrix} a & b \\ b & c \end{bmatrix}$ with $a \geq c$ has eigenvalues $\lambda_1 \geq \lambda_2 > 0$, then the $A_k$ converge to $\text{diag}(\lambda_1, \lambda_2)$.

P8.2.2 Prove (8.2.7).

P8.2.3 Suppose $A \in \mathbb{R}^{n \times n}$ is symmetric and define the function $f: \mathbb{R}^{n+1} \to \mathbb{R}^{n+1}$ by

$$
f \left( \begin{array}{c} x \\ \lambda \end{array} \right) = \left[ \begin{array}{c} Ax - \lambda x \\ (x^T x - 1)/2 \end{array} \right]
$$

where $x \in \mathbb{R}^n$ and $\lambda \in \mathbb{R}$. Suppose $x_+$ and $\lambda_+$ are produced by applying Newton's method to $f$ at the "current point" defined by $x_c$ and $\lambda_c$. Give expressions for $x_+$ and $\lambda_+$ assuming that $\|x_c\|_2 = 1$ and $\lambda_c = x_c^T A x_c$.

Notes and References for Sec. 8.2

The following references are concerned with the method of orthogonal iteration (a.k.a. the method of simultaneous iteration):

References for the Rayleigh quotient method include

### 8.3 The Symmetric QR Algorithm

The symmetric QR iteration (8.2.1) can be made very efficient in two ways. First, we show how to compute an orthogonal $U_0$ such that $U_0^T A U = T$ is tridiagonal. With this reduction, the iterates produced by (8.2.1) are all tridiagonal and this reduces the work per step to $O(n^2)$. Second, the idea of shifts are introduced and with this change the convergence to diagonal form proceeds at a cubic rate. This is far better than having the off-diagonal entries going to to zero like $|\lambda_{i+1}/\lambda_i|^k$ as discussed in §8.2.5.

#### 8.3.1 Reduction to Tridiagonal Form

If $A$ is symmetric, then it is possible to find an orthogonal $Q$ such that

$$Q^T A Q = T$$  \hspace{1cm} (8.3.1)

is tridiagonal. We call this the tridiagonal decomposition and as a compression of data, it represents a very big step towards diagonalization.

We show how to compute (8.3.1) with Householder matrices. Suppose that Householder matrices $P_1, \ldots, P_{k-1}$ have been determined such that if $A_{k-1} = (P_1 \cdots P_{k-1})^T A (P_1 \cdots P_{k-1})$, then

$$A_{k-1} = \begin{bmatrix} B_{11} & B_{12} & 0 & \cdots & 0 \\ B_{21} & B_{22} & B_{23} & & \\ 0 & B_{32} & B_{33} & & \\\end{bmatrix} \begin{bmatrix} k-1 \\ 1 \\ \vdots \\ n-k \end{bmatrix}$$

is tridiagonal through its first $k-1$ columns. If $\tilde{P}_k$ is an order $n-k$ Householder matrix such that $\tilde{P}_k B_{32}$ is a multiple of $I_{n-k}(;1)$ and if $P_k =$
diag(I_k, \tilde{P}_k), then the leading k-by-k principal submatrix of

\[
A_k = P_k A_{k-1} P_k = \begin{bmatrix}
B_{11} & B_{12} & 0 \\
B_{21} & B_{22} & B_{23} \tilde{P}_k \\
0 & \tilde{P}_k B_{32} & \tilde{P}_k B_{33} \tilde{P}_k \\
k-1 & 1 & n-k
\end{bmatrix}
k-1

\]
is tridiagonal. Clearly, if U_0 = P_1 \cdots P_{n-2}, then U_0^T A U_0 = T is tridiagonal.

In the calculation of A_k it is important to exploit symmetry during the formation of the matrix \tilde{P}_k B_{33} \tilde{P}_k. To be specific, suppose that \tilde{P}_k has the form

\[
\tilde{P}_k = I - \beta vv^T, \quad \beta = 2/v^T v, \quad 0 \neq v \in \mathbb{R}^{n-k}.
\]

Note that if p = \beta B_{33} v and w = p - (\beta p^T v/2)v, then

\[
\tilde{P}_k B_{33} \tilde{P}_k = B_{33} - vw^T - wv^T.
\]

Since only the upper triangular portion of this matrix needs to be calculated, we see that the transition from A_{k-1} to A_k can be accomplished in only 4(n-k)^2 flops.

Algorithm 8.3.1 (Householder Tridiagonalization) Given a symmetric A ∈ \mathbb{R}^{n \times n}, the following algorithm overwrites A with T = Q^T A Q, where T is tridiagonal and Q = H_1 \cdots H_{n-2} is the product of Householder transformations.

\[
\text{for } k = 1:n-2 \\
[v, \beta] = \text{house}(A(k+1:n,k)) \\
p = \beta A(k+1:n,k+1:n)v \\
w = p - (\beta p^T v/2)v \\
A(k+1,k) = \|A(k+1:n,k)\|_2; \quad A(k,k+1) = A(k+1,k) \\
A(k+1:n,k+1:n) = A(k+1:n,k+1:n) - vw^T - wv^T
\]

This algorithm requires 4n^3/3 flops when symmetry is exploited in calculating the rank-2 update. The matrix Q can be stored in factored form in the subdiagonal portion of A. If Q is explicitly required, then it can be formed with an additional 4n^3/3 flops.

Example 8.3.1

\[
\begin{bmatrix}
1 & 0 & 0 \\
0 & .6 & .8 \\
0 & .8 & -.6
\end{bmatrix}^T \begin{bmatrix}
1 & 3 & 4 \\
3 & 2 & 8 \\
4 & 8 & 3
\end{bmatrix} \begin{bmatrix}
1 & 0 & 0 \\
0 & .6 & .8 \\
0 & .8 & -.6
\end{bmatrix} = \begin{bmatrix}
1 & 5 & 0 \\
5 & 10.32 & 1.76 \\
0 & 1.76 & -5.32
\end{bmatrix}.
\]

Note that if T has a zero subdiagonal, then the eigenproblem splits into a pair of smaller eigenproblems. In particular, if t_{k+1,k} = 0, then \lambda(T) =
\[ \lambda(T(1:k, 1:k)) \cup \lambda(T(k + 1:n, k + 1:n)) \]. If \( T \) has no zero subdiagonal entries, then it is said to be unreduced.

Let \( \hat{T} \) denote the computed version of \( T \) obtained by Algorithm 8.3.1. It can be shown that \( \hat{T} = \hat{Q}^T (A + E) \hat{Q} \) where \( \hat{Q} \) is exactly orthogonal and \( E \) is a symmetric matrix satisfying \( \| E \|_F \leq c \| A \|_F \) where \( c \) is a small constant. See Wilkinson (1965, p. 297).

### 8.3.2 Properties of the Tridiagonal Decomposition

We prove two theorems about the tridiagonal decomposition both of which have key roles to play in the sequel. The first connects (8.3.1) to the QR factorization of a certain Krylov matrix. These matrices have the form

\[
K(A, v, k) = [v, Av, \ldots, A^{k-1}v] \quad A \in \mathbb{R}^{n \times n}, \ v \in \mathbb{R}^n.
\]

**Theorem 8.3.1** If \( Q^T AQ = T \) is the tridiagonal decomposition of the symmetric matrix \( A \in \mathbb{R}^{n \times n} \), then \( Q^T K(A, Q(:,1), n) = R \) is upper triangular. If \( R \) is nonsingular, then \( T \) is unreduced. If \( R \) is singular and \( k \) is the smallest index so \( r_{kk} = 0 \), then \( k \) is also the smallest index so \( t_{k,k-1} \) is zero. See also Theorem 7.4.3.

**Proof.** It is clear that if \( q_1 = Q(:,1) \), then

\[
Q^T K(A, Q(:,1), n) = \begin{bmatrix} Q^T q_1, (Q^T AQ)(Q^T q_1), \ldots, (Q^T AQ)^{n-1}(Q^T q_1) \end{bmatrix} = \begin{bmatrix} e_1, Te_1, \ldots, T^{n-1}e_1 \end{bmatrix} = R
\]

is upper triangular with the property that \( r_{11} = 1 \) and \( r_{ii} = t_{21}t_{32}\cdots t_{i-1,i-1} \) for \( i = 2:n \). Clearly, if \( R \) is nonsingular, then \( T \) is unreduced. If \( R \) is singular and \( r_{kk} \) is its first zero diagonal entry, then \( k \geq 2 \) and \( t_{k,k-1} \) is the first zero subdiagonal entry. \( \square \)

The next result shows that \( Q \) is essentially unique once \( Q(:,1) \) is specified.

**Theorem 8.3.2 (Implicit Q Theorem)** Suppose \( Q = [q_1, \ldots, q_n] \) and \( V = [v_1, \ldots, v_n] \) are orthogonal matrices with the property that both \( Q^T AQ = T \) and \( V^T AV = S \) are tridiagonal where \( A \in \mathbb{R}^{n \times n} \) is symmetric. Let \( k \) denote the smallest positive integer for which \( t_{k+1,k} = 0 \), with the convention that \( k = n \) if \( T \) is unreduced. If \( v_1 = q_1 \), then \( v_i = \pm q_i \) and \( |t_{i,i-1}| = |s_{i,i-1}| \) for \( i = 2:k \). Moreover, if \( k < n \), then \( s_{k+1,k} = 0 \). See also Theorem 7.4.2.

**Proof.** Define the orthogonal matrix \( W = Q^T V \) and observe that \( W(:,1) = I_n(:,1) = e_1 \) and \( W^T TW = S \). By Theorem 8.3.1, \( W^T K(T,e_1,k) \) is upper triangular with full column rank. But \( K(T,e_1,k) \) is upper triangular and so by the essential uniqueness of the thin QR factorization,

\[
W(:,1:k) = I_n(:,1:k)\text{diag}(\pm1, \ldots, \pm1).
\]
This says that \( Q(:,i) = \pm V(:,i) \) for \( i = 1:k \). The comments about the subdiagonal entries follows from this since \( t_{i+1,i} = Q(:,i+1)^T A Q(:,i) \) and \( s_{i+1,i} = V(:,i+1)^T A V(:,i) \) for \( i = 1:n-1 \). \( \square \)

### 8.3.3 The QR Iteration and Tridiagonal Matrices

We quickly state four facts that pertain to the QR iteration and tridiagonal matrices. Complete verifications are straightforward.

1. **Preservation of Form.** If \( T = QR \) is the QR factorization of a symmetric tridiagonal matrix \( T \in \mathbb{R}^{n \times n} \), then \( Q \) has lower bandwidth 1 and \( R \) has upper bandwidth 2 and it follows that

\[
T_+ = RQ = Q^T (QR) Q = Q^T T Q
\]

is also symmetric and tridiagonal.

2. **Shifts.** If \( s \in \mathbb{R} \) and \( T - sI = QR \) is the QR factorization, then

\[
T_+ = RQ + sI = Q^T T Q
\]

is also tridiagonal. This is called a shifted QR step.

3. **Perfect Shifts.** If \( T \) is unreduced, then the first \( n - 1 \) columns of \( T - sI \) are independent regardless of \( s \). Thus, if \( s \in \lambda(T) \) and

\[
QR = T - sI
\]

is a QR factorization, then \( r_{nn} = 0 \) and the last column of \( T_+ = RQ + sI \) equals \( s I_n(:,n) = se_n \).

4. **Cost.** If \( T \in \mathbb{R}^{n \times n} \) is tridiagonal, then its QR factorization can be computed by applying a sequence of \( n - 1 \) Givens rotations:

\[
\text{for } k = 1:n - 1 \\
[ c, s ] = \text{givens}(t_{kk}, t_{k+1,k}) \\
m = \min\{k + 2, n\} \\
T(k:k + 1, k:m) = \begin{bmatrix} c & s \\ -s & c \end{bmatrix}^T T(k:k + 1, k:m)
\]

end

This requires \( O(n) \) flops. If the rotations are accumulated, then \( O(n^2) \) flops are needed.
8.3.4 Explicit Single Shift QR Iteration

If $s$ is a good approximate eigenvalue, then we suspect that the $(n,n-1)$ will be small after a QR step with shift $s$. This is the philosophy behind the following iteration:

$$ T = U_0^T A U_0 \quad \text{(tridiagonal)} $$

for $k = 0, 1, \ldots$

Determine real shift $\mu$. \hspace{1cm} \hspace{1cm} (8.3.2)

$$ T - \mu I = UR \quad \text{(QR factorization)} $$

$$ T = RU + \mu I $$

end

If

$$ T = \begin{bmatrix}
    a_1 & b_1 & & \\
    b_1 & a_2 & & \\
    & & \ddots & \\
    & & & b_{n-1}
\end{bmatrix}. $$

then one reasonable choice for the shift is $\mu = a_n$. However, a more effective choice is to shift by the eigenvalue of

$$ T(n-1:n, n-1:n) = \begin{bmatrix}
    a_{n-1} & b_{n-1} \\
    b_{n-1} & a_n
\end{bmatrix} $$

that is closer to $a_n$. This is known as the Wilkinson shift and it is given by

$$ \mu = a_n + d - \text{sign}(d) \sqrt{d^2 + b_{n-1}^2} \hspace{1cm} (8.3.3) $$

where $d = (a_{n-1} - a_n)/2$. Wilkinson (1968b) has shown that (8.3.2) is cubically convergent with either shift strategy, but gives heuristic reasons why (8.3.3) is preferred.

8.3.5 Implicit Shift Version

It is possible to execute the transition from $T$ to $T_+ = RU + \mu I = U^T T U$ without explicitly forming the matrix $T - \mu I$. This has advantages when the shift is much larger than some of the $a_i$. Let $c = \cos(\theta)$ and $s = \sin(\theta)$ be computed such that

$$ \begin{bmatrix}
    c & s \\
    -s & c
\end{bmatrix}^T \begin{bmatrix}
    a_1 - \mu \\
    b_1
\end{bmatrix} = \begin{bmatrix}
    \times \\
    0
\end{bmatrix}. $$
If we set \( G_1 = G(1, 2, \theta) \) then \( G_1 e_1 = U e_1 \) and

\[
T \leftarrow G_1^T T G_1 = \begin{bmatrix}
\times & \times & + & 0 & 0 & 0 \\
\times & \times & \times & 0 & 0 & 0 \\
+ & \times & \times & 0 & 0 & 0 \\
0 & 0 & \times & \times & \times & 0 \\
0 & 0 & 0 & \times & \times & \times \\
0 & 0 & 0 & 0 & \times & \times
\end{bmatrix}.
\]

We are thus in a position to apply the Implicit Q theorem provided we can compute rotations \( G_2, \ldots, G_{n-1} \) with the property that if \( Z = G_1 G_2 \cdots G_{n-1} \) then \( Z e_1 = G_1 e_1 = U e_1 \) and \( Z^T T Z \) is tridiagonal.

Note that the first column of \( Z \) and \( U \) are identical provided we take each \( G_i \) to be of the form \( G_i = G(i, i+1, \theta_i) \), \( i = 2:n - 1 \). But \( G_i \) of this form can be used to chase the unwanted nonzero element “+” out of the matrix \( G_1^T T G_1 \) as follows:

\[
G_2 \rightarrow \begin{bmatrix}
\times & \times & 0 & 0 & 0 & 0 \\
\times & \times & + & 0 & 0 & 0 \\
0 & \times & \times & 0 & 0 & 0 \\
0 & + & \times & \times & 0 & 0 \\
0 & 0 & 0 & \times & \times & \times \\
0 & 0 & 0 & 0 & \times & \times
\end{bmatrix} \quad G_3 \rightarrow \begin{bmatrix}
\times & \times & 0 & 0 & 0 & 0 \\
\times & \times & \times & 0 & 0 & 0 \\
0 & \times & \times & \times & 0 & 0 \\
0 & 0 & + & \times & \times & \times \\
0 & 0 & 0 & 0 & \times & \times
\end{bmatrix}
\]

\[
G_4 \rightarrow \begin{bmatrix}
\times & \times & 0 & 0 & 0 & 0 \\
\times & \times & 0 & 0 & 0 & 0 \\
0 & \times & \times & 0 & 0 & 0 \\
0 & 0 & \times & \times & + & 0 \\
0 & 0 & 0 & \times & \times & \times \\
0 & 0 & 0 & + & \times & \times
\end{bmatrix} \quad G_5 \rightarrow \begin{bmatrix}
\times & \times & 0 & 0 & 0 & 0 \\
\times & \times & \times & 0 & 0 & 0 \\
0 & \times & \times & \times & 0 & 0 \\
0 & 0 & 0 & \times & \times & x \\
0 & 0 & 0 & 0 & \times & \times
\end{bmatrix}
\]

Thus, it follows from the Implicit Q theorem that the tridiagonal matrix \( Z^T T Z \) produced by this zero-chasing technique is essentially the same as the tridiagonal matrix \( T \) obtained by the explicit method. (We may assume that all tridiagonal matrices in question are unreduced for otherwise the problem decouples.)

Note that at any stage of the zero-chasing, there is only one nonzero entry outside the tridiagonal band. How this nonzero entry moves down the matrix during the update \( T \leftarrow G_k^T T G_k \) is illustrated in the following:

\[
\begin{bmatrix}
1 & 0 & 0 & 0 \\
0 & c & s & 0 \\
0 & -s & c & 0 \\
0 & 0 & 0 & 1
\end{bmatrix}^T \begin{bmatrix}
a_k & b_k & z_k & 0 \\
b_k & a_p & b_p & 0 \\
z_k & b_p & a_q & b_q \\
0 & 0 & b_q & a_r
\end{bmatrix} \begin{bmatrix}
1 & 0 & 0 & 0 \\
0 & c & s & 0 \\
0 & -s & c & 0 \\
0 & 0 & 0 & 1
\end{bmatrix} = \begin{bmatrix}
a_k & b_k & 0 & 0 \\
b_k & a_p & b_p & z_p \\
0 & b_p & a_q & b_q \\
0 & z_p & b_q & a_r
\end{bmatrix}.
\]

Here \((p, q, r) = (k + 1, k + 2, k + 3)\). This update can be performed in about
26 flops once \( c \) and \( s \) have been determined from the equation \( b_k s + z_k c = 0 \). Overall we obtain

**Algorithm 8.3.2 (Implicit Symmetric QR Step with Wilkinson Shift)** Given an unreduced symmetric tridiagonal matrix \( T \in \mathbb{R}^{n \times n} \), the following algorithm overwrites \( T \) with \( Z^T T Z \), where \( Z = G_1 \cdots G_{n-1} \) is a product of Givens rotations with the property that \( Z^T(T - \mu I) \) is upper triangular and \( \mu \) is that eigenvalue of \( T \)'s trailing 2-by-2 principal submatrix closer to \( t_{nn} \).

\[
d = \frac{(t_{n-1,n-1} - t_{nn})}{2} \\
\mu = \frac{t_{nn} - t_{n,n-1}^2}{(d + \text{sign}(d)\sqrt{d^2 + t_{n,n-1}^2})} \\
x = t_{11} - \mu \\
z = t_{21} \\
\text{for } k = 1:n-1 \\
\quad [c, s] = \text{givens}(x, z) \newline
\quad T = G_k^T T G_k, \quad \text{where } G_k = G(k, k+1, \theta) \\
\quad \text{if } k < n-1 \\
\quad \quad x = t_{k+1,k} \\
\quad \quad z = t_{k+2,k} \\
\text{end}
\]

This algorithm requires about \( 30n \) flops and \( n \) square roots. If a given orthogonal matrix \( Q \) is overwritten with \( QG_1 \cdots G_{n-1} \), then an additional \( 6n^2 \) flops are needed. Of course, in any practical implementation the tridiagonal matrix \( T \) would be stored in a pair of \( n \)-vectors and not in an \( n \)-by-\( n \) array.

**Example 8.3.2** If Algorithm 8.3.2 is applied to

\[
T = \begin{bmatrix}
1 & 1 & 0 & 0 \\
1 & 2 & 1 & 0 \\
0 & 1 & 3 & .01 \\
0 & 0 & .01 & 4
\end{bmatrix},
\]

then the new tridiagonal matrix \( T \) is given by

\[
T = \begin{bmatrix}
.5000 & .5916 & 0 & 0 \\
.5916 & 1.785 & .1808 & 0 \\
0 & .1808 & 3.7140 & .0000044 \\
0 & 0 & .0000044 & 4.002497
\end{bmatrix}.
\]

Algorithm 8.3.2 is the basis of the symmetric QR algorithm—the standard means for computing the Schur decomposition of a dense symmetric matrix.
Algorithm 8.3.3 (Symmetric QR Algorithm) Given $A \in \mathbb{R}^{n \times n}$ (symmetric) and a tolerance $tol$ greater than the unit roundoff, this algorithm computes an approximate symmetric Schur decomposition $Q^T AQ = D$. $A$ is overwritten with the tridiagonal decomposition.

Use Algorithm 8.3.1, compute the tridiagonalization

$$T = (P_1 \cdots P_{n-2})^T A (P_1 \cdots P_{n-2}).$$

Set $D = T$ and if $Q$ is desired, form $Q = P_1 \cdots P_{n-2}$. See §5.1.6.

until $q = n$

For $i = 1:n - 1$, set $d_{i+1,i}$ and $d_{i,i+1}$ to zero if

$$|d_{i+1,i}| = |d_{i,i+1}| \leq tol(|d_{ii}| + |d_{i+1,i+1}|)$$

Find the largest $q$ and the smallest $p$ such that if

$$D = \begin{bmatrix}
D_{11} & 0 & 0 & \cdots & 0 \\
0 & D_{22} & 0 & \cdots & 0 \\
0 & 0 & D_{33} & \cdots & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots \\
0 & 0 & 0 & \cdots & D_{nn}
\end{bmatrix}$$

then $D_{33}$ is diagonal and $D_{22}$ is unreduced.

if $q < n$

Apply Algorithm 8.3.2 to $D_{22}$:

$$D = \text{diag}(I_p, \tilde{Z}, I_q)^T D \text{diag}(I_p, \tilde{Z}, I_q)$$

If $Q$ is desired, then $Q = Q \text{ diag}(I_p, \tilde{Z}, I_q)$.

end

This algorithm requires about $4n^3/3$ flops if $Q$ is not accumulated and about $9n^3$ flops if $Q$ is accumulated.

Example 8.3.3 Suppose Algorithm 8.3.3 is applied to the tridiagonal matrix

$$A = \begin{bmatrix}
1 & 2 & 0 & 0 \\
2 & 3 & 4 & 0 \\
0 & 4 & 5 & 6 \\
0 & 0 & 6 & 7
\end{bmatrix}$$

The subdiagonal entries change as follows during the execution of Algorithm 8.3.3:

<table>
<thead>
<tr>
<th>Iteration</th>
<th>$a_{21}$</th>
<th>$a_{32}$</th>
<th>$a_{43}$</th>
</tr>
</thead>
<tbody>

<td></td>
<td></td>
</tr>
</tbody>
</table>
Upon completion we find \( \lambda(A) = \{-2.4848, 0.7046, 4.9366, 12.831\} \).

The computed eigenvalues \( \hat{\lambda}_i \) obtained via Algorithm 8.3.3 are the exact eigenvalues of a matrix that is near to \( A \), i.e., \( Q_0^T(A + E)Q_0 = \text{diag}(\hat{\lambda}_i) \) where \( Q_0^TQ_0 = I \) and \( \| E \|_2 \approx \| A \|_2 \). Using Corollary 8.1.6 we know that the absolute error in each \( \hat{\lambda}_i \) is small in the sense that \( | \hat{\lambda}_i - \lambda_i | \approx \| A \|_2 \). If \( \hat{Q} = [\hat{q}_1, \ldots, \hat{q}_n] \) is the computed matrix of orthonormal eigenvectors, then the accuracy of \( \hat{q}_i \) depends on the separation of \( \lambda_i \) from the remainder of the spectrum. See Theorem 8.1.12.

If all of the eigenvalues and a few of the eigenvectors are desired, then it is cheaper not to accumulate \( Q \) in Algorithm 8.3.3. Instead, the desired eigenvectors can be found via inverse iteration with \( T \). See §8.2.2. Usually just one step is sufficient to get a good eigenvector, even with a random initial vector.

If just a few eigenvalues and eigenvectors are required, then the special techniques in §8.5 are appropriate.

It is interesting to note the connection between Rayleigh quotient iteration and the symmetric QR algorithm. Suppose we apply the latter to the tridiagonal matrix \( T \in \mathbb{R}^{n \times n} \) with shift \( \sigma = e_n^TTe_n = t_{nn} \) where \( e_n = I_n(:, n) \). If \( T - \sigma I = QR \), then we obtain \( T = RQ + \sigma I \). From the equation \((T - \sigma I)Q = R^T\) it follows that

\[
(T - \sigma I)q_n = r_{nn}e_n,
\]

where \( q_n \) is the last column of the orthogonal matrix \( Q \). Thus, if we apply (8.2.6) with \( x_0 = e_n \), then \( x_1 = q_n \).

### 8.3.6 Orthogonal Iteration with Ritz Acceleration

Recall from §8.2.4 that an orthogonal iteration step involves a matrix-matrix product and a QR factorization:

\[
Z_k = A\tilde{Q}_{k-1} \\
\tilde{Q}_kR_k = Z_k \quad \text{(QR factorization)}
\]

Theorem 8.1.14 says that we can minimize \( \| A\tilde{Q}_k - \tilde{Q}_kS \|_F \) by setting \( S = S_k \equiv \tilde{Q}_k^TA\tilde{Q}_k \). If \( U_k^TS_kU_k = D_k \) is the Schur decomposition of \( S_k \in \mathbb{R}^{r \times r} \) and \( Q_k = \tilde{Q}_kU_k \), then

\[
\| AQ_k - Q_kD_k \|_F = \| A\tilde{Q}_k - \tilde{Q}_kS_k \|_F
\]

showing that the columns of \( Q_k \) are the best possible basis to take after \( k \) steps from the standpoint of minimizing the residual. This defines the Ritz acceleration idea:
8.3. **The Symmetric QR Algorithm**

\[ Q_0 \in \mathbb{R}^{n \times p} \text{ given with } Q_0^T Q_0 = I_p \]

**for** \( k = 1, 2, \ldots \)

\[
\begin{align*}
Z_k &= AQ_k - 1 \\
\tilde{Q}_k R_k &= Z_k \quad \text{(QR factorization)} \\
S_k &= \tilde{Q}_k^T A \tilde{Q}_k \quad \text{(8.3.6)} \\
U_k^T S_k U_k &= D_k \quad \text{(Schur decomposition)} \\
Q_k &= \tilde{Q}_k U_k
\end{align*}
\]

**end**

It can be shown that if

\[
D_k = \text{diag}(\theta_1^{(k)}, \ldots, \theta_r^{(k)}) \quad |\theta_1^{(k)}| \geq \cdots \geq |\theta_r^{(k)}|
\]

then

\[
|\theta_i^{(k)} - \lambda_i(A)| = O \left( \left| \frac{\lambda_{r+1}}{\lambda_i} \right|^k \right) \quad i = 1:r
\]

Recall that Theorem 8.2.2 says the eigenvalues of \( \tilde{Q}_k^T A \tilde{Q}_k \) converge with rate \( |\lambda_{r+1}/\lambda_r|^k \). Thus, the Ritz values converge at a more favorable rate. For details, see Stewart (1969).

**Example 8.3.4** If we apply (8.3.6) with

\[
A = \begin{bmatrix}
100 & 1 & 1 & 1 \\
1 & 99 & 1 & 1 \\
1 & 1 & 2 & 1 \\
1 & 1 & 1 & 1
\end{bmatrix}
\quad \text{and} \quad
Q_0 = \begin{bmatrix}
1 & 0 \\
0 & 1 \\
0 & 0 \\
0 & 0
\end{bmatrix}
\]

then

<table>
<thead>
<tr>
<th>( k )</th>
<th>\text{dist}(D_2(A), Q_k)</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>( 2 \times 10^{-1} )</td>
</tr>
<tr>
<td>1</td>
<td>( 5 \times 10^{-3} )</td>
</tr>
<tr>
<td>2</td>
<td>( 1 \times 10^{-4} )</td>
</tr>
<tr>
<td>3</td>
<td>( 3 \times 10^{-6} )</td>
</tr>
<tr>
<td>4</td>
<td>( 8 \times 10^{-8} )</td>
</tr>
</tbody>
</table>

Clearly, convergence is taking place at the rate \( (2/99)^k \).

**Problems**

**P8.3.1** Suppose \( \lambda \) is an eigenvalue of a symmetric tridiagonal matrix \( T \). Show that if \( \lambda \) has algebraic multiplicity \( k \), then at least \( k - 1 \) of \( T \)'s subdiagonal elements are zero.

**P8.3.2** Suppose \( A \) is symmetric and has bandwidth \( p \). Show that if we perform the shifted QR step \( A - \mu I = QR \), \( A = RQ + \mu I \), then \( A \) has bandwidth \( p \).

**P8.3.3** Suppose \( B \in \mathbb{R}^{n \times n} \) is upper bidiagonal with diagonal entries \( d(1:n) \) and superdiagonal entries \( f(1:n-1) \). State and prove a singular value version of Theorem 8.3.1.

**P8.3.4** Let \( A = \begin{bmatrix}
w & x \\
x & z
\end{bmatrix} \) be real and suppose we perform the following shifted QR step: \( A - zI = UR \), \( \bar{A} = RU + zI \). Show that if \( \bar{A} = \begin{bmatrix}
\bar{w} & \bar{x} \\
\bar{x} & \bar{z}
\end{bmatrix} \) then
\[
\begin{align*}
\bar{w} &= w + x^2(w - z)/[(w - z)^2 + x^2] \\
\bar{z} &= z - x^2(w - z)/[(w - z)^2 + x^2] \\
\bar{x} &= -x^3/[(w - z)^2 + x^2].
\end{align*}
\]

**P8.3.5** Suppose \(A \in \mathbb{C}^{n \times n}\) is Hermitian. Show how to construct unitary \(Q\) such that \(Q^H A Q = T\) is real, symmetric, and tridiagonal.

**P8.3.6** Show that if \(A = B + iC\) is Hermitian, then \(M = \begin{bmatrix} B & -C \\ C & B \end{bmatrix}\) is symmetric. Relate the eigenvalues and eigenvectors of \(A\) and \(M\).

**P8.3.7** Rewrite Algorithm 8.2.2 for the case when \(A\) is stored in two \(n\)-vectors. Justify the given flop count.

**P8.3.8** Suppose \(A = S + \sigma uu^T\) where \(S \in \mathbb{R}^{n \times n}\) is skew-symmetric (\(A^T = -A\), \(u \in \mathbb{R}^n\) has unit 2-norm, and \(\sigma \in \mathbb{R}\). Show how to compute an orthogonal \(Q\) such that \(Q^T A Q\) is tridiagonal and \(Q^T u = I_n(:, 1) = e_1\).

### Notes and References for Sec. 8.3

The tridiagonalization of a symmetric matrix is discussed in

The first two references contain Algol programs. Algol procedures for the explicit and implicit tridiagonal QR algorithm are given in

The "QL" algorithm is identical to the QR algorithm except that at each step the matrix \(T - \lambda J\) is factored into a product of an orthogonal matrix and a lower triangular matrix. Other papers concerned with these methods include

Extensions to Hermitian and skew-symmetric matrices are described in

The convergence properties of Algorithm 8.2.3 are detailed in Lawson and Hanson (1974, Appendix B), as well as in

For an analysis of the method when it is applied to normal matrices see

Interesting papers concerned with shifting in the tridiagonal QR algorithm include

Some parallel computation possibilities for the algorithms in this section are discussed in

Another way to compute a specified subset of eigenvalues is via the rational QR algorithm. In this method, the shift is determined using Newton’s method. This makes it possible to “steer” the iteration towards desired eigenvalues. See

Papers concerned with the symmetric QR algorithm for banded matrices include

8.4 Jacobi Methods

Jacobi methods for the symmetric eigenvalue problem attract current attention because they are inherently parallel. They work by performing a sequence of orthogonal similarity updates \( A \leftarrow Q^T A Q \) with the property that each new \( A \), although full, is “more diagonal” than its predecessor. Eventually, the off-diagonal entries are small enough to be declared zero.

After surveying the basic ideas behind the Jacobi approach we develop a parallel Jacobi procedure.

8.4.1 The Jacobi Idea

The idea behind Jacobi’s method is to systematically reduce the quantity

\[
\text{off}(A) = \sqrt{\sum_{i=1}^{n} \sum_{j=1, j\neq i}^{n} a_{ij}^2},
\]

i.e., the “norm” of the off-diagonal elements. The tools for doing this are rotations of the form

\[
J(p, q, \theta) =
\begin{bmatrix}
1 & \ldots & 0 & \ldots & 0 & \ldots & 0 \\
\vdots & \ddots & \vdots & \ddots & \vdots & \ddots & \vdots \\
0 & \ldots & c & \ldots & s & \ldots & 0 \\
\vdots & \vdots & \ddots & \ddots & \ddots & \ddots & \vdots \\
0 & \ldots & -s & \ldots & c & \ldots & 0 \\
\vdots & \vdots & \ddots & \ddots & \ddots & \ddots & \vdots \\
0 & \ldots & 0 & \ldots & 0 & \ldots & 1 \\
\end{bmatrix}
\]

which we call Jacobi rotations. Jacobi rotations are no different from Givens rotations, c.f. §5.1.8. We submit to the name change in this section to honor the inventor.

The basic step in a Jacobi eigenvalue procedure involves (1) choosing an index pair \((p, q)\) that satisfies \(1 \leq p < q \leq n\), (2) computing a cosine-sine pair \((c, s)\) such that

\[
\begin{bmatrix}
b_{pp} & b_{pq} \\
b_{qp} & b_{qq}
\end{bmatrix} =
\begin{bmatrix}
c & s \\
-s & c
\end{bmatrix}^T
\begin{bmatrix}
a_{pp} & a_{pq} \\
a_{qp} & a_{qq}
\end{bmatrix}
\begin{bmatrix}
c & s \\
-s & c
\end{bmatrix}
\]

(8.4.1)

is diagonal, and (3) overwriting \( A \) with \( B = J^T AJ \) where \( J = J(p, q, \theta) \). Observe that the matrix \( B \) agrees with \( A \) except in rows and columns \( p \)
and \( q \). Moreover, since the Frobenius norm is preserved by orthogonal transformations we find that
\[
\begin{align*}
    a_{pp}^2 + a_{qq}^2 + 2a_{pq}^2 &= b_{pp}^2 + b_{qq}^2 + 2b_{pq}^2 = b_{pp}^2 + b_{qq}^2
  \end{align*}
\]
and so
\[
\text{off}(B)^2 = \| B \|_F^2 - \sum_{i=1}^{n} b_{ii}^2 = \| A \|_F^2 - \sum_{i=1}^{n} a_{ii}^2 + (a_{pp}^2 + a_{qq}^2 - b_{pp}^2 - b_{qq}^2)
\]
\[
= \text{off}(A)^2 - 2a_{pq}^2.
\]
It is in this sense that \( A \) moves closer to diagonal form with each Jacobi step.

Before we discuss how the index pair \((p, q)\) can be chosen, let us look at the actual computations associated with the \((p, q)\) subproblem.

### 8.4.2 The 2-by-2 Symmetric Schur Decomposition

To say that we diagonalize in (8.4.1) is to say that
\[
0 = b_{pq} = a_{pq}(c^2 - s^2) + (a_{pp} - a_{qq})cs.
\]
(8.4.3)

If \( a_{pq} = 0 \), then we just set \((c, s) = (1, 0)\). Otherwise define
\[
\tau = \frac{a_{qq} - a_{pp}}{2a_{pq}} \quad \text{and} \quad t = s/c
\]
and conclude from (8.4.3) that \( t = \tan(\theta) \) solves the quadratic
\[
 t^2 + 2\tau t - 1 = 0.
\]
It turns out to be important to select the smaller of the two roots,
\[
t = -\tau \pm \sqrt{1 + \tau^2}
\]
whereupon \( c \) and \( s \) can be resolved from the formulae
\[
c = 1/\sqrt{1 + t^2} \quad s = tc.
\]
Choosing \( t \) to be the smaller of the two roots ensures that \(|\theta| \leq \pi/4\) and has the effect of minimizing the difference between \( B \) and \( A \) because
\[
\| B - A \|_F^2 = 4(1-c) \sum_{i=1, i \neq p,q}^{n} (a_{ip}^2 + a_{iq}^2) + 2a_{pq}^2/c^2
\]
We summarize the 2-by-2 computations as follows:

**Algorithm 8.4.1** Given an $n$-by-$n$ symmetric $A$ and integers $p$ and $q$ that satisfy $1 \leq p < q \leq n$, this algorithm computes a cosine-sine pair $(c, s)$ such that if $B = J(p, q, \theta)^T AJ(p, q, \theta)$ then $b_{pq} = b_{qp} = 0.$

function: $[c, s] = \text{sym.schur2}(A, p, q)$
  if $A(p, q) \neq 0$
    $\tau = (A(q, q) - A(p, p))/(2A(p, q))$
    if $\tau \geq 0$
      $t = 1/(\tau + \sqrt{1 + \tau^2});$
    else
      $t = -1/(\tau + \sqrt{1 + \tau^2});$
    end
    $c = 1/\sqrt{1 + t^2}$
    $s = tc$
  else
    $c = 1$
    $s = 0$
end

8.4.3 The Classical Jacobi Algorithm

As we mentioned above, only rows and columns $p$ and $q$ are altered when the $(p, q)$ subproblem is solved. Once $\text{sym.schur2}$ determines the 2-by-2 rotation, then the update $A \leftarrow J(p, q, \theta)^T AJ(p, q, \theta)$ can be implemented in $6n$ flops if symmetry is exploited.

How do we choose the indices $p$ and $q$? From the standpoint of maximizing the reduction of $\text{off}(A)$ in (8.4.2), it makes sense to choose $(p, q)$ so that $a_{pq}^2$ is maximal. This is the basis of the classical Jacobi algorithm.

**Algorithm 8.4.2 (Classical Jacobi)** Given a symmetric $A \in \mathbb{R}^{n \times n}$ and a tolerance $tol > 0,$ this algorithm overwrites $A$ with $V^T AV$ where $V$ is orthogonal and $\text{off}(V^T AV) \leq tol \| A \|_F.$

$V = I_n; \ eps = tol \| A \|_F$
while $\text{off}(A) > eps$
  Choose $(p, q)$ so $|a_{pq}| = \max_{i \neq j} |a_{ij}|.$
  $(c, s) = \text{sym.schur2}(A, p, q)$
  $A = J(p, q, \theta)^T AJ(p, q, \theta)$
  $V = V J(p, q, \theta)$
end

Since $|a_{pq}|$ is the largest off-diagonal entry, $\text{off}(A)^2 \leq N(a_{pq}^2 + a_{qp}^2)$ where
8.4. Jacobi Methods

\[ N = n(n - 1)/2. \] From (8.4.2) it follows that

\[ \text{off}(B)^2 \leq \left(1 - \frac{1}{N}\right)\text{off}(A)^2. \]

By induction, if \( A^{(k)} \) denotes the matrix \( A \) after \( k \) Jacobi updates, then

\[ \text{off}(A^{(k)})^2 \leq \left(1 - \frac{1}{N}\right)^k \text{off}(A^{(0)})^2. \]

This implies that the classical Jacobi procedure converges at a linear rate. However, the asymptotic convergence rate of the method is considerably better than linear. Schonhage (1964) and van Kempen (1966) show that for \( k \) large enough, there is a constant \( c \) such that

\[ \text{off}(A^{(k+N)}) \leq c \cdot \text{off}(A^{(k)})^2 \]

i.e., quadratic convergence. An earlier paper by Henrici (1958) established the same result for the special case when \( A \) has distinct eigenvalues. In the convergence theory for the Jacobi iteration, it is critical that \( |\theta| \leq \pi/4 \). Among other things this precludes the possibility of “interchanging” nearly converged diagonal entries. This follows from the formulae

\[ b_{pp} = a_{pp} - ta_{pq} \]

and

\[ b_{qq} = a_{qq} + ta_{pq}, \]

which can be derived from equations (8.4.1) and the definition \( t = \sin(\theta)/\cos(\theta) \).

It is customary to refer to \( N \) Jacobi updates as a sweep. Thus, after a sufficient number of iterations, quadratic convergence is observed when examining \( \text{off}(A) \) after every sweep.

Example 8.4.1 Applying the classical Jacobi iteration to

\[ A = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 1 & 2 & 3 & 4 \\ 1 & 3 & 6 & 10 \\ 1 & 4 & 10 & 20 \end{bmatrix} \]

we find

\[
\begin{array}{c|c}
\text{sweep} & O(\text{off}(A)) \\
\hline
0 & 10^2 \\
1 & 10^1 \\
2 & 10^{-2} \\
3 & 10^{-11} \\
4 & 10^{-17} \\
\end{array}
\]

There is no rigorous theory that enables one to predict the number of sweeps that are required to achieve a specified reduction in \( \text{off}(A) \). However, Brent and Luk (1985) have argued heuristically that the number of sweeps is proportional to \( \log(n) \) and this seems to be the case in practice.
8.4.4 The Cyclic-by-Row Algorithm

The trouble with the classical Jacobi method is that the updates involve $O(n)$ flops while the search for the optimal $(p, q)$ is $O(n^2)$. One way to address this imbalance is to fix the sequence of subproblems to be solved in advance. A reasonable possibility is to step through all the subproblems in row-by-row fashion. For example, if $n = 4$ we cycle as follows:

$$(p, q) = (1, 2), (1, 3), (1, 4), (2, 3), (2, 4), (3, 4), (1, 2), \ldots$$

This ordering scheme is referred to as cyclic-by-row and it results in the following procedure:

**Algorithm 8.4.3 (Cyclic Jacobi)** Given a symmetric $A \in \mathbb{R}^{n \times n}$ and a tolerance $tol > 0$, this algorithm overwrites $A$ with $V^T AV$ where $V$ is orthogonal and $\text{off}(V^T AV) \leq tol \| A \|_F$.

$$V = I_n$$
$$\text{eps} = tol \| A \|_F$$

while $\text{off}(A) > \text{eps}$

for $p = 1:n - 1$

for $q = p + 1:n$

$(c, s) = \text{sym.schur2}(A, p, q)$

$A = J(p, q, \theta)^T A J(p, q, \theta)$

$V = V J(p, q, \theta)$

end

end

Cyclic Jacobi converges also quadratically. (See Wilkinson (1962) and van Kempen (1966).) However, since it does not require off-diagonal search, it is considerably faster than Jacobi's original algorithm.

**Example 8.4.2** If the cyclic Jacobi method is applied to the matrix in Example 8.4.1 we find

<table>

</table>
8.4.5 Error Analysis

Using Wilkinson’s error analysis it is possible to show that if \( r \) sweeps are needed in Algorithm 8.4.3 then the computed \( d_i \) satisfy

\[
\sum_{i=1}^{n} (d_i - \lambda_i)^2 \leq (\delta + k_r)\|A\|_F u
\]

for some ordering of \( A \)'s eigenvalues \( \lambda_i \). The parameter \( k_r \) depends mildly on \( r \).

Although the cyclic Jacobi method converges quadratically, it is not generally competitive with the symmetric QR algorithm. For example, if we just count flops, then 2 sweeps of Jacobi is roughly equivalent to a complete QR reduction to diagonal form with accumulation of transformations. However, for small \( n \) this liability is not very dramatic. Moreover, if an approximate eigenvector matrix \( V \) is known, then \( V^T A V \) is almost diagonal, a situation that Jacobi can exploit but not QR.

Another interesting feature of the Jacobi method is that it can compute the eigenvalues with small relative error if \( A \) is positive definite. To appreciate this point, note that the Wilkinson analysis cited above coupled the §8.1 perturbation theory ensures that the computed eigenvalues \( \hat{\lambda}_1 \geq \cdots \geq \hat{\lambda}_n \) satisfy

\[
\left| \frac{\hat{\lambda}_i - \lambda_i(A)}{\lambda_i(A)} \right| \approx u \frac{\|A\|_2}{\hat{\lambda}_i(A)} \leq u \kappa_2(A).
\]

However, a refined, componentwise error analysis by Demmel and Veselić (1992) shows that in the positive definite case,

\[
\left| \frac{\hat{\lambda}_i - \lambda_i(A)}{\lambda_i(A)} \right| \approx u \kappa_2(D^{-1}AD^{-1}). \tag{8.4.4}
\]

where \( D = \text{diag}(\sqrt{a_{11}}, \ldots, \sqrt{a_{nn}}) \) and this is generally a much smaller approximating bound. The key to establishing this result is some new perturbation theory and a demonstration that if \( A_+ \) is a computed Jacobi update obtained from the current matrix \( A_c \), then the eigenvalues of \( A_+ \) are relatively close to the eigenvalues of \( A_c \) in the sense of (8.4.4). To make the whole thing work in practice, the termination criteria is not based upon the comparison of \( \text{off}(A) \) with \( u\|A\|_F \) but rather on the size of each \( |a_{ij}| \) compared to \( u \sqrt{a_{ii}a_{jj}} \). This work is typical of a new genre of research concerned with high-accuracy algorithms based upon careful, componentwise error analysis. See Mathias (1995).

8.4.6 Parallel Jacobi

Perhaps the most interesting distinction between the QR and Jacobi approaches to the symmetric eigenvalue problem is the rich inherent paral-
elism of the latter algorithm. To illustrate this, suppose \( n = 4 \) and group the six subproblems into three rotation sets as follows:

\[
\begin{align*}
\text{rot.set}(1) &= \{(1,2), (3,4)\} \\
\text{rot.set}(2) &= \{(1,3), (2,4)\} \\
\text{rot.set}(3) &= \{(1,4), (2,3)\}
\end{align*}
\]

Note that all the rotations within each of the three rotation sets are "non-conflicting." That is, subproblems (1,2) and (3,4) can be carried out in parallel. Likewise the (1,3) and (2,4) subproblems can be executed in parallel as can subproblems (1,4) and (2,3). In general, we say that

\[
(i_1, j_1), (i_2, j_2), \ldots, (i_N, j_N) \quad N = (n - 1)n/2
\]

is a parallel ordering of the set \( \{(i, j) \mid 1 \leq i < j \leq n\} \) if for \( s = 1:n - 1 \) the rotation set \( \text{rot.set}(s) = \{(i_r, j_r) : r = 1 + n(s - 1)/2:n/2\} \) consists of nonconflicting rotations. This requires \( n \) to be even, which we assume throughout this section. (The odd \( n \) case can be handled by bordering \( A \) with a row and column of zeros and being careful when solving the subproblems that involve these augmented zeros.)

A good way to generate a parallel ordering is to visualize a chess tournament with \( n \) players in which everybody must play everybody else exactly once. In the \( n = 8 \) case this entails 7 "rounds." During round one we have the following four games:

\[
\begin{array}{cccc}
1 & 3 & 5 & 7 \\
2 & 4 & 6 & 8
\end{array}
\quad \text{rot.set}(1) = \{(1,2), (3,4), (5,6), (7,8)\}
\]

i.e., 1 plays 2, 3 plays 4, etc. To set up rounds 2 through 7, player 1 stays put and players 2 through 8 embark on a merry-go-round:

\[
\begin{array}{cccc}
1 & 2 & 3 & 5 \\
4 & 6 & 8 & 7
\end{array} \quad \text{rot.set}(2) = \{(1,4), (2,6), (3,8), (5,7)\}
\]

\[
\begin{array}{cccc}
1 & 4 & 2 & 3 \\
6 & 8 & 7 & 5
\end{array} \quad \text{rot.set}(3) = \{(1,6), (4,8), (2,7), (3,5)\}
\]

\[
\begin{array}{cccc}
1 & 6 & 4 & 2 \\
8 & 7 & 5 & 3
\end{array} \quad \text{rot.set}(4) = \{(1,8), (6,7), (4,5), (2,3)\}
\]

\[
\begin{array}{cccc}
1 & 8 & 6 & 4 \\
7 & 5 & 3 & 2
\end{array} \quad \text{rot.set}(5) = \{(1,7), (5,8), (3,6), (2,4)\}
\]

\[
\begin{array}{cccc}
1 & 7 & 8 & 6 \\
5 & 3 & 2 & 4
\end{array} \quad \text{rot.set}(6) = \{(1,5), (3,7), (2,8), (4,6)\}
\]
rot.set(τ) = {(1, 3), (2, 5), (4, 7), (6, 8)}

We can encode these operations in a pair of integer vectors top(1:n/2) and bot(1:n/2). During a given round top(k) plays bot(k), k = 1:n/2. The pairings for the next round is obtained by updating top and bot as follows:

function: [new.top, new.bot] = music(top, bot, n)
    m = n/2
    for k = 1:m
        if k = 1
            new.top(1) = 1
        else if k = 2
            new.top(k) = bot(1)
        elseif k > 2
            new.top(k) = top(k - 1)
        end
        if k = m
            new.bot(k) = top(k)
        else
            new.bot(k) = bot(k + 1)
        end
    end
end

Using music we obtain the following parallel order Jacobi procedure.

Algorithm 8.4.4 (Parallel Order Jacobi) Given a symmetric \( A \in \mathbb{R}^{n \times n} \) and a tolerance tol > 0, this algorithm overwrites \( A \) with \( V^TAV \) where \( V \) is orthogonal and \( \text{off}(V^TAV) \leq tol\| A \|_F \). It is assumed that \( n \) is even.

\[
V = I_n \\
eps = tol\| A \|_F \\
top = 1:2:n; bot = 2:2:n \\
while \text{off}(A) > eps \\
    for set = 1:n - 1 \\
        for k = 1:n/2 \\
            p = \min(top(k), bot(k)) \\
            q = \max(top(k), bot(k)) \\
            (c, s) = \text{sym.schur2}(A, p, q) \\
            A = J(p, q, \theta)^T AJ(p, q, \theta) \\
            V = VJ(p, q, \theta)
        end
    end
end

[top, bot] = music(top, bot, n)
Notice that the \( k \)-loop steps through \( n/2 \) independent, nonconflicting subproblems.

### 8.4.7 A Ring Procedure

We now discuss how Algorithm 8.4.4 could be implemented on a ring of \( p \) processors. We assume that \( p = n/2 \) for clarity. At any instant, Proc(\( \mu \)) houses two columns of \( A \) and the corresponding \( V \) columns. For example, if \( n = 8 \) then here is how the column distribution of \( A \) proceeds from step to step:

\[
\begin{array}{cccc}
\text{Proc(1)} & \text{Proc(2)} & \text{Proc(3)} & \text{Proc(4)} \\
\text{etc.}
\end{array}
\]

The ordered pairs denote the indices of the housed columns. The first index names the left column and the second index names the right column. Thus, the left and right columns in Proc(3) during step 3 are 2 and 7 respectively.

Note that in between steps, the columns are shuffled according to the permutation implicit in music and that nearest neighbor communication prevails. At each step, each processor oversees a single subproblem. This involves (a) computing an orthogonal \( V_{\text{small}} \in \mathbb{R}^{2 \times 2} \) that solves a local 2-by-2 Schur problem, (b) using the 2-by-2 \( V_{\text{small}} \) to update the two housed columns of \( A \) and \( V \), (c) sending the 2-by-2 \( V_{\text{small}} \) to all the other processors, and (d) receiving the \( V_{\text{small}} \) matrices from the other processors and updating the local portions of \( A \) and \( V \) accordingly. Since \( A \) is stored by column, communication is necessary to carry out the \( V_{\text{small}} \) updates because they effect rows of \( A \). For example, in the second step of the \( n = 8 \) problem, Proc(2) must receive the 2-by-2 rotations associated with subproblems \((1,4), (3,8), \) and \((5,7)\). These come from Proc(1), Proc(3), and Proc(4) respectively. In general, the sharing of the rotation matrices can be conveniently implemented by circulating the 2-by-2 \( V_{\text{small}} \) matrices in "merry go round" fashion around the ring. Each processor copies a passing 2-by-2 \( V_{\text{small}} \) into its local memory and then appropriately updates the locally housed portions of \( A \) and \( V \).

The termination criteria in Algorithm 8.4.4 poses something of a problem in a distributed memory environment in that the value of \( \text{off}(\cdot) \) and \( \| A \|_F \) require access to all of \( A \). However, these global quantities can be computed during the \( V \) matrix merry-go-round phase. Before the circulation of the \( V \)'s begins, each processor can compute its contribution to \( \| A \|_F \) and \( \text{off}(\cdot) \). These quantities can then be summed by each processor if they are placed on the merry-go-round and read at each stop. By the end of one revolution each processor has its own copy of \( \| A \|_F \) and \( \text{off}(\cdot) \).
8.4.8 Block Jacobi Procedures

It is usually the case when solving the symmetric eigenvalue problem on a
p-processor machine that \( n \gg p \). In this case a block version of the Jacobi
algorithm may be appropriate. Block versions of the above procedures are
straightforward. Suppose that \( n = rN \) and that we partition the \( n \)-by-\( n \)
matrix \( A \) as follows:

\[
A = \begin{bmatrix}
A_{11} & \cdots & A_{1N} \\
\vdots & & \vdots \\
A_{N1} & \cdots & A_{NN}
\end{bmatrix}.
\]

Here, each \( A_{ij} \) is \( r \)-by-\( r \). In block Jacobi the \((p, q)\) subproblem involves
computing the \( 2r \)-by-\( 2r \) Schur decomposition

\[
\begin{bmatrix}
V_{pp} & V_{pq} \\
V_{qp} & V_{qq}
\end{bmatrix}^T \begin{bmatrix}
A_{pp} & A_{pq} \\
A_{qp} & A_{qq}
\end{bmatrix}
\begin{bmatrix}
V_{pp} & V_{pq} \\
V_{qp} & V_{qq}
\end{bmatrix} = \begin{bmatrix}
D_{pp} & 0 \\
0 & D_{qq}
\end{bmatrix}
\]

and then applying to \( A \) the block Jacobi rotation made up of the \( V_{ij} \). If
we call this block rotation \( V \) then it is easy to show that

\[
\text{off}(V^TAV)^2 = \text{off}(A)^2 - \left(2\|A_{pq}\|_F^2 + \text{off}(A_{pp})^2 + \text{off}(A_{qq})^2\right).
\]

Block Jacobi procedures have many interesting computational aspects. For
example, there are many ways to solve the subproblems and the choice
appears to be critical. See Bischof (1987).

Problems

P8.4.1 Let the scalar \( \gamma \) be given along with the matrix

\[
A = \begin{bmatrix}
w & x \\
x & z
\end{bmatrix}.
\]

It is desired to compute an orthogonal matrix

\[
J = \begin{bmatrix}
c & s \\
-s & c
\end{bmatrix}
\]

such that the \((1, 1)\) entry of \( J^T AJ \) equals \( \gamma \). Show that this requirement leads to the
equation

\[(w - \gamma)^2 - 2\tau \tau + (z - \gamma) = 0,
\]

where \( \tau = c/s \).Verify that this quadratic has real roots if \( \gamma \) satisfies \( \lambda_2 \leq \gamma \leq \lambda_1 \), where
\( \lambda_1 \) and \( \lambda_2 \) are the eigenvalues of \( A \).

P8.4.2 Let \( A \in \mathbb{R}^{n \times n} \) be symmetric. Give an algorithm that computes the factorization

\[Q^T AQ = \gamma I + F\]

where \( Q \) is a product of Jacobi rotations, \( \gamma = \text{trace}(A)/n \), and \( F \) has zero diagonal
entries. Discuss the uniqueness of \( Q \).

P8.4.3 Formulate Jacobi procedures for (a) skew symmetric matrices and (b) complex
Hermitian matrices.

**P8.4.4** Partition the $n$-by-$n$ real symmetric matrix $A$ as follows:

$$
A = \begin{bmatrix}
    a & v^T \\
    v & A_1 \\
\\n    1 & n-1
\end{bmatrix}
$$

Let $Q$ be a Householder matrix such that if $B = Q^T AQ$, then $B(3:n,1) = 0$. Let $J = J(1,2,\theta)$ be determined such that if $C = JT BJ$, then $c_{12} = 0$ and $c_{11} \geq c_{22}$. Show $c_{11} \geq a + \| v \|^2$. La Buddde (1964) formulated an algorithm for the symmetric eigenvalue problem based upon repetition of this Householder-Jacobi computation.

**P8.4.5** Organize function music so that it involves minimum workspace.

**P8.4.6** When implementing cyclic Jacobi, it is sensible to skip the annihilation of $a_{pq}$ if its modulus is less than some small, sweep-dependent parameter, because the net reduction in off($A$) is not worth the cost. This leads to what is called the threshold Jacobi method. Details concerning this variant of Jacobi's algorithm may be found in Wilkinson (1965, p.277). Show that appropriate thresholding can guarantee convergence.

**Notes and References for Sec. 8.4**

Jacobi's original paper is one of the earliest references found in the numerical analysis literature.

Prior to the QR algorithm, the Jacobi technique was the standard method for solving dense symmetric eigenvalue problems. Early attempts to improve upon it include

The computational aspects of Jacobi method are described in Wilkinson (1965, p.265). See also

The method is also useful when a nearly diagonal matrix must be diagonalized. See

Establishing the quadratic convergence of the classical and cyclic Jacobi iterations has attracted much attention:

8.4. Jacobi Methods

Detailed error analyses that establish important componentwise error bounds include

Attempts have been made to extend the Jacobi iteration to other classes of matrices and to push through corresponding convergence results. The case of normal matrices is discussed in

See also

Essentially, the analysis and algorithmic developments presented in the text carry over to the normal case with minor modification. For non-normal matrices, the situation is considerably more difficult. Consult

Jacobi methods for complex symmetric matrices have also been developed. See

Although the symmetric QR algorithm is generally much faster than the Jacobi method, there are special settings where the latter technique is of interest. As we illustrated, on a parallel-computer it is possible to perform several rotations concurrently, thereby accelerating the reduction of the off-diagonal elements. See

8.5 Tridiagonal Methods

In this section we develop special methods for the symmetric tridiagonal eigenproblem. The tridiagonal form

\[
T = \begin{bmatrix}
  a_1 & b_1 & \cdots & 0 \\
  b_1 & a_2 & \ddots & \vdots \\
  \vdots & \ddots & \ddots & \vdots \\
  0 & \cdots & b_{n-1} & a_n
\end{bmatrix}
\]  

(8.5.1)

can be obtained by Householder reduction (cf. §8.3.1). However, symmetric tridiagonal eigenproblems arise naturally in many settings.

We first discuss bisection methods that are of interest when selected portions of the eigensystem are required. This is followed by the presentation of a divide and conquer algorithm that can be used to acquire the full symmetric Schur decomposition in a way that is amenable to parallel processing.

8.5.1 Eigenvalues by Bisection

Let \( T_r \) denote the leading \( r \)-by-\( r \) principal submatrix of the matrix \( T \) in (8.5.1). Define the polynomials \( p_r(x) = \det(T_r - xI) \), \( r = 1:n \). A simple determinantal expansion shows that

\[
p_r(x) = (a_r - x)p_{r-1}(x) - b_{r-1}^2p_{r-2}(x)
\]

(8.5.2)

for \( r = 2:n \) if we set \( p_0(x) = 1 \). Because \( p_n(x) \) can be evaluated in \( O(n) \) flops, it is feasible to find its roots using the method of bisection. For example, if \( p_n(y)p_n(z) < 0 \) and \( y < z \), then the iteration

\[
\text{while } |y - z| > \epsilon(|y| + |z|) \\
x = (y + z)/2 \\
\text{if } p_n(x)p_n(y) < 0 \\
z = x \\
\text{else} \\
y = x
\]

end

is guaranteed to terminate with \((y + z)/2\) an approximate zero of \( p_n(x) \), i.e., an approximate eigenvalue of \( T \). The iteration converges linearly in that the error is approximately halved at each step.
8.5.2 Sturm Sequence Methods

Sometimes it is necessary to compute the \( k \)th largest eigenvalue of \( T \) for some prescribed value of \( k \). This can be done efficiently by using the bisection idea and the following classical result:

**Theorem 8.5.1 (Sturm Sequence Property)** If the tridiagonal matrix in (8.5.1) has no zero subdiagonal entries, then the eigenvalues of \( T_{r-1} \) strictly separate the eigenvalues of \( T_r \):

\[
\lambda_r(T_r) < \lambda_{r-1}(T_{r-1}) < \lambda_{r-1}(T_r) < \cdots < \lambda_2(T_r) < \lambda_1(T_{r-1}) < \lambda_1(T_r).
\]

Moreover, if \( a(\lambda) \) denotes the number of sign changes in the sequence

\[
\{ p_0(\lambda), p_1(\lambda), \ldots, p_n(\lambda) \}
\]

then \( a(\lambda) \) equals the number of \( T \)'s eigenvalues that are less than \( \lambda \). Here, the polynomials \( p_r(x) \) are defined by (8.5.2) and we have the convention that \( p_r(\lambda) \) has the opposite sign of \( p_{r-1}(\lambda) \) if \( p_r(\lambda) = 0 \).

**Proof.** It follows from Theorem 8.1.7 that the eigenvalues of \( T_{r-1} \) weakly separate those of \( T_r \). To prove that the separation must be strict, suppose that \( p_r(\mu) = p_{r-1}(\mu) = 0 \) for some \( r \) and \( \mu \). It then follows from (8.5.2) and the assumption that \( T \) is unreduced that \( p_0(\mu) = p_1(\mu) = \cdots = p_r(\mu) = 0 \), a contradiction. Thus, we must have strict separation.

The assertion about \( a(\lambda) \) is established in Wilkinson (1965, 300-301). We mention that if \( p_r(\lambda) = 0 \), then its sign is assumed to be opposite the sign of \( p_{r-1}(\lambda) \). \( \square \)

**Example 8.5.1** If

\[
T = \begin{bmatrix}
1 & -1 & 0 & 0 \\
-1 & 2 & -1 & 0 \\
0 & -1 & 3 & -1 \\
0 & 0 & -1 & 4
\end{bmatrix}
\]

then \( \lambda(T) \approx \{.254, 1.82, 3.18, 4.74\} \). The sequence

\[
\{ p_0(2), p_1(2), p_2(2), p_3(2), p_4(2) \} = \{ 1, -1, -1, 0, 1 \}
\]

confirms that there are two eigenvalues less than \( \lambda = 2 \).

Suppose we wish to compute \( \lambda_k(T) \). From the Gershgorin theorem (Theorem 8.1.3) it follows that \( \lambda_k(T) \in [y, z] \) where

\[
y = \min_{1 \leq i \leq n} a_i - |b_i| - |b_{i-1}| \quad z = \max_{1 \leq i \leq n} a_i + |b_i| + |b_{i-1}|
\]

if we define \( b_0 = b_n = 0 \). With these starting values, it is clear from the Sturm sequence property that the iteration
while $|x - y| > u(|y| + |z|)$
   $x = (y + z)/2$
if $a(x) \geq n - k$
   $z = x$   \hfill (8.5.3)
else
   $y = x$
end

produces a sequence of subintervals that are repeatedly halved in length but which always contain $\lambda_k(T)$.

**Example 8.5.2** If (8.5.3) is applied to the matrix of Example 8.5.1 with $k = 3$, then the values shown in the following table are generated:

<table>
<thead>
<tr>
<th>$y$</th>
<th>$z$</th>
<th>$x$</th>
<th>$a(x)$</th>
</tr>
</thead>
<tbody>
<tr>
<td>0.0000</td>
<td>5.0000</td>
<td>2.5000</td>
<td>2</td>
</tr>
<tr>
<td>0.0000</td>
<td>2.5000</td>
<td>1.2500</td>
<td>1</td>
</tr>
<tr>
<td>1.2500</td>
<td>2.5000</td>
<td>1.3750</td>
<td>1</td>
</tr>
<tr>
<td>1.3750</td>
<td>2.5000</td>
<td>1.9375</td>
<td>2</td>
</tr>
<tr>
<td>1.3750</td>
<td>1.9375</td>
<td>1.6563</td>
<td>1</td>
</tr>
<tr>
<td>1.6563</td>
<td>1.9375</td>
<td>1.7969</td>
<td>1</td>
</tr>
</tbody>
</table>

We conclude from the output that $\lambda_3(T) \in [1.7969, 1.9375]$. Note: $\lambda_3(T) \approx 1.82$.

During the execution of (8.5.3), information about the location of other eigenvalues is obtained. By systematically keeping track of this information it is possible to devise an efficient scheme for computing "contiguous" subsets of $\lambda(T)$, e.g., $\lambda_k(T), \lambda_{k+1}(T), \ldots, \lambda_{k+j}(T)$. See Barth, Martin, and Wilkinson (1967).

If selected eigenvalues of a general symmetric matrix $A$ are desired, then it is necessary first to compute the tridiagonalization $T = U_0^T T U_0$ before the above bisection schemes can be applied. This can be done using Algorithm 8.3.1 or by the Lanczos algorithm discussed in the next chapter. In either case, the corresponding eigenvectors can be readily found via inverse iteration since tridiagonal systems can be solved in $O(n)$ flops. See §4.3.6 and §8.2.2.

In those applications where the original matrix $A$ already has tridiagonal form, bisection computes eigenvalues with small relative error, regardless of their magnitude. This is in contrast to the tridiagonal QR iteration, where the computed eigenvalues $\hat{\lambda}_i$ can be guaranteed only to have small absolute error: $|\hat{\lambda}_i - \lambda_i(T)| \approx u \|T\|_2$

Finally, it is possible to compute specific eigenvalues of a symmetric matrix by using the $LDL^T$ factorization (see §4.2) and exploiting the Sylvester inertia theorem (Theorem 8.1.17). If

$$A - \mu I = LDL^T \quad A = A^T \in \mathbb{R}^{n \times n}$$
is the $LDL^T$ factorization of $A - \mu I$ with $D = \text{diag}(d_1, \ldots, d_n)$, then the number of negative $d_i$ equals the number of $\lambda_i(A)$ that are less than $\mu$. See Parlett (1980, p.46) for details.

### 8.5.3 Eigensystems of Diagonal Plus Rank-1 Matrices

Our next method for the symmetric tridiagonal eigenproblem requires that we be able to compute efficiently the eigenvalues and eigenvectors of a matrix of the form $D + \rho zz^T$ where $D \in \mathbb{R}^{n \times n}$ is diagonal, $z \in \mathbb{R}^n$, and $\rho \in \mathbb{R}$. This problem is important in its own right and the key computations rest upon the following pair of results.

**Lemma 8.5.2** Suppose $D = \text{diag}(d_1, \ldots, d_n) \in \mathbb{R}^{n \times n}$ has the property that $d_1 > \cdots > d_n$. Assume that $\rho \neq 0$ and that $z \in \mathbb{R}^n$ has no zero components. If

$$(D + \rho zz^T)v = \lambda v \quad v \neq 0$$

then $z^Tv \neq 0$ and $D - \lambda I$ is nonsingular.

**Proof.** If $\lambda \in \lambda(D)$, then $\lambda = d_i$ for some $i$ and thus

$$0 = e_i^T[(D - \lambda I)v + \rho(z^Tv)z] = \rho(z^Tv)z_i.$$ 

Since $\rho$ and $z_i$ are nonzero we must have $0 = z^Tv$ and so $Dv = \lambda v$. However, $D$ has distinct eigenvalues and therefore, $v \in \text{span}\{e_i\}$. But then $0 = z^Tv = z_i$, a contradiction. Thus, $D$ and $D + \rho zz^T$ do not have any common eigenvalues and $z^Tv \neq 0$. $\square$

**Theorem 8.5.3** Suppose $D = \text{diag}(d_1, \ldots, d_n) \in \mathbb{R}^{n \times n}$ and that the diagonal entries satisfy $d_1 > \cdots > d_n$. Assume that $\rho \neq 0$ and that $z \in \mathbb{R}^n$ has no zero components. If $V \in \mathbb{R}^{n \times n}$ is orthogonal such that

$$V^T(D + \rho zz^T)V = \text{diag}(\lambda_1, \ldots, \lambda_n)$$

with $\lambda_1 \geq \cdots \geq \lambda_n$ and $V = [v_1, \ldots, v_n]$, then

(a) The $\lambda_i$ are the $n$ zeros of $f(\lambda) = 1 + \rho z^T(D - \lambda I)^{-1}z$.

(b) If $\rho > 0$, then $\lambda_1 > d_1 > \lambda_2 > \cdots > d_n$.

If $\rho < 0$, then $d_1 > \lambda_1 > d_2 > \cdots > d_n > \lambda_n$.

(c) The eigenvector $v_i$ is a multiple of $(D - \lambda_i I)^{-1}z$.

**Proof.** If $(D + \rho zz^T)v = \lambda v$, then

$$(D - \lambda I)v + \rho(z^Tv)z = 0. \quad (8.5.4)$$
We know from Lemma 8.5.2 that \( D - \lambda I \) is nonsingular. Thus,

\[ v \in \text{span}\{(D - \lambda I)^{-1}z\} \]

thereby establishing (c). Moreover, if we apply \( z^T(D - \lambda I)^{-1} \) to both sides of equation (8.5.4) we obtain

\[ z^Tv \left(1 + \rho z^T(D - \lambda I)^{-1}z\right) = 0. \]

By Lemma 8.5.2, \( z^Tv \neq 0 \) and so this shows that if \( \lambda \in \lambda(D + \rho zz^T) \), then \( f(\lambda) = 0 \). We must show that all the zeros of \( f \) are eigenvalues of \( D + \rho zz^T \) and that the interlacing relations (b) hold.

To do this we look more carefully at the equations

\[
\begin{align*}
 f(\lambda) &= 1 + \rho \left( \frac{z_1^2}{d_1 - \lambda} + \cdots + \frac{z_n^2}{d_n - \lambda} \right) \\
 f'(\lambda) &= \rho \left( \frac{z_1^2}{(d_1 - \lambda)^2} + \cdots + \frac{z_n^2}{(d_n - \lambda)^2} \right)
\end{align*}
\]

Note that \( f \) is monotone in between its poles. This allows us to conclude that if \( \rho > 0 \), then \( f \) has precisely \( n \) roots, one in each of the intervals

\[(d_n, d_{n-1}), \ldots, (d_2, d_1), (d_1, \infty).\]

If \( \rho < 0 \) then \( f \) has exactly \( n \) roots, one in each of the intervals

\[(-\infty, d_n), (d_n, d_{n-1}), \ldots, (d_2, d_1).\]

In either case, it follows that the zeros of \( f \) are precisely the eigenvalues of \( D + \rho vu^T \). \( \square \)

The theorem suggests that to compute \( V \) we (a) find the roots \( \lambda_1, \ldots, \lambda_n \) of \( f \) using a Newton-like procedure and then (b) compute the columns of \( V \) by normalizing the vectors \((D - \lambda_i I)^{-1}z\) for \( i = 1:n \). The same plan of attack can be followed even if there are repeated \( d_i \) and zero \( z_i \).

**Theorem 8.5.4** If \( D = \text{diag}(d_1, \ldots, d_n) \) and \( z \in \mathbb{R}^n \), then there exists an orthogonal matrix \( V_1 \) such that if \( V_1^TDV_1 = \text{diag} (\mu_1, \ldots, \mu_n) \) and \( w = V_1^Tz \) then

\[ \mu_1 > \mu_2 > \cdots > \mu_r \geq \mu_{r+1} \geq \cdots \geq \mu_n, \]

\( w_i \neq 0 \) for \( i = 1:r \), and \( w_i = 0 \) for \( i = r + 1:n \).

**Proof.** We give a constructive proof based upon two elementary operations. (a) Suppose \( d_i = d_j \) for some \( i < j \). Let \( J(i, j, \theta) \) be a Jacobi rotation in the \((i, j)\) plane with the property that the \( j \)th component of \( J(i, j, \theta)^Tz \) is zero. It is not hard to show that \( J(i, j, \theta)^TDJ(i, j, \theta) = D \).

Thus, we can zero a component of \( z \) if there is a repeated \( d_i \). (b) If \( z_i = 0 \),
$z_j \neq 0$, and $i < j$, then let $P$ be the identity with columns $i$ and $j$ inter-
changed. It follows that $P^TDP$ is diagonal, $(P^Tz)_i \neq 0$, and $(P^Tz)_j = 0$. Thus, we can permute all the zero $z_i$ to the "bottom." Clearly, repetition 
of (a) and (b) eventually renders the desired canonical structure. $V_1$ is the 
product of the rotations. □

See Barlow (1993) and the references therein for a discussion of the solution 
procedures that we have outlined above.

8.5.4 A Divide and Conquer Method

We now present a divide-and-conquer method for computing the Schur 
decomposition

$$Q^T T Q = \Lambda = \text{diag}(\lambda_1, \ldots, \lambda_n) \quad Q^T Q = I \quad (8.5.5)$$

for tridiagonal $T$ that involves (a) "tearing" $T$ in half, (b) computing the the 
Schur decompositions of the two parts, and (c) combining the two half-sized 
Schur decompositions into the required full size Schur decomposition. The 
overall procedure, developed by Dongarra and Sorensen (1987), is suitable 
for parallel computation.

We first show how $T$ can be "torn" in half with a rank-one modification. 
For simplicity, assume $n = 2m$. Define $v \in \mathbb{R}^n$ as follows

$$v = \begin{bmatrix} e^{(m)}_m \\ \theta e^{(m)}_1 \end{bmatrix}. \quad (8.5.6)$$

Note that for all $\rho \in \mathbb{R}$ the matrix $\tilde{T} = T - \rho vv^T$ is identical to $T$ except 
in its "middle four" entries:

$$\tilde{T}(m:m+1, m:m+1) = \begin{bmatrix} a_m - \rho & b_m - \rho \theta \\ b_m - \rho \theta & a_{m+1} - \rho \theta^2 \end{bmatrix}.$$ 

If we set $\rho \theta = b_m$ then

$$T = \begin{bmatrix} T_1 & 0 \\ 0 & T_2 \end{bmatrix} + \rho vv^T$$

where

$$T_1 = \begin{bmatrix} a_1 & b_1 & \cdots & 0 \\ b_1 & a_2 & \cdots & \vdots \\ \vdots & \vdots & \ddots & \vdots \\ 0 & \cdots & b_{m-1} & a_m \end{bmatrix},$$
and \( \tilde{a}_m = a_m - \rho \) and \( \tilde{a}_{m+1} = a_{m+1} - \rho \theta^2 \).

Now suppose that we have \( m \)-by-\( m \) orthogonal matrices \( Q_1 \) and \( Q_2 \) such that \( Q_1^T T_1 Q_1 = D_1 \) and \( Q_2^T T_2 Q_2 = D_2 \) are each diagonal. If we set

\[
U = \begin{bmatrix} Q_1 & 0 \\ 0 & Q_2 \end{bmatrix},
\]

then

\[
U^T T U = U^T \left( \begin{bmatrix} T_1 & 0 \\ 0 & T_2 \end{bmatrix} + \rho vv^T \right) U = D + \rho zz^T
\]

where

\[
D = \begin{bmatrix} D_1 & 0 \\ 0 & D_2 \end{bmatrix}
\]

is diagonal and

\[
z = U^T v = \begin{bmatrix} Q_1^T e_m \\ \theta Q_1^T e_1 \end{bmatrix}.
\]

Comparing these equations we see that the effective synthesis of the two half-sized Schur decompositions requires the quick and stable computation of an orthogonal \( V \) such that

\[
V^T (D + \rho zz^T) V = \Lambda = \text{diag}(\lambda_1, \ldots, \lambda_n)
\]

which we discussed in §8.5.3.

### 8.5.5 A Parallel Implementation

Having stepped through the tearing and synthesis operations, we are ready to illustrate the overall process and how it can be implemented on a multiprocessor. For clarity, assume that \( n = 8N \) for some positive integer \( N \) and that three levels of tearing are performed. We can depict this with a binary tree as shown in Fig. 8.5.1. The indices are specified in binary. Fig. 8.5.2 depicts a single node and should be interpreted to mean that the eigensystem for the tridiagonal \( T(b) \) is obtained from the eigensystems of the tridiagonals \( T(b0) \) and \( T(b1) \). For example, the eigensystems for the \( N \)-by-\( N \) matrices \( T(110) \) and \( T(111) \) are combined to produce the eigensystem for the \( 2N \)-by-\( 2N \) tridiagonal matrix \( T(11) \).
With tree-structured algorithms there is always the danger that parallelism is lost as the tree is "climbed" towards the root, but this is not the case in our problem. To see this suppose we have 8 processors and that the first task of Proc(b) is to compute the Schur decomposition of $T(b)$ where $b = 000, 001, 010, 011, 100, 101, 110, 111$. This portion of the computation is perfectly load balanced and does not involve interprocessor communication. (We are ignoring the Theorem 8.5.4 deflations, which are unlikely to cause significant load imbalance.)

At the next level there are four gluing operations to perform: $T(00)$, $T(01)$, $T(10)$, $T(11)$. However, each of these computations neatly subdivides and we can assign two processors to each task. For example, once the secular equation that underlies the $T(00)$ synthesis is known to both Proc(000) and Proc(001), then they each can go about getting half of the eigenvalues and corresponding eigenvectors. Likewise, 4 processors can each be assigned to the $T(0)$ and $T(1)$ problem. All 8 processors can participate in computing the eigensystem of $T$. Thus, at every level full parallelism
can be maintained because the eigenvalue/eigenvector computations are independent of one another.

Problems

P8.5.1 Suppose \( \lambda \) is an eigenvalue of a symmetric tridiagonal matrix \( T \). Show that if \( \lambda \) has algebraic multiplicity \( k \), then at least \( k - 1 \) of \( T \)'s subdiagonal elements are zero.

P8.5.2 Give an algorithm for determining \( \rho \) and \( \theta \) in (8.5.6) with the property that \( \theta \in (-1, 1) \) and \( \min\{ |a_{r} - \rho|, |a_{r+1} - \rho| \} \) is maximized.

P8.5.3 Let \( p_{r}(\lambda) = \det(T(1; r, 1; r) - \lambda I_{r}) \) where \( T \) is given by (8.5.1). Derive a recursion for evaluating \( p'_{n}(\lambda) \) and use it to develop a Newton iteration that can compute eigenvalues of \( T \).

P8.5.4 What communication is necessary between the processors assigned to a particular \( T_{i} \)? Is it possible to share the work associated with the processing of repeated \( d_{i} \) and zero \( z_{i} \)?

P8.5.5 If \( T \) is positive definite, does it follow that the matrices \( T_{1} \) and \( T_{2} \) in §8.5.4 are positive definite?

P8.5.6 Suppose that

\[
A = \begin{bmatrix} D & v \\ v^T & d_{n} \end{bmatrix}
\]

where \( D = \text{diag}(d_{1}, \ldots, d_{n-1}) \) has distinct diagonal entries and \( v \in \mathbb{R}^{n-1} \) has no zero entries. (a) Show that if \( \lambda \in \lambda(A) \), then \( D - \lambda I_{n-1} \) is nonsingular. (b) Show that if \( \lambda \in \lambda(A) \), then \( \lambda \) is a zero of

\[
f(\lambda) = \lambda + \sum_{k=1}^{n-1} \frac{v_{k}^2}{d_{k} - \lambda} = d_{n}.
\]

P8.5.7 Suppose \( A = S + \sigma uu^T \) where \( S \in \mathbb{R}^{n \times n} \) is skew-symmetric, \( u \in \mathbb{R}^{n} \), and \( \sigma \in \mathbb{R} \). Show how to compute an orthogonal \( Q \) such that \( Q^TAQ = T + \sigma e_{1}e_{1}^T \) where \( T \) is tridiagonal and skew-symmetric and \( e_{1} \) is the first column of \( I_{n} \).

P8.5.8 It is known that \( \lambda \in \lambda(T) \) where \( T \in \mathbb{R}^{n \times n} \) is symmetric and tridiagonal with no zero subdiagonal entries. Show how to compute \( x(1:n-1) \) from the equation \( Tx = \lambda x \) given that \( x_{n} = 1 \).

Notes and References for Sec. 8.5

Bisection/Strum sequence methods are discussed in

Various aspects of the divide and conquer algorithm discussed in this section is detailed in

The very delicate computations required by the method are carefully analyzed in

Various generalizations to banded symmetric eigenproblems have been explored.

A related divide and conquer method based on the “arrowhead” matrix (see P8.5.7) is given in

### 8.6 Computing the SVD

There are important relationships between the singular value decomposition of a matrix $A$ and the Schur decompositions of the symmetric matrices $A^TA$, $AA^T$, and \[
\begin{bmatrix}
0 & A^T \\
A & 0
\end{bmatrix}.
\]

Indeed, if

$$U^TAV = \text{diag}(\sigma_1, \ldots, \sigma_n)$$

is the SVD of $A \in \mathbb{R}^{m \times n}$ ($m \geq n$), then

$$V^T(A^TA)V = \text{diag}(\sigma_1^2, \ldots, \sigma_n^2) \in \mathbb{R}^{n \times n} \quad (8.6.1)$$

and

$$U^T(AA^T)U = \text{diag}(\sigma_1^2, \ldots, \underbrace{\sigma_n^2, 0, \ldots, 0}_{m-n}) \in \mathbb{R}^{m \times m} \quad (8.6.2)$$

Moreover, if

$$U = \begin{bmatrix} U_1 & U_2 \end{bmatrix}$$

$$n \quad m-n$$

and we define the orthogonal matrix $Q \in \mathbb{R}^{(m+n) \times (m+n)}$ by

$$Q = \frac{1}{\sqrt{2}} \begin{bmatrix} V & V & 0 \\
U_1 & -U_1 & \sqrt{2} U_2 \end{bmatrix}$$
then
\begin{equation}
Q^T \begin{bmatrix}
0 & A^T \\
A & 0
\end{bmatrix} Q = \text{diag}(\sigma_1, \ldots, \sigma_n, -\sigma_1, \ldots, -\sigma_n, 0, \ldots, 0).
\end{equation}

These connections to the symmetric eigenproblem allow us to adapt the mathematical and algorithmic developments of the previous sections to the singular value problem. Good references for this section include Lawson and Hanson (1974) and Stewart and Sun (1990).

### 8.6.1 Perturbation Theory and Properties

We first establish perturbation results for the SVD based on the theorems of §8.1. Recall that \( \sigma_i(A) \) denotes the \( i \)th largest singular value of \( A \).

**Theorem 8.6.1** If \( A \in \mathbb{R}^{m \times n} \), then for \( k = 1: \min\{m, n\} \)

\[
\sigma_k(A) = \max_{\dim(S) = k} \min_{x \in S} \frac{y^T A x}{\|x\|_2 \|y\|_2} = \max_{\dim(S) = k} \min_{x \in S} \frac{\|Ax\|_2}{\|x\|_2}.
\]

*Note that in this expression \( S \subseteq \mathbb{R}^n \) and \( T \subseteq \mathbb{R}^m \) are subspaces.*

**Proof.** The right-most characterization follows by applying Theorem 8.1.2 to \( A^T A \). The remainder of the proof we leave as an exercise. \( \square \)

**Corollary 8.6.2** If \( A \) and \( A+E \) are in \( \mathbb{R}^{m \times n} \) with \( m \geq n \), then for \( k = 1:n \)

\[
|\sigma_k(A+E) - \sigma_k(A)| \leq \sigma_1(E) = \|E\|_2.
\]

**Proof.** Apply Corollary 8.1.6 to
\[
\begin{bmatrix}
0 & A^T \\
A & 0
\end{bmatrix} \quad \text{and} \quad \begin{bmatrix}
0 & (A+E)^T \\
A+E & 0
\end{bmatrix}.
\]

\( \square \)

**Example 8.6.1** If
\[
A = \begin{bmatrix}
1 & 4 \\
2 & 5 \\
3 & 6
\end{bmatrix} \quad \text{and} \quad A+E = \begin{bmatrix}
1 & 4 \\
2 & 5 \\
3 & 6.01
\end{bmatrix}
\]

then \( \sigma(A) = \{9.5080, .7729\} \) and \( \sigma(A+E) = \{9.5145, .7706\} \). It is clear that for \( i = 1:2 \) we have \( |\sigma_i(A+E) - \sigma_i(A)| \leq \|E\|_2 = .01 \).

**Corollary 8.6.3** Let \( A = [a_1, \ldots, a_n] \in \mathbb{R}^{m \times n} \) be a column partitioning with \( m \geq n \). If \( A_r = [a_1, \ldots, a_r] \), then for \( r = 1:n-1 \)

\[
\sigma_1(A_{r+1}) \geq \sigma_1(A_r) \geq \sigma_2(A_{r+1}) \geq \cdots \geq \sigma_r(A_{r+1}) \geq \sigma_r(A_r) \geq \sigma_{r+1}(A_{r+1}).
\]
Proof. Apply Corollary 8.1.7 to $A^T A$. □

This last result says that by adding a column to a matrix, the largest singular value increases and the smallest singular value is diminished.

Example 8.3.2

$$A = \begin{bmatrix} 1 & 6 & 11 \\ 2 & 7 & 12 \\ 3 & 8 & 13 \\ 4 & 9 & 14 \\ 5 & 10 & 15 \end{bmatrix} \Rightarrow \begin{cases} \sigma(A_1) = \{7.4162\} \\ \sigma(A_2) = \{19.5377, 1.8095\} \\ \sigma(A_3) = \{35.1272, 2.4654, 0.0000\} \end{cases}$$

thereby confirming Corollary 8.6.3.

The next result is a Wielandt-Hoffman theorem for singular values:

Theorem 8.6.4 If $A$ and $A + E$ are in $\mathbb{R}^{m \times n}$ with $m \geq n$, then

$$\sum_{k=1}^{n} (\sigma_k(A + E) - \sigma_k(A))^2 \leq \| E \|_F^2.$$

Proof. Apply Theorem 8.1.4 to $\begin{bmatrix} 0 & A^T \\ A & 0 \end{bmatrix}$ and $\begin{bmatrix} 0 & (A + E)^T \\ A + E & 0 \end{bmatrix}$. □

Example 8.6.3 If

$$A = \begin{bmatrix} 1 & 4 \\ 2 & 5 \\ 3 & 6 \end{bmatrix} \quad \text{and} \quad A + E = \begin{bmatrix} 1 & 4 \\ 2 & 5 \\ 3 & 6.01 \end{bmatrix}$$

then

$$\sum_{k=1}^{2} (\sigma_k(A + E) - \sigma_k(A))^2 = .472 \times 10^{-4} \leq 10^{-4} = \| E \|_F^2.$$ 

See Example 8.6.1.

For $A \in \mathbb{R}^{m \times n}$ we say that the $k$-dimensional subspaces $S \subseteq \mathbb{R}^n$ and $T \subseteq \mathbb{R}^m$ form a singular subspace pair if $x \in S$ and $y \in T$ imply $Ax \in T$ and $A^Ty \in S$. The following result is concerned with the perturbation of singular subspace pairs.

Theorem 8.6.5 Let $A, E \in \mathbb{R}^{m \times n}$ with $m \geq n$ be given and suppose that $V \in \mathbb{R}^{n \times n}$ and $U \in \mathbb{R}^{m \times m}$ are orthogonal. Assume that

$$V = \begin{bmatrix} V_1 & V_2 \\ r & n - r \end{bmatrix} \quad U = \begin{bmatrix} U_1 & U_2 \\ r & m - r \end{bmatrix}$$

and that ran$(V_1)$ and ran$(U_1)$ form a singular subspace pair for $A$. Let

$$U^H A V = \begin{bmatrix} A_{11} & 0 \\ 0 & A_{22} \end{bmatrix} \begin{bmatrix} r \\ n - r \end{bmatrix}$$
\[ U^H E V = \begin{bmatrix} E_{11} & E_{12} \\ E_{21} & E_{22} \end{bmatrix} \frac{\tau}{m - r} \]
and assume that
\[ \delta = \min_{\sigma \in \sigma(A_{11}), \gamma \in \sigma(A_{22})} |\sigma - \gamma| > 0. \]

If
\[ \| E \|_F \leq \frac{\delta}{4}, \]
then there exist matrices \( P \in \mathbb{R}^{(n-r) \times r} \) and \( Q \in \mathbb{R}^{(m-r) \times r} \) satisfying
\[ \| \begin{bmatrix} Q \\ P \end{bmatrix} \|_F \leq 4 \frac{\| E \|_F}{\delta} \]
such that \( \text{ran}(V_1 + V_2 Q) \) and \( \text{ran}(U_1 + U_2 P) \) is a singular subspace pair for \( A + E \).

Proof. See Stewart (1973), Theorem 6.4. \( \square \)

Roughly speaking, the theorem says that \( O(\epsilon) \) changes in \( A \) can alter a singular subspace by an amount \( \epsilon/\delta \), where \( \delta \) measures the separation of the relevant singular values.

**Example 8.6.4** The matrix \( A = \text{diag}(2.000, 1.001, .999) \in \mathbb{R}^{3 \times 3} \) has singular subspace pairs \( (\text{span}\{v_i\}, \text{span}\{u_i\}) \) for \( i = 1, 2, 3 \) where \( v_i = e_i^{(3)} \) and \( u_i = e_i^{(4)} \). Suppose
\[ A + E = \begin{bmatrix} 2.000 & .010 & .010 \\ .010 & 1.001 & .010 \\ .010 & .010 & .999 \\ .010 & .010 & .010 \end{bmatrix} \]
The corresponding columns of the matrices
\[ \hat{U} = [\hat{u}_1 \ \hat{u}_2 \ \hat{u}_3] = \begin{bmatrix} .9999 & -.0144 & .0007 \\ .0101 & .7415 & .6708 \\ .0101 & .6707 & -.7616 \\ .0051 & .0138 & -.0007 \end{bmatrix} \]
\[ \hat{V} = [\hat{v}_1 \ \hat{v}_2 \ \hat{v}_3] = \begin{bmatrix} .9999 & -.0143 & .0007 \\ .0101 & .7416 & .6708 \\ .0101 & .6707 & -.7416 \end{bmatrix} \]
define singular subspace pairs for \( A+E \). Note that the pair \( \{\text{span}\{\hat{v}_i\}, \text{span}\{\hat{u}_i\}\} \), is close to \( \{\text{span}\{v_i\}, \text{span}\{u_i\}\} \) for \( i = 1 \) but not for \( i = 2 \) or \( 3 \). On the other hand, the singular subspace pair \( \{\text{span}\{\hat{v}_2, \hat{v}_3\}, \text{span}\{\hat{u}_2, \hat{u}_3\}\} \) is close to \( \{\text{span}\{v_2, v_3\}, \text{span}\{u_2, u_3\}\} \).
8.6.2 The SVD Algorithm

We now show how a variant of the QR algorithm can be used to compute the SVD of an \( A \in \mathbb{R}^{m \times n} \) with \( m \geq n \). At first glance, this appears straightforward. Equation (8.6.1) suggests that we

- form \( C = A^T A \),

- use the symmetric QR algorithm to compute \( V_1^T CV_1 = \text{diag}(\sigma_i^2) \),

- apply QR with column pivoting to \( AV_1 \) obtaining \( U^T (AV_1) \Pi = R \).

Since \( R \) has orthogonal columns, it follows that \( U^T A(V_1 \Pi) \) is diagonal. However, as we saw in Example 5.3.2, the formation of \( A^T A \) can lead to a loss of information. The situation is not quite so bad here, since the original \( A \) is used to compute \( U \).

A preferable method for computing the SVD is described in Golub and Kahan (1965). Their technique finds \( U \) and \( V \) simultaneously by implicitly applying the symmetric QR algorithm to \( A^T A \). The first step is to reduce \( A \) to upper bidiagonal form using Algorithm 5.4.2:

\[
U_B^T A V_B = \begin{bmatrix} B \\ 0 \end{bmatrix} \quad B = \begin{bmatrix} d_1 & f_1 & \cdots & 0 \\ 0 & d_2 & \ddots & \vdots \\ \vdots & \ddots & \ddots & f_{n-1} \\ 0 & \cdots & 0 & d_n \end{bmatrix} \in \mathbb{R}^{n \times n}.
\]

The remaining problem is thus to compute the SVD of \( B \). To this end, consider applying an implicit-shift QR step (Algorithm 8.3.2) to the tridiagonal matrix \( T = B^T B \):

- Compute the eigenvalue \( \lambda \) of

\[
T(m:n, m:n) = \begin{bmatrix} d_m^2 + f_{m-1}^2 & d_m f_m \\ d_m f_m & d_n^2 + f_m^2 \end{bmatrix} \quad m = n - 1
\]

that is closer to \( d_n^2 + f_m^2 \).

- Compute \( c_1 = \cos(\theta_1) \) and \( s_1 = \sin(\theta_1) \) such that

\[
\begin{bmatrix} c_1 & s_1 \\ -s_1 & c_1 \end{bmatrix}^T \begin{bmatrix} d_1^2 - \lambda \\ d_1 f_1 \end{bmatrix} = \begin{bmatrix} x \\ 0 \end{bmatrix}
\]

and set \( G_1 = G(1, 2, \theta_1) \).
• Compute Givens rotations $G_2, \ldots, G_{n-1}$ so that if $Q = G_1 \cdots G_{n-1}$ then $Q^T T Q$ is tridiagonal and $Q e_1 = G_1 e_1$.

Note that these calculations require the explicit formation of $B^T B$, which, as we have seen, is unwise from the numerical standpoint.

Suppose instead that we apply the Givens rotation $G_1$ above to $B$ directly. Illustrating with the $n = 6$ case this gives

$$
B \leftarrow B G_1 = \begin{bmatrix}
\times & \times & 0 & 0 & 0 & 0 \\
+ & \times & \times & 0 & 0 & 0 \\
0 & 0 & \times & \times & 0 & 0 \\
0 & 0 & 0 & \times & \times & 0 \\
0 & 0 & 0 & 0 & \times & \times \\
0 & 0 & 0 & 0 & 0 & \times
\end{bmatrix}.
$$

We then can determine Givens rotations $U_1, V_2, U_2, \ldots, V_{n-1},$ and $U_{n-1}$ to chase the unwanted nonzero element down the bidiagonal:

$$
B \leftarrow U_1^T B = \begin{bmatrix}
\times & \times & + & 0 & 0 & 0 \\
0 & \times & \times & 0 & 0 & 0 \\
0 & 0 & \times & \times & 0 & 0 \\
0 & 0 & 0 & \times & \times & 0 \\
0 & 0 & 0 & 0 & \times & \times \\
0 & 0 & 0 & 0 & 0 & \times
\end{bmatrix}
$$

$$
B \leftarrow B V_2 = \begin{bmatrix}
\times & \times & 0 & 0 & 0 & 0 \\
0 & \times & \times & 0 & 0 & 0 \\
0 & + & \times & \times & 0 & 0 \\
0 & 0 & 0 & \times & \times & 0 \\
0 & 0 & 0 & 0 & \times & \times \\
0 & 0 & 0 & 0 & 0 & \times
\end{bmatrix}
$$

$$
B \leftarrow U_2^T B = \begin{bmatrix}
\times & \times & 0 & 0 & 0 & 0 \\
0 & \times & \times & + & 0 & 0 \\
0 & 0 & \times & \times & 0 & 0 \\
0 & 0 & 0 & \times & \times & 0 \\
0 & 0 & 0 & 0 & \times & \times \\
0 & 0 & 0 & 0 & 0 & \times
\end{bmatrix}
$$

and so on. The process terminates with a new bidiagonal $\tilde{B}$ that is related to $B$ as follows:

$$
\tilde{B} = (U_{n-1}^T \cdots U_1^T) B (G_1 V_2 \cdots V_{n-1}) = \tilde{U}^T B \tilde{V}.
$$
Since each $V_i$ has the form $V_i = G(i, i + 1, \theta_i)$ where $i = 2:n - 1$, it follows that $\tilde{V}e_1 = Qe_1$. By the implicit $Q$ theorem we can assert that $\tilde{V}$ and $Q$ are essentially the same. Thus, we can implicitly effect the transition from $T$ to $\tilde{T} = B^T \tilde{B}$ by working directly on the bidiagonal matrix $B$.

Of course, for these claims to hold it is necessary that the underlying tridiagonal matrices be unreduced. Since the subdiagonal entries of $B^T B$ are of the form $d_{i-1}, f_i$, it is clear that we must search the bidiagonal band for zeros. If $f_k = 0$ for some $k$, then

$$B = \begin{bmatrix} B_1 & 0 \\ 0 & B_2 \end{bmatrix} \begin{bmatrix} k \\ n-k \end{bmatrix}$$

and the original SVD problem decouples into two smaller problems involving the matrices $B_1$ and $B_2$. If $d_k = 0$ for some $k < n$, then premultiplication by a sequence of Givens transformations can zero $f_k$. For example, if $n = 6$ and $k = 3$, then by rotating in row planes $(3,4)$, $(3,5)$, and $(3,6)$ we can zero the entire third row:

$$B = \begin{bmatrix} \times & \times & 0 & 0 & 0 & 0 \\ 0 & \times & \times & 0 & 0 & 0 \\ 0 & 0 & 0 & \times & 0 & 0 \\ 0 & 0 & 0 & 0 & \times & 0 \\ 0 & 0 & 0 & 0 & 0 & \times \end{bmatrix} \begin{bmatrix} \times & \times & 0 & 0 & 0 & 0 \\ 0 & \times & \times & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & + & 0 \\ 0 & 0 & 0 & \times & \times & 0 \\ 0 & 0 & 0 & 0 & \times & \times \end{bmatrix} \begin{bmatrix} \times & \times & 0 & 0 & 0 & 0 \\ 0 & \times & \times & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & \times & \times & 0 \\ 0 & 0 & 0 & 0 & \times & \times \end{bmatrix} \begin{bmatrix} \times & \times & 0 & 0 & 0 & 0 \\ 0 & \times & \times & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & \times & \times & 0 \\ 0 & 0 & 0 & 0 & \times & \times \end{bmatrix}$$

If $d_n = 0$, then the last column can be zeroed with a series of column rotations in planes $(n-1,n), (n-2,n), \ldots, (1,n)$. Thus, we can decouple if $f_1 \cdots f_{n-1} = 0$ or $d_1 \cdots d_n = 0$.

**Algorithm 8.6.1 (Golub-Kahan SVD Step)** Given a bidiagonal matrix $B \in \mathbb{R}^{m \times n}$ having no zeros on its diagonal or superdiagonal, the following algorithm overwrites $B$ with the bidiagonal matrix $\tilde{B} = \tilde{U}^T B \tilde{V}$ where $\tilde{U}$ and $\tilde{V}$ are orthogonal and $\tilde{V}$ is essentially the orthogonal matrix that would be obtained by applying Algorithm 8.3.2 to $T = B^T B$. 
Let $\mu$ be the eigenvalue of the trailing 2-by-2 submatrix of $T = B^T B$
that is closer to $t_{nn}$.

$y = t_{11} - \mu$
$z = t_{12}$

for $k = 1:n - 1$

Determine $c = \cos(\theta)$ and $s = \sin(\theta)$ such that

$$
\begin{bmatrix}
  y & z \\
  -s & c
\end{bmatrix}
\begin{bmatrix}
  c & s \\
  -s & c
\end{bmatrix}
= \begin{bmatrix}
  * & 0 \\
  0 & 0
\end{bmatrix}
$$

$B = BG(k, k + 1, \theta)$
$y = b_{kk}; z = b_{k+1,k}$

Determine $c = \cos(\theta)$ and $s = \sin(\theta)$ such that

$$
\begin{bmatrix}
  c & s \\
  -s & c
\end{bmatrix}^T
\begin{bmatrix}
  y \\
  z
\end{bmatrix}
= \begin{bmatrix}
  * \\
  0
\end{bmatrix}
$$

$B = G(k, k + 1, \theta)^T B$

if $k < n - 1$
$y = b_{k,k+1}; z = b_{k,k+2}$

end

An efficient implementation of this algorithm would store $B$’s diagonal and
superdiagonal in vectors $a(1:n)$ and $f(1:n - 1)$ respectively and would re-
quire $30n$ flops and $2n$ square roots. Accumulating $U$ requires $6mn$ flops.
Accumulating $V$ requires $6n^2$ flops.

Typically, after a few of the above SVD iterations, the superdiagonal
entry $f_{n-1}$ becomes negligible. Criteria for smallness within $B$’s band are
usually of the form

$$
|f_i| \leq \epsilon(|d_i| + |d_{i+1}|)
$$

$$
|d_i| \leq \epsilon \| B \|
$$

where $\epsilon$ is a small multiple of the unit roundoff and $\| \cdot \|$ is some com-
putationally convenient norm.

Combining Algorithm 5.4.2 (bidiagonalization), Algorithm 8.6.1, and
the decoupling calculations mentioned earlier gives

Algorithm 8.6.2 (The SVD Algorithm) Given $A \in \mathbb{R}^{m \times n}$ ($m \geq n$) and
$\epsilon$, a small multiple of the unit roundoff, the following algorithm overwrites
$A$ with $U^T AV = D + E$, where $U \in \mathbb{R}^{m \times n}$ is orthogonal, $V \in \mathbb{R}^{n \times n}$ is
orthogonal, $D \in \mathbb{R}^{m \times n}$ is diagonal, and $E$ satisfies $\| E \|^2_2 \approx \| U \| \| A \|_2$.

Use Algorithm 5.4.2 to compute the bidiagonalization

$$
\begin{bmatrix}
  B \\
  0
\end{bmatrix}
\leftarrow (U_1 \cdots U_n)^T A (V_1 \cdots V_{n-2})
$$
until \( q = n \)

Set \( b_{i,i+1} \) to zero if \( |b_{i,i+1}| \leq \epsilon(|b_{ii}| + |b_{i+1,i+1}|) \) for any \( i = 1:n - 1 \).

Find the largest \( q \) and the smallest \( p \) such that if

\[
B = \begin{bmatrix}
B_{11} & 0 & 0 \\
0 & B_{22} & 0 \\
0 & 0 & B_{33}
\end{bmatrix}
\begin{bmatrix}
p \\
n - p - q \\
q
\end{bmatrix}
\]

then \( B_{33} \) is diagonal and \( B_{22} \) has nonzero superdiagonal.

if \( q < n \)

if any diagonal entry in \( B_{22} \) is zero, then zero the superdiagonal entry in the same row.

else

Apply Algorithm 8.6.1 to \( B_{22} \),

\[ B = \text{diag}(I_p, U, I_{q+m-n})^T B \text{diag}(I_p, V, I_q) \]

end

end

The amount of work required by this algorithm and its numerical properties are discussed in §5.4.5 and §5.5.8.

**Example 8.6.5** If Algorithm 8.6.2 is applied to

\[
A = \begin{bmatrix}
1 & 1 & 0 & 0 \\
0 & 2 & 1 & 0 \\
0 & 0 & 3 & 1 \\
0 & 0 & 0 & 4
\end{bmatrix}
\]

then the superdiagonal elements converge to zero as follows:

<table>
<thead>
<tr>
<th>Iteration</th>
<th>( O(|a_{21}|) )</th>
<th>( O(|a_{32}|) )</th>
<th>( O(|a_{43}|) )</th>

</tbody>
</table>

Observe the cubic-like convergence.
8.6.3 Jacobi SVD Procedures

It is straightforward to adapt the Jacobi procedures of §8.4 to the SVD problem. Instead of solving a sequence of 2-by-2 symmetric eigenproblems, we solve a sequence of 2-by-2 SVD problems. Thus, for a given index pair \((p, q)\) we compute a pair of rotations such that

\[
\begin{bmatrix}
  c_1 & s_1 \\
  -s_1 & c_1
\end{bmatrix}^T \begin{bmatrix}
  a_{pp} & a_{pq} \\
  a_{qp} & a_{qq}
\end{bmatrix} \begin{bmatrix}
  c_2 & s_2 \\
  -s_2 & c_2
\end{bmatrix} = \begin{bmatrix}
  d_p & 0 \\
  0 & d_q
\end{bmatrix}.
\]

See P8.6.8. The resulting algorithm is referred to as two-sided because each update involves a pre- and post-multiplication.

A one-sided Jacobi algorithm involves a sequence of pairwise column orthogonalizations. For a given index pair \((p, q)\) a Jacobi rotation \(J(p, q, \theta)\) is determined so that columns \(p\) and \(q\) of \(AJ(p, q, \theta)\) are orthogonal to each other. See P8.6.8. Note that this corresponds to zeroing the \((p, q)\) and \((q, p)\) entries in \(A^T A\). Once \(AV\) has sufficiently orthogonal columns, the rest of the SVD \((U\) and \(\Sigma\)) follows from column scaling: \(AV = U\Sigma\).

Problems

P8.6.1 Show that if \(B \in \mathbb{R}^{n \times n}\) is an upper bidiagonal matrix having a repeated singular value, then \(B\) must have a zero on its diagonal or superdiagonal.

P8.6.2 Give formulae for the eigenvectors of \( \begin{bmatrix} 0 & A^T \\ A & 0 \end{bmatrix} \) in terms of the singular vectors of \( A \in \mathbb{R}^{m \times n}\) where \(m \geq n\).

P8.6.3 Give an algorithm for reducing a complex matrix \(A\) to real bidiagonal form using complex Householder transformations.

P8.6.4 Relate the singular values and vectors of \(A = B + iC\) \((B, C \in \mathbb{R}^{m \times n})\) to those of \(\begin{bmatrix} B & -C \\ C & B \end{bmatrix}\).

P8.6.5 Complete the proof of Theorem 8.6.1.

P8.6.6 Assume that \(n = 2m\) and that \(S \in \mathbb{R}^{n \times n}\) is skew-symmetric and tridiagonal. Show that there exists a permutation \(P \in \mathbb{R}^{n \times n}\) such that \(P^T SP\) has the following form:

\[
P^T SP = \begin{bmatrix}
  0 & -B^T \\
  B & 0 \\
  m & m
\end{bmatrix}^m.
\]

Describe \(B\). Show how to compute the eigenvalues and eigenvectors of \(S\) via the SVD of \(B\). Repeat for the case \(n = 2m + 1\).

P8.6.7 (a) Let

\[
C = \begin{bmatrix}
  w & z \\
  y & z
\end{bmatrix}
\]

be real. Give a stable algorithm for computing \(c\) and \(s\) with \(c^2 + s^2 = 1\) such that

\[
B = \begin{bmatrix}
  c & s \\
  -s & c
\end{bmatrix} C
\]

is symmetric. (b) Combine (a) with the Jacobi trigonometric calculations in the text to obtain a stable algorithm for computing the SVD of \(C\). (c) Part (b) can be used to
develop a Jacobi-like algorithm for computing the SVD of $A \in \mathbb{R}^{n \times n}$. For a given $(p, q)$ with $p < q$, Jacobi transformations $J(p, q, \theta_1)$ and $J(p, q, \theta_2)$ are determined such that if

$$B = J(p, q, \theta_1)^T A J(p, q, \theta_2),$$

then $b_{pq} = b_{qp} = 0$. Show

$$\text{off}(B)^2 = \text{off}(A)^2 - b_{pq}^2 - b_{qp}^2.$$

How might $p$ and $q$ be determined? How could the algorithm be adapted to handle the case when $A \in \mathbb{R}^{m \times n}$ with $m > n$?

P8.6.8 Let $x$ and $y$ be in $\mathbb{R}^m$ and define the orthogonal matrix $Q$ by

$$Q = \left[ \begin{array}{cc} c & s \\ -s & c \end{array} \right].$$

Give a stable algorithm for computing $c$ and $s$ such that the columns of $[x, y]Q$ are orthogonal to each other.

P8.6.9 Suppose $B \in \mathbb{R}^{n \times n}$ is upper bidiagonal with $b_{nn} = 0$. Show how to construct orthogonal $U$ and $V$ (product of Givens rotations) so that $U^T B V$ is upper bidiagonal with a zero $n$th column.

P8.6.10 Suppose $B \in \mathbb{R}^{n \times n}$ is upper bidiagonal with diagonal entries $d(1:n)$ and super-diagonal entries $f(1:n - 1)$. State and prove a singular value version of Theorem 8.5.1.

Notes and References for Sec. 8.6

The mathematical properties of the SVD are discussed in Stewart and Sun (1990) as well as

The idea of adapting the symmetric QR algorithm to compute the SVD first appeared in

and then came some early implementations:

Interesting algorithmic developments associated with the SVD appear in
8.6. Computing the SVD

The Polar decomposition of a matrix can be computed immediately from its SVD. However, special algorithms have been developed just for this purpose.

Jacobi methods for the SVD fall into two categories. The two-sided Jacobi algorithms repeatedly perform the update $A \leftarrow U^TAV$ producing a sequence of iterates that are increasingly diagonal.

The one-sided Jacobi SVD procedures repeatedly perform the update $A \leftarrow AV$ producing a sequence of iterates with columns that are increasingly orthogonal.

Numerous parallel implementations have been developed.

The divide and conquer algorithms devised for for the symmetric eigenproblem have SVD analogs:

Careful analyses of the SVD calculation include

High accuracy SVD calculation and connections among the Cholesky, Schur, and singular value computations are discussed in

8.7 Some Generalized Eigenvalue Problems

Given a symmetric matrix \( A \in \mathbb{R}^{n \times n} \) and a symmetric positive definite \( B \in \mathbb{R}^{n \times n} \), we consider the problem of finding a nonzero vector \( x \) and a scalar \( \lambda \) so \( Ax = \lambda Bx \). This is the symmetric-definite generalized eigenproblem. The scalar \( \lambda \) can be thought of as a generalized eigenvalue. As \( \lambda \) varies, \( A - \lambda B \) defines a pencil and our job is to determine

\[
\lambda(A, B) = \{ \lambda \mid \det(A - \lambda B) = 0 \}.
\]

A symmetric-definite generalized eigenproblem can be transformed to an equivalent problem with a congruence transformation:

\[
A - \lambda B \text{ is singular} \iff (X^TAX) - \lambda(X^T BX) \text{ is singular}
\]

Thus, if \( X \) is nonsingular, then \( \lambda(A, B) = \lambda(X^T AX, X^T BX) \).

In this section we present various structure-preserving procedures that solve such eigenproblems through the careful selection of \( X \). The related generalized singular value decomposition problem is also discussed.

8.7.1 Mathematical Background

We seek is a stable, efficient algorithm that computes \( X \) such that \( X^TAX \) and \( X^T BX \) are both in “canonical form.” The obvious form to aim for is diagonal form.

Theorem 8.7.1 Suppose \( A \) and \( B \) are \( n \)-by-\( n \) symmetric matrices, and define \( C(\mu) \) by

\[
C(\mu) = \mu A + (1 - \mu) B \quad \mu \in \mathbb{R}.
\]

(8.7.1)

If there exists a \( \mu \in [0, 1] \) such that \( C(\mu) \) is non-negative definite and

\[
\text{null}(C(\mu)) = \text{null}(A) \cap \text{null}(B)
\]

then there exists a nonsingular \( X \) such that both \( X^TAX \) and \( X^T BX \) are diagonal.

Proof. Let \( \mu \in [0, 1] \) be chosen so that \( C(\mu) \) is non-negative definite with the property that \( \text{null}(C(\mu)) = \text{null}(A) \cap \text{null}(B) \). Let

\[
Q_1^T C(\mu) Q_1 = \begin{bmatrix} D & 0 \\ 0 & 0 \end{bmatrix} \quad D = \text{diag}(d_1, \ldots, d_k), \quad d_i > 0
\]

be the Schur decomposition of \( C(\mu) \) and define \( X_1 = Q_1 \text{diag}(D^{-1/2}, I_{n-k}) \).

If \( A_1 = X_1^T AX_1 \), \( B_1 = X_1^T BX_1 \), and \( C_1 = X_1^T C(\mu) X_1 \), then

\[
C_1 = \begin{bmatrix} I_k & 0 \\ 0 & 0 \end{bmatrix} = \mu A_1 + (1 - \mu) B_1.
\]
Since \( \text{span}\{e_{k+1}, \ldots, e_n\} = \text{null}(C_1) = \text{null}(A_1) \cap \text{null}(B_1) \) it follows that \( A_1 \) and \( B_1 \) have the following block structure:

\[
A_1 = \begin{bmatrix}
A_{11} & 0 \\
0 & 0 \\
k & n-k
\end{bmatrix}^k_{n-k} \quad B_1 = \begin{bmatrix}
B_{11} & 0 \\
0 & 0 \\
k & n-k
\end{bmatrix}^k_{n-k}.
\]

Moreover \( I_k = \mu A_{11} + (1 - \mu) B_{11} \).

Suppose \( \mu \neq 0 \). It then follows that if \( Z^T B_{11} Z = \text{diag}(b_1, \ldots, b_k) \) is the Schur decomposition of \( B_{11} \) and we set \( X = X_1 \text{diag}(Z, I_{n-k}) \) then

\[
X^T B X = \text{diag}(b_1, \ldots, b_k, 0, \ldots, 0) \equiv D_B
\]

and

\[
X^T A X = \frac{1}{\mu} X^T (C(\mu) - (1 - \mu) B) X
= \frac{1}{\mu} \left( \begin{bmatrix} I_k & 0 \\ 0 & 0 \end{bmatrix} - (1 - \mu) D_B \right) \equiv D_A.
\]

On the other hand, if \( \mu = 0 \), then let \( Z^T A_{11} Z = \text{diag}(a_1, \ldots, a_k) \) be the Schur decomposition of \( A_{11} \) and set \( X = X_1 \text{diag}(Z, I_{n-k}) \). It is easy to verify that in this case as well, both \( X^T A X \) and \( X^T B X \) are diagonal. \( \square \)

Frequently, the conditions in Theorem 8.7.1 are satisfied because either \( A \) or \( B \) is positive definite.

**Corollary 8.7.2** If \( A - \lambda B \in \mathbb{R}^{n \times n} \) is symmetric-definite, then there exists a nonsingular \( X = [x_1, \ldots, x_n] \) such that

\[
X^T A X = \text{diag}(a_1, \ldots, a_n) \quad \text{and} \quad X^T B X = \text{diag}(b_1, \ldots, b_n).
\]

Moreover, \( A x_i = \lambda_i B x_i \) for \( i = 1:n \) where \( \lambda_i = a_i/b_i \).

**Proof.** By setting \( \mu = 0 \) in Theorem 8.7.1 we see that symmetric-definite pencils can be simultaneously diagonalized. The rest of the corollary is easily verified. \( \square \)

**Example 8.7.1** If

\[
A = \begin{bmatrix}
229 & 163 \\
163 & 116
\end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix}
81 & 59 \\
59 & 43
\end{bmatrix}
\]

then \( A - \lambda B \) is symmetric-definite and \( \lambda(A, B) = \{5, -1/2\} \). If

\[
X = \begin{bmatrix}
3 & -5 \\
-4 & 7
\end{bmatrix}
\]
then \(X^TAX = \text{diag}(5, -1)\) and \(X^TBX = \text{diag}(1, 2)\).

Stewart (1979) has worked out a perturbation theory for symmetric pencils \(A - \lambda B\) that satisfy

\[
c(A, B) = \min_{\|x\|_2 = 1} (x^T Ax)^2 + (x^T Bx)^2 > 0 \tag{8.7.2}
\]

The scalar \(c(A, B)\) is called the Crawford number of the pencil \(A - \lambda B\).

**Theorem 8.7.3** Suppose \(A - \lambda B\) is an \(n\)-by-\(n\) symmetric-definite pencil with eigenvalues

\[
\lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_n.
\]

Suppose \(E_A\) and \(E_B\) are symmetric \(n\)-by-\(n\) matrices that satisfy

\[
\varepsilon^2 = \|E_A\|_2^2 + \|E_B\|_2^2 < c(A, B).
\]

Then \((A + E_A) - (B + E_B)\) is symmetric-definite with eigenvalues

\[
\mu_1 \geq \cdots \geq \mu_n
\]

that satisfy

\[
|\arctan(\lambda_i) - \arctan(\mu_i)| \leq \arctan(\varepsilon/c(A, B))
\]

for \(i = 1:n\).

**Proof.** See Stewart (1979). \(\Box\)

### 8.7.2 Methods for the Symmetric-Definite Problem

Turning to algorithmic matters, we first present a method for solving the symmetric-definite problem that utilizes both the Cholesky factorization and the symmetric QR algorithm.

**Algorithm 8.7.1** Given \(A = A^T \in \mathbb{R}^{n \times n}\) and \(B = B^T \in \mathbb{R}^{n \times n}\) with \(B\) positive definite, the following algorithm computes a nonsingular \(X\) such that \(X^T B X = I_n\) and \(X^T A X = \text{diag}(a_1, \ldots, a_n)\).

1. Compute the Cholesky factorization \(B = G G^T\) using Algorithm 4.2.2.
2. Compute \(C = G^{-1} A G^{-T}\).
3. Use the symmetric QR algorithm to compute the Schur decomposition \(Q^T C Q = \text{diag}(a_1, \ldots, a_n)\).
4. Set \(X = G^{-T} Q\).
This algorithm requires about $14n^3$ flosps. In a practical implementation, $A$ can be overwritten by the matrix $C$. See Martin and Wilkinson (1968c) for details. Note that

$$
\lambda(A, B) = \lambda(A, GG^T) = \lambda(G^{-1}AG^{-T}, I) = \lambda(C) = \{a_1, \ldots, a_n\}.
$$

If $\hat{a}_i$ is a computed eigenvalue obtained by Algorithm 8.7.1, then it can be shown that $\hat{a}_i \in \lambda(G^{-1}AG^{-T} + E_i)$, where $\|E_i\|_2 \approx u\|A\|_2\|B^{-1}\|_2$. Thus, if $B$ is ill-conditioned, then $\hat{a}_i$ may be severely contaminated with roundoff error even if $a_i$ is a well-conditioned generalized eigenvalue. The problem, of course, is that in this case, the matrix $C = G^{-1}AG^{-T}$ can have some very large entries if $B$, and hence $G$, is ill-conditioned. This difficulty can sometimes be overcome by replacing the matrix $G$ in Algorithm 8.7.1 with $VD^{-1/2}$ where $V^TBV = D$ is the Schur decomposition of $B$. If the diagonal entries of $D$ are ordered from smallest to largest, then the large entries in $C$ are concentrated in the upper left-hand corner. The small eigenvalues of $C$ can then be computed without excessive roundoff error contamination (or so the heuristic goes). For further discussion, consult Wilkinson (1965, pp.337–38).

**Example 8.7.2** If

$$
A = \begin{bmatrix}
1 & 2 & 3 \\
2 & 4 & 5 \\
3 & 5 & 6
\end{bmatrix}
\quad \text{and} \quad
G = \begin{bmatrix}
.001 & 0 & 0 \\
1 & .001 & 0 \\
2 & 1 & .001
\end{bmatrix}
$$

and $B = GG^T$, then the two smallest eigenvalues of $A - \lambda B$ are

$$
a_1 = -0.619402940600584 \quad a_2 = 1.627440079051887.
$$

If 17-digit floating point arithmetic is used, then these eigenvalues are computed to full machine precision when the symmetric QR algorithm is applied to $f(I(D^{-1/2}V^TAVD^{-1/2}))$, where $B = VDV^T$ is the Schur decomposition of $B$. On the other hand, if Algorithm 8.7.1 is applied, then

$$
\hat{a}_1 = -0.619373517376444 \quad \hat{a}_2 = 1.627516601905228.
$$

The reason for obtaining only four correct significant digits is that $\kappa_2(B) \approx 10^{18}$.

The condition of the matrix $X$ in Algorithm 8.7.1 can sometimes be improved by replacing $B$ with a suitable convex combination of $A$ and $B$. The connection between the eigenvalues of the modified pencil and those of the original are detailed in the proof of Theorem 8.7.1.

Other difficulties concerning Algorithm 8.7.1 revolve around the fact that $G^{-1}AG^{-T}$ is generally full even when $A$ and $B$ are sparse. This is a serious problem, since many of the symmetric-definite problems arising in practice are large and sparse.

Crawford (1973) has shown how to implement Algorithm 8.7.1 effectively when $A$ and $B$ are banded. Aside from this case, however, the simultaneous diagonalization approach is impractical for the large, sparse symmetric-definite problem.
An alternative idea is to extend the Rayleigh quotient iteration (8.4.4) as follows:

\[ x_0 \text{ given with } \| x_0 \|_2 = 1 \]
\[ \text{for } k = 0, 1, \ldots \]
\[ \mu_k = x_k^T A x_k / x_k^T B x_k \quad (8.7.3) \]
\[ \text{Solve } (A - \mu_k B) z_{k+1} = B x_k \text{ for } z_{k+1}. \]
\[ x_{k+1} = z_{k+1} / \| z_{k+1} \|_2 \]
end

The mathematical basis for this iteration is that

\[ \lambda = \frac{x^T A x}{x^T B x} \quad (8.7.4) \]

minimizes

\[ f(\lambda) = \| A x - \lambda B x \|_B \quad (8.7.5) \]

where \( \| \cdot \|_B \) is defined by \( \| z \|_B^2 = z^T B^{-1} z \). The mathematical properties of (8.7.3) are similar to those of (8.4.4). Its applicability depends on whether or not systems of the form \( (A - \mu B) z = x \) can be readily solved. A similar comment pertains to the following generalized orthogonal iteration:

\[ Q_0 \in \mathbb{R}^{n \times p} \text{ given with } Q_0^T Q_0 = I_p \]
\[ \text{for } k = 1, 2, \ldots \]
\[ \text{Solve } B Z_k = A Q_{k-1} \text{ for } Z_k. \quad (8.7.6) \]
\[ Z_k = Q_k R_k \quad (\text{QR factorization}) \]
end

This is mathematically equivalent to (7.3.4) with \( A \) replaced by \( B^{-1} A \). Its practicality depends on how easy it is to solve linear systems of the form \( B z = y \).

Sometimes \( A \) and \( B \) are so large that neither (8.7.3) nor (8.7.6) can be invoked. In this situation, one can resort to any of a number of gradient and coordinate relaxation algorithms. See Stewart (1976) for an extensive guide to the literature.

### 8.7.3 The Generalized Singular Value Problem

We conclude with some remarks about symmetric pencils that have the form \( A^T A - \lambda B^T B \) where \( A \in \mathbb{R}^{m \times n} \) and \( B \in \mathbb{R}^{p \times n} \). This pencil underlies the *generalized singular value decomposition (GSVD)*, a decomposition that is useful in several constrained least squares problems. (Cf. §12.1.) Note that by Theorem 8.7.1 there exists a nonsingular \( X \in \mathbb{R}^{n \times n} \) such that \( X^T (A^T A) X \) and \( X^T (B^T B) X \) are both diagonal. The value of the GSVD
is that these diagonalizations can be achieved without forming $A^T A$ and $B^T B$.

**Theorem 8.7.4 (Generalized Singular Value Decomposition)** If we have $A \in \mathbb{R}^{m \times n}$ with $m \geq n$ and $B \in \mathbb{R}^{p \times n}$, then there exist orthogonal $U \in \mathbb{R}^{m \times m}$ and $V \in \mathbb{R}^{p \times p}$ and an invertible $X \in \mathbb{R}^{n \times n}$ such that

$$U^T A X = C = \text{diag}(c_1, \ldots, c_n) \quad c_i \geq 0$$

and

$$V^T B X = S = \text{diag}(s_1, \ldots, s_q) \quad s_i \geq 0$$

where $q = \min(p, n)$.

**Proof.** The proof of this decomposition appears in Van Loan (1976). We present a more constructive proof along the lines of Paige and Saunders (1981). For clarity we assume that $\text{null}(A) \cap \text{null}(B) = \{0\}$ and $p \geq n$. We leave it to the reader to extend the proof so that it covers theses cases.

Let

$$\begin{bmatrix} A \\ B \end{bmatrix} = \begin{bmatrix} Q_1 \\ Q_2 \end{bmatrix} R \quad (8.7.6)$$

be a QR factorization with $Q_1 \in \mathbb{R}^{m \times n}$, $Q_2 \in \mathbb{R}^{p \times n}$, and $R \in \mathbb{R}^{n \times n}$. Paige and Saunders show that the SVD's of $Q_1$ and $Q_2$ are related in the sense that

$$Q_1 = U C W^T \quad Q_2 = V S W^T \quad (8.7.7)$$

Here, $U, V,$ and $W$ are orthogonal, $C = \text{diag}(c_i)$ with $0 \leq c_1 \leq \cdots \leq c_n$, $S = \text{diag}(s_i)$ with $s_1 \geq \cdots \geq s_n$, and $C^T C + S^T S = I_n$. The decomposition (8.7.7) is a variant of the CS decomposition in §2.6 and from it we conclude that $A = Q_1 R = U C (W^T R)$ and $B = Q_2 R = V S (W^T R)$. The theorem follows by setting $X = (W^T R)^{-1}$, $D_A = C$, and $D_B = S$. The invertibility of $R$ follows from our assumption that $\text{null}(A) \cap \text{null}(B) = \{0\}$. \qed

The elements of the set $\sigma(A, B) \equiv \{ c_1/s_1, \ldots, c_n/s_q \}$ are referred to as the generalized singular values of $A$ and $B$. Note that $\sigma \in \sigma(A, B)$ implies that $\sigma^2 \in \lambda(A^T A, B^T B)$. The theorem is a generalization of the SVD in that if $B = I_n$, then $\sigma(A, B) = \sigma(A)$.

Our proof of the GSVD is of practical importance since Stewart (1983) and Van Loan (1985) have shown how to stably compute the CS decomposition. The only tricky part is the inversion of $W^T R$ to get $X$. Note that the columns of $X = [x_1, \ldots, x_n]$ satisfy

$$s_i^2 A^T A x_i = c_i^2 B^T B x_i \quad i = 1:n$$

and so if $s_i \neq 0$ then $A^T A x_i = \sigma_i^2 B^T B x_i$ where $\sigma_i = c_i/s_i$. Thus, the $x_i$ are aptly termed the generalized singular vectors of the pair $(A, B)$. 
In several applications an orthonormal basis for some designated generalized singular vector subspace space \( \text{span}\{x_1, \ldots, x_k\} \) is required. We show how this can be accomplished without any matrix inversions or cross products:

- Compute the QR factorization
  \[
  \begin{bmatrix}
  A \\
  B
  \end{bmatrix} = \begin{bmatrix}
  Q_1 \\
  Q_2
  \end{bmatrix} R.
  \]

- Compute the CS decomposition
  \[ Q_1 = UCW^T \quad Q_2 = VSW^T \]
  and order the diagonals of \( C \) and \( S \) so that
  \[ \{ c_1/s_1, \ldots, c_k/s_k \} = \{ c_{i_1}/s_{i_1}, \ldots, c_{i_k}/s_{i_k} \}. \]

- Compute orthogonal \( Z \) and upper triangular \( T \) so \( TZ = W^TR \). (See P8.7.5.) Note that if \( X^{-1} = W^TR = TZ \), then \( X = Z^TT^{-1} \) and so the first \( k \) rows of \( Z \) are an orthonormal basis for \( \text{span}\{x_1, \ldots, x_k\} \).

### Problems

**P8.7.1** Suppose \( A \in \mathbb{R}^{n \times n} \) is symmetric and \( G \in \mathbb{R}^{n \times n} \) is lower triangular and nonsingular. Give an efficient algorithm for computing \( C = G^{-1}AG^{-T} \).

**P8.7.2** Suppose \( A \in \mathbb{R}^{n \times n} \) is symmetric and \( B \in \mathbb{R}^{n \times n} \) is symmetric positive definite. Give an algorithm for computing the eigenvalues of \( AB \) that uses the Cholesky factorization and the symmetric QR algorithm.

**P8.7.3** Show that if \( C \) is real and diagonalizable, then there exist symmetric matrices \( A \) and \( B \) nonsingular, such that \( C = AB^{-1} \). This shows that symmetric pencils \( A - \lambda B \) are essentially general.

**P8.7.4** Show how to convert an \( Ax = \lambda Bx \) problem into a generalized singular value problem if \( A \) and \( B \) are both symmetric and non-negative definite.

**P8.7.5** Given \( Y \in \mathbb{R}^{n \times n} \) show how to compute Householder matrices \( H_2, \ldots, H_n \) so that \( YH_n \cdots H_2 = T \) is upper triangular. Hint: \( H_k \) zeros out the \( k \)th row.

**P8.7.6** Suppose
\[
\begin{bmatrix}
  0 \\
  A^T
\end{bmatrix}
\begin{bmatrix}
  y \\
  z
\end{bmatrix} = \lambda
\begin{bmatrix}
  B_1 & 0 \\
  0 & B_2
\end{bmatrix}
\begin{bmatrix}
  y \\
  z
\end{bmatrix}
\]
where \( A \in \mathbb{R}^{m \times n} \), \( B_1 \in \mathbb{R}^{m \times m} \), and \( B_2 \in \mathbb{R}^{n \times n} \). Assume that \( B_1 \) and \( B_2 \) are positive definite with Cholesky triangles \( G_1 \) and \( G_2 \) respectively. Relate the generalized eigenvalues of this problem to the singular values of \( G_1^{-1}AG_2^{-T} \).

**P8.7.7** Suppose \( A \) and \( B \) are both symmetric positive definite. Show how to compute \( \lambda(A, B) \) and the corresponding eigenvectors using the Cholesky factorization and CS decomposition.

Lanczos Methods

§9.1 Derivation and Convergence Properties
§9.2 Practical Lanczos Procedures
§9.3 Applications to $Ax = b$ and Least Squares
§9.4 Arnoldi and Unsymmetric Lanczos

In this chapter we develop the Lanczos method, a technique that can be used to solve certain large, sparse, symmetric eigenproblems $Ax = \lambda x$. The method involves partial tridiagonalizations of the given matrix $A$. However, unlike the Householder approach, no intermediate, full submatrices are generated. Equally important, information about $A$'s extremal eigenvalues tends to emerge long before the tridiagonalization is complete. This makes the Lanczos algorithm particularly useful in situations where a few of $A$'s largest or smallest eigenvalues are desired.

The derivation and exact arithmetic attributes of the method are presented in §9.1. The key aspects of the Kaniel-Paige theory are detailed. This theory explains the extraordinary convergence properties of the Lanczos process. Unfortunately, roundoff errors make the Lanczos method somewhat difficult to use in practice. The central problem is a loss of orthogonality among the Lanczos vectors that the iteration produces. There are several ways to cope with this as we discuss §9.2.

In §9.3 we show how the "Lanczos idea" can be applied to solve an assortment of singular value, least squares, and linear equations problems. Of particular interest is the development of the conjugate gradient method for symmetric positive definite linear systems. The Lanczos-conjugate gradient connection is explored further in the next chapter. In §9.4 we discuss the Arnoldi iteration which is based on the Hessenberg decomposition and a
version of the Lanczos process that can (sometimes) be used to tridiagonalize unsymmetric matrices.

Before You Begin

Chapters 5 and 8 are required for §9.1-9.3 and Chapter 7 is needed for §9.4. Within this chapter there are the following dependencies:

§9.1 $\rightarrow$ §9.2 $\rightarrow$ §9.3

$\downarrow$

§9.4

A wide range of Lanczos papers are collected in Brown, Chu, Ellison, and Plemmons (1994). Other complementary references include Parlett (1980), Saad (1992), and Chatelin (1993). The two volume work by Cullum and Willoughby (1985a,1985b) includes both analysis and software.

9.1 Derivation and Convergence Properties

Suppose $A \in \mathbb{R}^{n \times n}$ is large, sparse, and symmetric and assume that a few of its largest and/or smallest eigenvalues are desired. This problem can be solved by a method attributed to Lanczos (1950). The method generates a sequence of tridiagonal matrices $T_k$ with the property that the extremal eigenvalues of $T_k \in \mathbb{R}^{k \times k}$ are progressively better estimates of $A$'s extremal eigenvalues. In this section, we derive the technique and investigate its exact arithmetic properties. Throughout the section $\lambda_i(\cdot)$ designates the $i$th largest eigenvalue.

9.1.1 Krylov Subspaces

The derivation of the Lanczos algorithm can proceed in several ways. So that its remarkable convergence properties do not come as a complete surprise, we prefer to lead into the technique by considering the optimization of the Rayleigh quotient

$$r(x) = \frac{x^T A x}{x^T x}, \quad x \neq 0.$$ 

Recall from Theorem 8.1.2 that the maximum and minimum values of $r(x)$ are $\lambda_1(A)$ and $\lambda_n(A)$, respectively. Suppose $\{q_i\} \subseteq \mathbb{R}^n$ is a sequence of orthonormal vectors and define the scalars $M_k$ and $m_k$ by

$$M_k = \lambda_1(Q_k^T A Q_k) = \max_{y \neq 0} \frac{y^T (Q_k^T A Q_k) y}{y^T y} = \max_{\|y\|_2 = 1} r(Q_k y) \leq \lambda_1(A)$$
\[ m_k = \lambda_k(Q_k^TAQ_k) = \min_{y \neq 0} \frac{y^T(Q_k^TAQ_k)y}{y^Ty} = \min_{\|y\|_2 = 1} r(Q_ky) \geq \lambda_n(A) \]

where \( Q_k = [q_1, \ldots, q_k] \). The Lanczos algorithm can be derived by considering how to generate the \( q_k \) so that \( M_k \) and \( m_k \) are increasingly better estimates of \( \lambda_1(A) \) and \( \lambda_n(A) \).

Suppose \( u_k \in \text{span}\{q_1, \ldots, q_k\} \) is such that \( M_k = r(u_k) \). Since \( r(x) \) increases most rapidly in the direction of the gradient
\[ \nabla r(x) = \frac{2}{x^Tx} (Ax - r(x)x), \]
we can ensure that \( M_{k+1} > M_k \) if \( q_{k+1} \) is determined so
\[ \nabla r(u_k) \in \text{span}\{q_1, \ldots, q_{k+1}\}. \]  \hspace{1cm} (9.1.1)
(This assumes \( \nabla r(u_k) \neq 0 \).) Likewise, if \( u_k \in \text{span}\{q_1, \ldots, q_k\} \) satisfies \( r(u_k) = m_k \), then it makes sense to require
\[ \nabla r(u_k) \in \text{span}\{q_1, \ldots, q_{k+1}\} \]  \hspace{1cm} (9.1.2)
since \( r(x) \) decreases most rapidly in the direction of \(-\nabla r(x)\).

At first glance, the task of finding a single \( q_{k+1} \) that satisfies these two requirements appears impossible. However, since \( \nabla r(x) \in \text{span}\{x, Ax\} \), it is clear that (9.1.1) and (9.1.2) can be simultaneously satisfied if
\[ \text{span}\{q_1, \ldots, q_k\} = \text{span}\{q_1, Aq_1, \ldots, A^{k-1}q_1\} \]
and we choose \( q_{k+1} \) so
\[ \text{span}\{q_1, \ldots, q_{k+1}\} = \text{span}\{q_1, Aq_1, \ldots, A^{k-1}q_1, A^kq_1\}. \]

Thus, we are led to the problem of computing orthonormal bases for the Krylov subspaces
\[ K(A, q_1, k) = \text{span}\{q_1, Aq_1, \ldots, A^{k-1}q_1\}. \]

These are just the range spaces of the Krylov matrices
\[ K(A, q_1, n) = [q_1, Aq_1, A^2q_1, \ldots, A^{n-1}q_1]. \]

presented in §8.3.2.

### 9.1.2 Tridiagonalization

In order to find this basis efficiently we exploit the connection between the tridiagonalization of \( A \) and the QR factorization of \( K(A, q_1, n) \). Recall that if \( Q^TAQ = T \) is tridiagonal with \( Qe_1 = q_1 \), then
\[ K(A, q_1, n) = Q \left[ e_1, Te_1, T^2e_1, \ldots, T^{n-1}e_1 \right] \]
is the QR factorization of $K(A, q_1, n)$ where $e_1 = I_n(:, 1)$. Thus the $q_k$ can effectively be generated by tridiagonalizing $A$ with an orthogonal matrix whose first column is $q_1$.

Householder tridiagonalization, discussed in §8.3.1, can be adapted for this purpose. However, this approach is impractical if $A$ is large and sparse because Householder similarity transformations tend to destroy sparsity. As a result, unacceptably large, dense matrices arise during the reduction.

Loss of sparsity can sometimes be controlled by using Givens rather than Householder transformations. See Duff and Reid (1976). However, any method that computes $T$ by successively updating $A$ is not useful in the majority of cases when $A$ is sparse.

This suggests that we try to compute the elements of the tridiagonal matrix $T = Q^T AQ$ directly. Setting $Q = [q_1, \ldots, q_n]$ and

$$
T = \begin{bmatrix}
\alpha_1 & \beta_1 & \cdots & 0 \\
\beta_1 & \alpha_2 & \cdots & \\
& \ddots & \ddots & \\
& & \ddots & \beta_{n-1} \\
0 & \cdots & \beta_{n-1} & \alpha_n
\end{bmatrix}
$$

and equating columns in $AQ = QT$, we find

$$
Aq_k = \beta_{k-1}q_{k-1} + \alpha_kq_k + \beta_kq_{k+1}, \quad \beta_0q_0 \equiv 0
$$

for $k = 1:n - 1$. The orthonormality of the $q_i$ implies $q_k = q_k^T AQ_k$. Moreover, if $r_k = \langle A - \alpha_k I \rangle q_k - \beta_{k-1}q_{k-1}$ is nonzero, then $q_{k+1} = r_k/\beta_k$ where $\beta_k = \pm \| r_k \|_2$. If $r_k = 0$, then the iteration breaks down but (as we shall see) not without the acquisition of valuable invariant subspace information. So by properly sequencing the above formulae we obtain the Lanczos iteration:

$$
\begin{align*}
r_0 &= q_1; \quad \beta_0 = 1; \quad q_0 = 0; \quad k = 0 \\
\text{while} & \quad (\beta_k \neq 0) \\
q_{k+1} &= r_k/\beta_k; \quad k = k + 1; \quad \alpha_k = q_k^T AQ_k \\
r_k &= (A - \alpha_k I)q_k - \beta_{k-1}q_{k-1}; \quad \beta_k = \| r_k \|_2
\end{align*}
$$

There is no loss of generality in choosing the $\beta_k$ to be positive. The $q_k$ are called Lanczos vectors.

### 9.1.3 Termination and Error Bounds

The iteration halts before complete tridiagonalization if $q_1$ is contained in a proper invariant subspace. This is one of several mathematical properties of the method that we summarize in the following theorem.
Theorem 9.1.1 Let $A \in \mathbb{R}^{n \times n}$ be symmetric and assume $q_1 \in \mathbb{R}^n$ has unit 2-norm. Then the Lanczos iteration (9.1.3) runs until $k = m$, where $m = \text{rank}(K(A, q_1, n))$. Moreover, for $k = 1:m$ we have

$$AQ_k = Q_kT_k + r_k e_k^T$$  \hspace{1cm} (9.1.4)

where

$$T_k = \begin{bmatrix}
\alpha_1 & \beta_1 & \cdots & 0 \\
\beta_1 & \alpha_2 & \cdots & \\
& \ddots & \ddots & \\
& & \ddots & \beta_{k-1} \\
0 & \cdots & \beta_{k-1} & \alpha_k
\end{bmatrix}$$

and $Q_k = [q_1, \ldots, q_k]$ has orthonormal columns that span $\mathcal{K}(A, q_1, k)$.

Proof. The proof is by induction on $k$. Suppose the iteration has produced $Q_k = [q_1, \ldots, q_k]$ such that $\text{ran}(Q_k) = \mathcal{K}(A, q_1, k)$ and $Q_k^T Q_k = I_k$. It is easy to see from (9.1.3) that (9.1.4) holds. Thus, $Q_k^T AQ_k = T_k + Q_k^T r_k e_k^T$.

Since $\alpha_i = q_i^T A q_i$ for $i = 1:k$ and

$$q_{i+1}^T A q_i = q_{i+1}^T (A q_i - \alpha_i q_i - \beta_i q_{i-1}) = q_{i+1}^T (\beta_i q_{i+1}) = \beta_i$$

for $i = 1:k - 1$, we have $Q_k^T AQ_k = T_k$. Consequently, $Q_k^T r_k = 0$.

If $r_k \neq 0$, then $q_{k+1} = r_k / \| r_k \|_2$ is orthogonal to $q_1, \ldots, q_k$ and

$$q_{k+1} \in \text{span}\{ A q_k, q_k, q_{k-1} \} \subseteq \mathcal{K}(A, q_1, k + 1).$$

Thus, $Q_{k+1}^T Q_{k+1} = I_{k+1}$ and $\text{ran}(Q_{k+1}) = \mathcal{K}(A, q_1, k + 1)$. On the other hand, if $r_k = 0$, then $AQ_k = Q_k T_k$. This says that $\text{ran}(Q_k) = \mathcal{K}(A, q_1, k)$ is invariant. From this we conclude that $k = m = \text{rank}(K(A, q_1, n))$. \hfill $\square$

Encountering a zero $\beta_k$ in the Lanczos iteration is a welcome event in that it signals the computation of an exact invariant subspace. However, an exact zero or even a small $\beta_k$ is a rarity in practice. Nevertheless, the extremal eigenvalues of $T_k$ turn out to be surprisingly good approximations to $A$'s extremal eigenvalues. Consequently, other explanations for the convergence of $T_k$'s eigenvalues must be sought. The following result is a step in this direction.

Theorem 9.1.2 Suppose that $k$ steps of the Lanczos algorithm have been performed and that $S_k^T T_k S_k = \text{diag}(\theta_1, \ldots, \theta_k)$ is the Schur decomposition of the tridiagonal matrix $T_k$. If $Y_k = [y_1, \ldots, y_k] = Q_k S_k \in \mathbb{R}^{n \times k}$, then for $i = 1:k$ we have $\| A y_i - \theta_i y_i \|_2 = |\beta_i| |s_{k+i}|$ where $S_k = (s_{pq})$.

Proof. Post-multiplying (9.1.4) by $S_k$ gives

$$AY_k = Y_k \text{diag}(\theta_1, \ldots, \theta_k) + r_k e_k^T S_k,$$
and so \( A y_i = \theta_i y_i + r_k (e_k^T S e_i) \). The proof is complete by taking norms and recalling that \( \| r_k \|_2 = \| \beta_k \| \). □

The theorem provides computable error bounds for \( T_k \)'s eigenvalues:

\[
\min_{\mu \in \lambda(A)} |\theta_i - \mu| \leq |\beta_i| \left| s_{ki} \right| \quad i = 1:k
\]

Note that in the terminology of Theorem 8.1.15, the \((\theta_i, y_i)\) are Ritz pairs for the subspace \( \text{ran}(Q_k) \).

Another way that \( T_k \) can be used to provide estimates of \( A \)'s eigenvalues is described in Golub (1974) and involves the judicious construction of a rank-one matrix \( E \) such that \( \text{ran}(Q_k) \) is invariant for \( A + E \). In particular, if we use the Lanczos method to compute \( AQ_k = Q_k T_k + r_k e_k^T \) and set \( E = \tau \omega w^T \), where \( \tau = \pm 1 \) and \( w = a q_k + b r_k \), then it can be shown that

\[
(A + E) Q_k = Q_k (T_k + \tau a^2 e_k e_k^T) + (1 + \tau ab) r_k e_k^T.
\]

If \( 0 = 1 + \tau a b \), then the eigenvalues of \( \bar{T}_k = T_k + \tau a^2 e_k e_k^T \), a tridiagonal matrix, are also eigenvalues of \( A + E \). Using Theorem 8.1.8 it can be shown that the interval \([\lambda_i(\bar{T}_k), \lambda_{i-1}(\bar{T}_k)]\) contains an eigenvalue of \( A \) for \( i = 2:k \).

These bracketing intervals depend on the choice of \( \tau a^2 \). Suppose we have an approximate eigenvalue of \( \lambda \) of \( A \). One possibility is to choose \( \tau a^2 \) so that \( \det(T_k - \lambda I_k) = (\alpha_2 + \tau a^2 - \lambda) p_{k-1}(\lambda) - \beta_{k-1}^2 p_{k-2}(\lambda) = 0 \) where the polynomials \( p_i(x) = \det(T_i - x I_i) \) can be evaluated at \( \lambda \) using the three-term recurrence (8.5.2). (This assumes that \( p_{k-1}(\lambda) \neq 0 \).) Eigenvalue estimation in this spirit is discussed in Lehmann (1963) and Householder (1968).

### 9.1.4 The Kaniel-Paige Convergence Theory

The preceding discussion indicates how eigenvalue estimates can be obtained via the Lanczos algorithm, but it reveals nothing about rate of convergence. Results of this variety constitute what is known as the Kaniel-Paige theory, a sample of which follows.

**Theorem 9.1.3** Let \( A \) be an \( n \times n \) symmetric matrix with eigenvalues \( \lambda_1 \geq \cdots \geq \lambda_n \) and corresponding orthonormal eigenvectors \( z_1, \ldots, z_n \). If \( \theta_1 \geq \cdots \geq \theta_k \) are the eigenvalues of the matrix \( T_k \) obtained after \( k \) steps of the Lanczos iteration, then

\[
\lambda_1 \geq \theta_1 \geq \lambda_1 - \frac{(\lambda_1 - \lambda_n) \tan(\phi_1)^2}{(c_{k-1}(1 + 2 \rho_1))^2}
\]

where \( \cos(\phi_1) = |q_1^T z_1| \), \( \rho_1 = (\lambda_1 - \lambda_2)/(\lambda_2 - \lambda_n) \), and \( c_{k-1}(x) \) is the Chebyshev polynomial of degree \( k - 1 \).
Proof. From Theorem 8.1.2, we have 
\[ \theta_1 = \max_{y \neq 0} \frac{y^T T_k y}{y^T y} = \max_{y \neq 0} \frac{(Q_k y)^T A(Q_k y)}{(Q_k y)^T(Q_k y)} = \max_{0 \neq w \in \mathcal{K}(A,q_1,k)} \frac{w^T A w}{w^T w} \]

Since \( \lambda_1 \) is the maximum of \( w^T A w/w^T w \) over all nonzero \( w \), it follows that \( \lambda_1 \geq \theta_1 \). To obtain the lower bound for \( \theta_1 \), note that
\[ \theta_1 = \max_{p \in \mathcal{P}_{k-1}} \frac{q_1^T p(A) A p(A) q_1}{q_1^T p(A)^2 q_1} \]

where \( \mathcal{P}_{k-1} \) is the set of \( k - 1 \) degree polynomials. If \( q_1 = \sum_{i=1}^{n} d_i z_i \) then
\[ \frac{q_1^T p(A) A p(A) q_1}{q_1^T p(A)^2 q_1} = \frac{\sum_{i=1}^{n} d_i^2 p(\lambda_i)^2 \lambda_i}{\sum_{i=1}^{n} d_i^2 p(\lambda_i)^2} \geq \lambda_1 - (\lambda_1 - \lambda_n) \frac{\sum_{i=2}^{n} d_i^2 p(\lambda_i)^2}{d_1^2 p(\lambda_1)^2 + \sum_{i=2}^{n} d_i^2 p(\lambda_i)^2}. \]

We can make the lower bound tight by selecting a polynomial \( p(x) \) that is large at \( x = \lambda_1 \) in comparison to its value at the remaining eigenvalues. One way of doing this is to set
\[ p(x) = c_{k-1} \left(-1 + 2 \frac{x - \lambda_n}{\lambda_2 - \lambda_n}\right) \]

where \( c_{k-1}(z) \) is the \((k - 1)\)-st Chebyshev polynomial generated via the recursion
\[ c_k(z) = 2z c_{k-1}(z) - c_{k-2}(z) \quad c_0 = 1, \ c_1 = z. \]

These polynomials are bounded by unity on \([-1, 1]\), but grow very rapidly outside this interval. By defining \( p(x) \) this way it follows that \( |p(\lambda_i)| \) is bounded by unity for \( i = 2:n \), while \( p(\lambda_1) = c_{k-1}(1 + 2\rho_1) \). Thus,
\[ \theta_1 \geq \lambda_1 - (\lambda_1 - \lambda_n) \frac{1 - d_1^2}{d_1^2} \frac{1}{c_{k-1}(1 + 2\rho_1)^2}. \]

The desired lower bound is obtained by noting that \( \tan(\phi_1)^2 = (1 - d_1^2)/d_1^2. \) □

An analogous result pertaining to \( \theta_k \) follows immediately from this theorem:
Corollary 9.1.4 Using the same notation as the theorem,

\[ \lambda_n \leq \theta_k \leq \lambda_n + \frac{(\lambda_1 - \lambda_n) \tan(\phi_n)}{c_{k-1}(1 + 2\rho_n)^2} \]

where \( \rho_n = (\lambda_{n-1} - \lambda_n)/(\lambda_1 - \lambda_{n-1}) \) and \( \cos(\phi_n) = q_n^T z_n \).

Proof. Apply Theorem 9.1.3 with \( A \) replaced by \(-A\). \( \square \)

9.1.5 The Power Method Versus the Lanczos Method

It is worthwhile to compare \( \theta_1 \) with the corresponding power method estimate of \( \lambda_1 \). (See §8.2.1.) For clarity, assume \( \lambda_1 \geq \cdots \geq \lambda_n \geq 0 \). After \( k-1 \) power method steps applied to \( q_1 \), a vector is obtained in the direction of

\[ v = A^{k-1}q_1 = \sum_{i=1}^{n} c_i \lambda_i^{k-1} z_i \]

along with an eigenvalue estimate

\[ \gamma_1 = \frac{v^T Av}{v^T v} \]

Using the proof and notation of Theorem 9.1.3, it is easy to show that

\[ \lambda_1 \geq \gamma_1 \geq \lambda_1 - (\lambda_1 - \lambda_n) \tan(\phi_1)^2 \left( \frac{\lambda_2}{\lambda_1} \right)^{2k-1} \]  \hspace{1cm} (9.1.5)

(Hint: Set \( p(x) = x^{k-1} \) in the proof.) Thus, we can compare the quality of the lower bounds for \( \theta_1 \) and \( \gamma_1 \) by comparing

\[ L_{k-1} = \frac{1}{c_{k-1} \left( \frac{2\lambda_1}{\lambda_2} - 1 \right)^2} \geq \frac{1}{[c_{k-1}(1 + 2\rho_1)]^2} \]

and

\[ R_{k-1} = \left( \frac{\lambda_2}{\lambda_1} \right)^{2(k-1)} \]

This is done in following table for representative values of \( k \) and \( \lambda_2/\lambda_1 \).

The superiority of the Lanczos estimate is self-evident. This should be no surprise, since \( \theta_1 \) is the maximum of \( r(x) = x^T Ax/x^T x \) over all of \( K(A, q_1, k) \), while \( \gamma_1 = r(v) \) for a particular \( v \) in \( K(A, q_1, k) \), namely \( v = A^{k-1}q_1 \).
\[ \begin{array}{cccccc}
\lambda_1/\lambda_2 & k = 5 & k = 10 & k = 15 & k = 20 & k = 25 \\
1.50 & 1.1 \times 10^{-4} & 2.0 \times 10^{-10} & 3.9 \times 10^{-16} & 7.4 \times 10^{-22} & 1.4 \times 10^{-27} \\
& 3.9 \times 10^{-2} & 6.8 \times 10^{-4} & 1.2 \times 10^{-5} & 2.0 \times 10^{-7} & 3.5 \times 10^{-9} \\
1.10 & 2.7 \times 10^{-2} & 5.5 \times 10^{-5} & 1.1 \times 10^{-7} & 2.1 \times 10^{-10} & 4.2 \times 10^{-13} \\
& 4.7 \times 10^{-1} & 1.8 \times 10^{-1} & 6.9 \times 10^{-2} & 2.7 \times 10^{-2} & 1.0 \times 10^{-2} \\
1.01 & 5.6 \times 10^{-1} & 1.0 \times 10^{-1} & 1.5 \times 10^{-2} & 2.0 \times 10^{-3} & 2.8 \times 10^{-4} \\
& 9.2 \times 10^{-1} & 8.4 \times 10^{-1} & 7.6 \times 10^{-1} & 6.9 \times 10^{-1} & 6.2 \times 10^{-1} \\
\end{array} \]

**Table 9.1.1** $L_{k-1}/R_{k-1}$

### 9.1.6 Convergence of Interior Eigenvalues

We conclude with some remarks about error bounds for $T_k$’s interior eigenvalues. The key idea in the proof of Theorem 9.1.3 is the use of the translated Chebyshev polynomial. With this polynomial we amplified the component of $q_1$ in the direction $z_1$. A similar idea can be used to obtain bounds for an interior Ritz value $\theta_i$. However, the bounds are not as satisfactory because the “amplifying polynomial” has the form $q(x)\Pi_{i=1}^{k-1}(x - \lambda_i)$, where $q(x)$ is the $(k - 1)$ degree of the Chebyshev polynomial on the interval $[\lambda_{i+1}, \lambda_n]$. For details, see Kaniel (1966), Paige (1971), or Saad (1980).

**Problems**

**P9.1.1** Suppose $A \in \mathbb{R}^{n \times n}$ is skew-symmetric. Derive a Lanczos-like algorithm for computing a skew-symmetric tridiagonal matrix $T_m$ such that $AQ_m = Q_mT_m$, where $Q_m^TQ_m = I_m$.

**P9.1.2** Let $A \in \mathbb{R}^{n \times n}$ be symmetric and define $\tau(x) = x^TAx/z^Tx$. Suppose $S \subseteq \mathbb{R}^n$ is a subspace with the property that $x \in S$ implies $\nabla \tau(x) \in S$. Show that $S$ is invariant for $A$.

**P9.1.3** Show that if a symmetric matrix $A \in \mathbb{R}^{n \times n}$ has a multiple eigenvalue, then the Lanczos iteration terminates prematurely.

**P9.1.4** Show that the index $m$ in Theorem 9.1.1 is the dimension of the smallest invariant subspace for $A$ that contains $q_1$.

**P9.1.5** Let $A \in \mathbb{R}^{n \times n}$ be symmetric and consider the problem of determining an orthonormal sequence $q_1, q_2, \ldots$ with the property that once $Q_k = [q_1, \ldots, q_k]$ is known, $q_{k+1}$ is chosen so as to minimize $\mu_k = \| (I - Q_k^TQ_k)Aq_k \|_F$. Show that if $\text{span}\{q_1, \ldots, q_k\} = \mathcal{K}(A, q_1, k)$, then it is possible to choose $q_{k+1}$ so $\mu_k = 0$. Explain how this optimization problem leads to the Lanczos iteration.

**P9.1.6** Suppose $A \in \mathbb{R}^{n \times n}$ is symmetric and that we wish to compute its largest eigenvalue. Let $\eta$ be an approximate eigenvector and set

\[ \alpha = \frac{\eta^TA\eta}{\eta^T\eta}, \quad z = A\eta - \alpha \eta. \]
9.2 Practical Lanczos Procedures

(a) Show that the interval \([\alpha - \delta, \alpha + \delta]\) must contain an eigenvalue of \(A\) where \(\delta = \| z \|_2 / \| \eta \|_2\). (b) Consider the new approximation \(\eta = a\eta + b\) and show how to determine the scalars \(a\) and \(b\) so that

\[
\bar{\alpha} = \frac{\eta^T A \eta}{\eta^T \eta}
\]

is maximized. (c) Relate the above computations to the first two steps of the Lanczos process.

Notes and References for Sec. 9.1

The classic reference for the Lanczos method is

Although the convergence of the Ritz values is alluded to this paper, for more details we refer the reader to

The connections between the Lanczos algorithm, orthogonal polynomials, and the theory of moments are discussed in

We motivated our discussion of the Lanczos algorithm by discussing the inevitability of fill-in when Householder or Givens transformations are used to tridiagonalize. Actually, fill-in can sometimes be kept to an acceptable level if care is exercised. See

9.2 Practical Lanczos Procedures

Rounding errors greatly affect the behavior of the Lanczos iteration. The basic difficulty is caused by loss of orthogonality among the Lanczos vectors, a phenomenon that muddies the issue of termination and complicates the relationship between \(A\)'s eigenvalues and those of the tridiagonal matrices \(T_k\). This troublesome feature, coupled with the advent of Householder's perfectly stable method of tridiagonalization, explains why the Lanczos
algorithm was disregarded by numerical analysts during the 1950's and 1960's. However, interest in the method was rejuvenated with the development of the Kaniel-Paige theory and because the pressure to solve large, sparse eigenproblems increased with increased computer power. With many fewer than \( n \) iterations typically required to get good approximate extremal eigenvalues, the Lanczos method became attractive as a sparse matrix technique rather than as a competitor of the Householder approach.

Successful implementations of the Lanczos iteration involve much more than a simple encoding of (9.1.3). In this section we outline some of the practical ideas that have been proposed to make Lanczos procedure viable in practice.

### 9.2.1 Exact Arithmetic Implementation

With careful overwriting in (9.1.3) and exploitation of the formula

\[
\alpha_k = q_k^T(Aq_k - \beta_{k-1}q_{k-1}),
\]

the whole Lanczos process can be implemented with just two \( n \)-vectors of storage.

**Algorithm 9.2.1. (The Lanczos Algorithm)** Given a symmetric \( A \in \mathbb{R}^{n \times n} \) and \( w \in \mathbb{R}^n \) having unit 2-norm, the following algorithm computes a \( k \)-by-\( k \) symmetric tridiagonal matrix \( T_k \) with the property that \( \lambda(T_k) \subset \lambda(A) \). It assumes the existence of a function \( A.\text{mult}(w) \) that returns the matrix-vector product \( Aw \). The diagonal and subdiagonal elements of \( T_k \) are stored in \( \alpha(1:k) \) and \( \beta(1:k-1) \) respectively.

\[
\begin{align*}
 v(1:n) &= 0; \ \beta_0 = 1; \ k = 0 \\
 \text{while } &\beta_k \neq 0 \\
 &\quad \text{if } k \neq 0 \\
 &\quad \quad \text{for } i = 1:n \\
 &\quad \quad \quad t = w_i; \ w_i = v_i/\beta_k; \ v_i = -\beta_k t \\
 &\quad \quad \text{end} \\
 &\quad \text{end} \\
 &\quad v = v + A.\text{mult}(w) \\
 &\quad k = k + 1; \ \alpha_k = w^T v; \ v = v - \alpha_k w; \ \beta_k = \|v\|_2 \\
 \end{align*}
\]

Note that \( A \) is not altered during the entire process. Only a procedure \( A.\text{mult}(\cdot) \) for computing matrix-vector products involving \( A \) need be supplied. If \( A \) has an average of about \( i \) nonzeros per row, then approximately \( (2i + 8)n \) flops are involved in a single Lanczos step.

Upon termination the eigenvalues of \( T_k \) can be found using the symmetric tridiagonal QR algorithm or any of the special methods of §8.5, such as bisection.
The Lanczos vectors are generated in the \( n \)-vector \( w \). If they are desired for later use, then special arrangements must be made for their storage. In the typical sparse matrix setting they could be stored on a disk or some other secondary storage device until required.

### 9.2.2 Roundoff Properties

The development of a practical, easy-to-use Lanczos procedure requires an appreciation of the fundamental error analyses of Paige (1971, 1976, 1980). An examination of his results is the best way to motivate the several modified Lanczos procedures of this section.

After \( j \) steps of the algorithm we obtain the matrix of computed Lanczos vectors \( \hat{Q}_k = [\hat{q}_1, \ldots, \hat{q}_k] \) and the associated tridiagonal matrix

\[
\hat{T}_k = \begin{bmatrix}
\hat{\alpha}_1 & \hat{\beta}_1 & \cdots & 0 \\
\hat{\beta}_1 & \hat{\alpha}_2 & \cdots & \vdots \\
\vdots & \ddots & \ddots & \hat{\beta}_{k-1} \\
0 & \cdots & \hat{\beta}_{k-1} & \hat{\alpha}_k
\end{bmatrix}
\]

Paige (1971, 1976) shows that if \( \hat{r}_k \) is the computed analog of \( r_k \), then

\[
A\hat{Q}_k = \hat{Q}_k\hat{T}_k + \hat{r}_k e_k^T + E_k
\]

where

\[
\| E_k \|_2 \approx u\| A \|_2 .
\]

(9.2.1)

This indicates that the important equation \( A\hat{Q}_k = \hat{Q}_k\hat{T}_k + r_k e_k^T \) is satisfied to working precision.

Unfortunately, the picture is much less rosy with respect to the orthogonality among the \( \hat{q}_i \). (Normality is not an issue. The computed Lanczos vectors essentially have unit length.) If \( \hat{\beta}_k = f_1(\| \hat{r}_k \|_2) \) and we compute \( \hat{q}_{k+1} = f_1(\hat{r}_k/\hat{\beta}_k) \), then a simple analysis shows that \( \hat{\beta}_k \hat{q}_{k+1} \approx \hat{r}_k + w_k \) where \( \| w_k \|_2 \approx u\| \hat{r}_k \|_2 \approx u\| A \|_2 \). Thus, we may conclude that

\[
|\hat{q}_{k+1}^T \hat{q}_i| \approx \frac{|\hat{r}_k^T \hat{q}_i| + u\| A \|_2}{|\hat{\beta}_k|}
\]

(9.2.2)

for \( i = 1:k \). In other words, significant departures from orthogonality can be expected when \( \hat{\beta}_k \) is small, even in the ideal situation where \( \hat{r}_k^T \hat{Q}_k \) is zero. A small \( \hat{\beta}_k \) implies cancellation in the computation of \( \hat{r}_k \). We stress that loss of orthogonality is due to this cancellation and is not the result of
the gradual accumulation of roundoff error.

**Example 9.2.1** The matrix

\[
A = \begin{bmatrix} 2.64 & -.48 \\ -.48 & 2.36 \end{bmatrix}
\]

has eigenvalues \( \lambda_1 = 3 \) and \( \lambda_2 = 2 \). If the Lanczos algorithm is applied to this matrix with \( q_1 = [.810, -.586]^T \) and three-digit floating point arithmetic is performed, then \( q_2 = [.707, .707]^T \). Loss of orthogonality occurs because \( \text{span}\{q_1\} \) is almost invariant for \( A \). (The vector \( x = [.8, -.6]^T \) is the eigenvector affiliated with \( \lambda_1 \).)

Further details of the Paige analysis are given shortly. Suffice it to say now that loss of orthogonality always occurs in practice and with it, an apparent deterioration in the quality of \( \hat{T}_k \)'s eigenvalues. This can be quantified by combining (9.2.1) with Theorem 8.1.16. In particular, if in that theorem we set \( F_1 = \hat{\tau}_k e_k^T + E_k \), \( X_1 = \hat{Q}_k \), \( S = \hat{T}_k \), and assume that

\[
\tau = \| \hat{Q}_k^T \hat{Q}_k - I_k \|_2
\]

satisfies \( \tau < 1 \), then there exist eigenvalues \( \mu_1, \ldots, \mu_k \in \lambda(A) \) such that

\[
|\mu_i - \lambda_i(T_k)| \leq \sqrt{2} (\| \hat{\tau}_k \|_2 + \| E_k \|_2 + \tau(2 + \tau) \| A \|_2)
\]

for \( i = 1:k \). An obvious way to control the \( \tau \) factor is to orthogonalize each newly computed Lanczos vector against its predecessors. This leads directly to our first "practical" Lanczos procedure.

### 9.2.3 Lanczos with Complete Reorthogonalization

Let \( r_0, \ldots, r_{k-1} \in \mathbb{R}^n \) be given and suppose that Householder matrices \( H_0, \ldots, H_{k-1} \) have been computed such that \( (H_0 \cdots H_{k-1})^T [r_0, \ldots, r_{k-1}] \) is upper triangular. Let \( [q_1, \ldots, q_k] \) denote the first \( k \) columns of the Householder product \( (H_0 \cdots H_{k-1}) \). Now suppose that we are given a vector \( r_k \in \mathbb{R}^n \) and wish to compute a unit vector \( q_{k+1} \) in the direction of

\[
w = r_k - \sum_{i=1}^{k} (q_i^T r_k) q_i \in \text{span}\{q_1, \ldots, q_k\}^\perp.
\]

If a Householder matrix \( H_k \) is determined so \( (H_0 \cdots H_k)^T [r_0, \ldots, r_k] \) is upper triangular, then it follows that column \( (k + 1) \) of \( H_0 \cdots H_k \) is the desired unit vector.

If we incorporate these Householder computations into the Lanczos process, then we can produce Lanczos vectors that are orthogonal to machine precision:
\( r_0 = q_1 \) (given unit vector)
Determine Householder \( H_0 \) so \( H_0 r_0 = e_1 \).
\[
\alpha_1 = q_1^T A q_1
\]
for \( k = 1:n - 1 \)
\[
\begin{align*}
 r_k &= (A - \alpha_k I)q_k - \beta_{k-1} q_{k-1} \quad (\beta_0 q_0 \equiv 0) \\
 w &= (H_{k-1} \cdots H_0) r_k
\end{align*}
\]
Determine Householder \( H_k \) so \( H_k w = (w_1, \ldots, w_k, \beta_k, 0, \ldots, 0)^T \).
\[
q_{k+1} = H_0 \cdots H_k e_{k+1}; \quad \alpha_{k+1} = q_{k+1}^T A q_{k+1}
\]
end

This is an example of a complete reorthogonalization Lanczos scheme. A thorough analysis may be found in Paige (1970). The idea of using Householder matrices to enforce orthogonality appears in Golub, Underwood, and Wilkinson (1972).

That the computed \( \hat{q}_k \) in (9.2.3) are orthogonal to working precision follows from the roundoff properties of Householder matrices. Note that by virtue of the definition of \( q_{k+1} \), it makes no difference if \( \beta_k = 0 \). For this reason, the algorithm may safely run until \( k = n - 1 \). (However, in practice one would terminate for a much smaller value of \( k \).

Of course, in any implementation of (9.2.3), one stores the Householder vectors \( v_k \) and never explicitly forms the corresponding \( P_k \). Since we have \( H_k(1:k, 1:k) = I_k \) there is no need to compute the first \( k \) components of \( w = (H_{k-1} \cdots H_0)r_k \), for in exact arithmetic these components would be zero.

Unfortunately, these economies make but a small dent in the computational overhead associated with complete reorthogonalization. The Householder calculations increase the work in the \( k \)th Lanczos step by \( O(kn) \) flops. Moreover, to compute \( q_{k+1} \), the Householder vectors associated with \( H_0, \ldots, H_k \) must be accessed. For large \( n \) and \( k \), this usually implies a prohibitive amount of data transfer.

Thus, there is a high price associated with complete reorthogonalization. Fortunately, there are more effective courses of action to take, but these demand that we look more closely at how orthogonality is lost.

### 9.2.4 Selective Orthogonalization

A remarkable, ironic consequence of the Paige (1971) error analysis is that loss of orthogonality goes hand in hand with convergence of a Ritz pair. To be precise, suppose the symmetric QR algorithm is applied to \( \hat{T}_k \) and renders computed Ritz values \( \hat{\theta}_1, \ldots, \hat{\theta}_k \) and a nearly orthogonal matrix of eigenvectors \( \hat{S}_k = (\hat{s}_{pq}) \). If \( \hat{Y}_k = [\hat{y}_1, \ldots, \hat{y}_k] = f(\hat{Q}_k \hat{S}_k) \), then it can be shown that for \( i = 1:k \) we have

\[
|\hat{q}_{k+1}^T \hat{y}_i| \approx \frac{||u||}{|\hat{\beta}_k|} \left| \hat{s}_{ki} \right|\]

(9.2.4)
and
\[ \| A\hat{y}_i - \hat{\theta}_i\hat{y}_i \|_2 \approx |\hat{\beta}_k| |\hat{s}_{ki}|. \] (9.2.5)

That is, the most recently computed Lanczos vector \( \hat{q}_{k+1} \) tends to have a nontrivial and unwanted component in the direction of any converged Ritz vector. Consequently, instead of orthogonalizing \( \hat{q}_{k+1} \) against all of the previously computed Lanczos vectors, we can achieve the same effect by orthogonalizing it against the much smaller set of converged Ritz vectors.

The practical aspects of enforcing orthogonality in this way are discussed in Parlett and Scott (1979). In their scheme, known as selective orthogonalization, a computed Ritz pair \((\hat{\theta}, \hat{y})\) is called "good" if it satisfies
\[ \| A\hat{y} - \hat{\theta}\hat{y} \|_2 \approx \sqrt{\mu} \| A \|_2. \]

As soon as \( \hat{q}_{k+1} \) is computed, it is orthogonalized against each good Ritz vector. This is much less costly than complete reorthogonalization, since there are usually many fewer good Ritz vectors than Lanczos vectors.

One way to implement selective orthogonalization is to diagonalize \( \hat{T}_k \) at each step and then examine the \( \hat{s}_{ki} \) in light of (9.2.4) and (9.2.5). A much more efficient approach is to estimate the loss-of-orthogonality measure \( \| I_k - \hat{Q}_k^T \hat{Q}_k \|_2 \) using the following result:

**Lemma 9.2.1** Suppose \( S_+ = [S \ d] \) where \( S \in \mathbb{R}^{n \times k} \) and \( d \in \mathbb{R}^n \). If \( S \) satisfies \( \| I_k - S^T S \|_2 \leq \mu \) and \( |1 - d^T d| \leq \delta \) then \( \| I_{k+1} - S_+^T S_+ \|_2 \leq \mu_+ \) where
\[ \mu_+ = \frac{1}{2} \left( \mu + \delta + \sqrt{(\mu - \delta)^2 + 4 \| S^T d \|_2^2} \right) \]

**Proof.** See Kahan and Parlett (1974) or Parlett and Scott (1979). \( \square \)

Thus, if we have a bound for \( \| I_k - \hat{Q}_k^T \hat{Q}_k \|_2 \) we can generate a bound for \( \| I_{k+1} - \hat{Q}_{k+1}^T \hat{Q}_{k+1} \|_2 \) by applying the lemma with \( S = \hat{Q}_k \) and \( d = \hat{q}_{k+1} \). (In this case \( \delta \approx \mu \) and we assume that \( \hat{q}_{k+1} \) has been orthogonalized against the set of currently good Ritz vectors.) It is possible to estimate the norm of \( \hat{Q}_k^T \hat{q}_{k+1} \) from a simple recurrence that spares one the need for accessing \( \hat{q}_1, \ldots, \hat{q}_k \). See Kahan and Parlett (1974) or Parlett and Scott (1979). The overhead is minimal, and when the bounds signal loss of orthogonality, it is time to contemplate the enlargement of the set of good Ritz vectors. Then and only then is \( \hat{T}_k \) diagonalized.

### 9.2.5 The Ghost Eigenvalue Problem

Considerable effort has been spent in trying to develop a workable Lanczos procedure that does not involve any kind of orthogonality enforcement. Research in this direction focuses on the problem of "ghost” or “spurious”
eigenvalues. These are multiple eigenvalues of \( \hat{T}_k \) that correspond to simple eigenvalues of \( A \). They arise because the iteration essentially restarts itself when orthogonality to a converged Ritz vector is lost. (By way of analogy, consider what would happen during orthogonal iteration §8.2.8 if we “forgot” to orthogonalize.)

The problem of identifying ghost eigenvalues and coping with their presence is discussed in Cullum and Willoughby (1979) and Parlett and Reid (1981). It is a particularly pressing problem in those applications where all of \( A \)’s eigenvalues are desired, for then the above orthogonalization procedures are too expensive to implement.

Difficulties with the Lanczos iteration can be expected even if \( A \) has a genuinely multiple eigenvalue. This follows because the \( \hat{T}_k \) are unreduced, and unreduced tridiagonal matrices cannot have multiple eigenvalues. Our next practical Lanczos procedure attempts to circumvent this difficulty.

### 9.2.6 Block Lanczos

Just as the simple power method has a block analog in simultaneous iteration, so does the Lanczos algorithm have a block version. Suppose \( n = rp \) and consider the decomposition

\[
Q^T A Q = \hat{T} = \begin{bmatrix}
M_1 & B_1^T & \cdots & 0 \\
B_1 & M_2 & \ddots & \vdots \\
& \ddots & \ddots & \vdots \\
& & \ddots & B_{r-1}^T \\
0 & \cdots & B_{r-1} & M_r
\end{bmatrix}
\]  

(9.2.6)

where

\[
Q = [ X_1, \ldots, X_r ] \quad X_i \in \mathbb{R}^{n \times p}
\]

is orthogonal, each \( M_i \in \mathbb{R}^{p \times p} \), and each \( B_i \in \mathbb{R}^{p \times p} \) is upper triangular.

Comparing blocks in \( A Q = Q \hat{T} \) shows that

\[
AX_k = X_{k-1}B_{k-1}^T + X_kM_k + X_{k+1}B_k \quad X_0B_0 = 0
\]

for \( k = 1:r - 1 \). From the orthogonality of \( Q \) we have

\[
M_k = X_k^T AX_k
\]

for \( k = 1:r \). Moreover, if we define

\[
R_k = AX_k - X_kM_k - X_{k-1}B_{k-1}^T \in \mathbb{R}^{n \times p}
\]

then \( X_{k+1}B_k = R_k \) is a QR factorization of \( R_k \). These observations suggest that the block tridiagonal matrix \( \hat{T} \) in (9.2.6) can be generated as follows:
\(X_1 \in \mathbb{R}^{p \times p}\) given with \(X_1^T X_1 = I_p\).

\[ M_1 = X_1^T A X_1 \]

for \(k = 1:r - 1\)

\[ R_k = A X_k - X_k M_k - X_{k-1} B_{k-1}^T \quad (X_0 B_0^T \equiv 0) \]

\[ X_{k+1} B_k = R_k \quad \text{(QR factorization of } R_k) \]

\[ M_{k+1} = X_{k+1}^T A X_{k+1} \]

end

At the beginning of the \(k\)th pass through the loop we have

\[ A [ X_1, \ldots, X_k ] = [ X_1, \ldots, X_k ] \tilde{T}_k + R_k[0, \ldots, 0, I_p] \quad (9.2.8) \]

where

\[
\tilde{T}_k = \begin{bmatrix}
M_1 & B_1^T & \cdots & 0 \\
B_1 & M_2 & \cdots & \vdots \\
& \ddots & \ddots & \vdots \\
& & B_{k-1}^T & B_{k-1}
\end{bmatrix}.
\]

Using an argument similar to the one used in the proof of Theorem 9.1.1, we can show that the \(X_k\) are mutually orthogonal provided none of the \(R_k\) are rank-deficient. However, if \(\text{rank}(R_k) < p\) for some \(k\), then it is possible to choose the columns of \(X_{k+1}\) such that \(X_{k+1}^T X_i = 0\), for \(i = 1:k\). See Golub and Underwood (1977).

Because \(\tilde{T}_k\) has bandwidth \(p\), it can be efficiently reduced to tridiagonal form using an algorithm of Schwartz (1968). Once tridiagonal form is achieved, the Ritz values can be obtained via the symmetric QR algorithm.

In order to intelligently decide when to use block Lanczos, it is necessary to understand how the block dimension affects convergence of the Ritz values. The following generalization of Theorem 9.1.3 sheds light on this issue.

**Theorem 9.2.2** Let \(A\) be an \(n\)-by-\(n\) symmetric matrix with eigenvalues \(\lambda_1 \geq \cdots \geq \lambda_n\) and corresponding orthonormal eigenvectors \(z_1, \ldots, z_n\). Let \(\mu_1 \geq \cdots \geq \mu_p\) be the \(p\) largest eigenvalues of the matrix \(\tilde{T}_k\) obtained after \(k\) steps of the block Lanczos iteration (9.2.7). If \(Z_1 = [z_1, \ldots, z_p]\) and \(\cos(\theta_p) = \sigma_p(Z_1^T X_1) > 0\), then for \(i = 1:p\), \(\lambda_i \geq \mu_i \geq \lambda_i - \epsilon_i^2\) where

\[
\epsilon_i^2 = \frac{(\lambda_i - \lambda_i) \tan^2(\theta_p)}{\left[ c_{k-1} \left( \frac{1 + \gamma_i}{1 - \gamma_i} \right) \right]^2}, \quad \gamma_i = \frac{\lambda_i - \lambda_{p+1}}{\lambda_i - \lambda_n}.
\]
and $c_{k-1}(z)$ is the Chebyshev polynomial of degree $k - 1$.

Analogous inequalities can be obtained for $\bar{T}_k$'s smallest eigenvalues by applying the theorem with $A$ replaced by $-A$.

Based on Theorem 9.2.2 and scrutiny of the block Lanczos iteration (9.2.7) we may conclude that:

- the error bound for the Ritz values improve with increased $p$.
- the amount of work required to compute $\bar{T}_k$'s eigenvalues is proportional to $p^2$.
- the block dimension should be at least as large as the largest multiplicity of any sought-after eigenvalue.

How to determine block dimension in the face of these tradeoffs is discussed in detail by Scott (1979).

Loss of orthogonality also plagues the block Lanczos algorithm. However, all of the orthogonality enforcement schemes described above can be extended to the block setting.

### 9.2.7 s-Step Lanczos

The block Lanczos algorithm (9.2.7) can be used in an iterative fashion to calculate selected eigenvalues of $A$. To fix ideas, suppose we wish to calculate the $p$ largest eigenvalues. If $X_1 \in \mathbb{R}^{n \times p}$ is a given matrix having orthonormal columns, we may proceed as follows:

```
until $\| A X_1 - X_1 \bar{T}_s \|_F$ is small enough
Generate $X_2, \ldots, X_s \in \mathbb{R}^{n \times p}$ via the block Lanczos algorithm.
Form $\bar{T}_s = [X_1, \ldots, X_s]^T A [X_1, \ldots, X_s]$, an $sp$-by-$sp$,
p-diagonal matrix.
Compute an orthogonal matrix $U = [u_1, \ldots, u_{sp}]$ such that
$U^T \bar{T}_s U = \text{diag}(\theta_1, \ldots, \theta_{sp})$ with $\theta_1 \geq \cdots \geq \theta_{sp}$.
Set $X_1 = [X_1, \ldots, X_s][u_1, \ldots, u_p]$.
end
```

This is the block analog of the *s-step Lanczos algorithm*, which has been extensively analyzed by Cullum and Donath (1974) and Underwood (1975).

The same idea can also be used to compute several of $A$'s smallest eigenvalues or a mixture of both large and small eigenvalues. See Cullum (1978). The choice of the parameters $s$ and $p$ depends upon storage constraints as well as upon the factors we mentioned above in our discussion of block dimension. The block dimension $p$ may be diminished as the good Ritz
vectors emerge. However this demands that orthogonality to the converged vectors be enforced. See Cullum and Donath (1974).

Problems

P9.2.1 Prove Lemma 9.2.1.

P9.2.2 If \( \text{rank}(R_k) < p \) in (9.2.7), does it follow that range([\( X_1, \ldots, X_k \)]) contains an eigenvector of \( A \)?

Notes and References for Sec. 9.2

Of the several computational variants of the Lanczos Method, Algorithm 9.2.1 is the most stable. For details, see

Other practical details associated with the implementation of the Lanczos procedure are discussed in

The behavior of the Lanczos method in the presence of roundoff error was originally reported in

Important follow-up papers include

For a discussion about various reorthogonalization schemes, see

Without any reorthogonalization it is necessary either to monitor the loss of orthogonality and quit at the appropriate instant or else to devise some scheme that will aid in the
distinction between the ghost eigenvalues and the actual eigenvalues. See

The block Lanczos algorithm is discussed in

The block Lanczos algorithm generates a symmetric band matrix whose eigenvalues can be computed in any of several ways. One approach is described in

In some applications it is necessary to obtain estimates of interior eigenvalues. The Lanczos algorithm, however, tends to find the extreme eigenvalues first. The following papers deal with this issue:

9.3 Applications to $Ax = b$ and Least Squares

In this section we briefly show how the Lanczos iteration can be embellished to solve large sparse linear equation and least squares problems. For further details, we recommend Saunders (1995).

9.3.1 Symmetric Positive Definite Systems

Suppose $A \in \mathbb{R}^{n \times n}$ is symmetric and positive definite and consider the functional $\phi(x)$ defined by

$$\phi(x) = \frac{1}{2} x^T A x - x^T b$$

where $b \in \mathbb{R}^n$. Since $\nabla \phi(x) = A x - b$, it follows that $x = A^{-1} b$ is the unique minimizer of $\phi$. Hence, an approximate minimizer of $\phi$ can be regarded as an approximate solution to $Ax = b$.

Suppose $x_0 \in \mathbb{R}^n$ is an initial guess. One way to produce a vector sequence $\{x_k\}$ that converges to $x$ is to generate a sequence of orthonormal vectors $\{q_k\}$ and to let $x_k$ minimize $\phi$ over the set

$$x_0 + \text{span}\{q_1, \ldots, q_k\} = \{x_0 + a_1 q_1 + \cdots + a_k q_k : a_k \in \mathbb{R}\}$$

for $k = 1:n$. If $Q_k = [q_1, \ldots, q_k]$, then this just means choosing $y \in \mathbb{R}^k$ such that

$$\phi(x_0 + Q_k y) = \frac{1}{2} (x_0 + Q_k y)^T A (x_0 + Q_k y) - (x_0 + Q_k y)^T b$$

$$= \frac{1}{2} y^T (Q_k^T A Q_k) y - y^T Q_k^T (b - A x_0) + \phi(x_0)$$

is minimized. By looking at the gradient of this expression with respect to $y$ we see that

$$x_k = x_0 + Q_k y_k$$

(9.3.1)

where

$$(Q_k^T A Q_k) y_k = Q_k^T (b - A x_0).$$

(9.3.2)

When $k = n$ the minimization is over all of $\mathbb{R}^n$ and so $A x_n = b$.

For large sparse $A$ it is necessary to overcome two hurdles in order to make this an effective solution process:

- the linear system (9.3.2) must be "easily" solved.
- we must be able to compute $x_k$ without having to refer to $q_1, \ldots, q_k$ explicitly as (9.3.1) suggests. Otherwise there would be an excessive amount of data movement.
We show that both of these requirements are met if the $q_k$ are Lanczos vectors.

After $k$ steps of the Lanczos algorithm we obtain the factorization

$$AQ_k = Q_kT_k + r_ke_k^T$$  \hspace{1cm} (9.3.3)

where

$$T_k = Q_k^T AQ_k = \begin{bmatrix}
\alpha_1 & \beta_1 & \cdots & 0 \\
\beta_1 & \alpha_2 & \cdots & \\
& \ddots & \ddots & \vdots \\
& & \ddots & \beta_{k-1} \\
0 & \cdots & \beta_{k-1} & \alpha_k
\end{bmatrix}. \hspace{1cm} (9.3.4)$$

With this approach (9.3.2) becomes a symmetric positive definite tridiagonal system which may be solved via the $L D L^T$ factorization. (See Algorithm 4.3.6.) In particular, by setting

$$L_k = \begin{bmatrix}
1 & 0 & 0 & 0 \\
\mu_1 & 1 & 0 & 0 \\
& \ddots & \ddots & \vdots \\
0 & \cdots & \mu_{k-1} & 1
\end{bmatrix} \quad \text{and} \quad D_k = \begin{bmatrix}
d_1 & 0 & \cdots & 0 \\
0 & d_2 & \cdots & \\
& \ddots & \ddots & \vdots \\
0 & \cdots & 0 & d_k
\end{bmatrix}$$

we find by comparing entries in

$$T_k = L_k D_k L_k^T$$  \hspace{1cm} (9.3.5)

that

$$d_1 = \alpha_1$$

for $i = 2:k$

$$\mu_{i-1} = \beta_{i-1}/d_{i-1}$$

$$d_i = \alpha_i - \beta_{i-1}\mu_{i-1}$$

end

Note that we need only calculate the quantities

$$\mu_{k-1} = \beta_{k-1}/d_{k-1}$$

$$d_k = \alpha_k - \beta_{k-1}\mu_{k-1}$$  \hspace{1cm} (9.3.6)

in order to obtain $L_k$ and $D_k$ from $L_{k-1}$ and $D_{k-1}$.

As we mentioned, it is critical to be able to compute $x_k$ in (9.3.1) efficiently. To this end we define $C_k \in \mathbb{R}^{n \times k}$ and $p_k \in \mathbb{R}^k$ by the equations

$$C_k L_k^T = Q_k$$

$$L_k D_k p_k = Q_k^T (b - Ax_0)$$  \hspace{1cm} (9.3.7)
and observe that if \( r_0 = b - Ax_0 \) then

\[
x_k = x_0 + Q_k T_k^{-1} Q_k^T r_0 = x_0 + Q_k (L_k D_k L_k^T)^{-1} Q_k^T r_0 = x_0 + C_k p_k.
\]

Let \( C_k = [c_1, \ldots, c_k] \) be a column partitioning. It follows from (9.3.7) that

\[
[ c_1, \mu_1 c_1 + c_2, \ldots, \mu_{k-1} c_{k-1} + c_k ] = [q_1, \ldots, q_k]
\]

and therefore \( C_k = [C_{k-1}, c_k] \) where

\[
c_k = q_k - \mu_{k-1} c_{k-1}.
\]

Also observe that if we set \( p_k = [\rho_1, \ldots, \rho_k]^T \) in \( L_k D_k p_k = Q_k^T r_0 \), then that equation becomes

\[
\begin{bmatrix}
L_{k-1} D_{k-1} & 0 \\
0 & \vdots & \vdots \\
0 & \mu_{k-1} d_{k-1} & d_k
\end{bmatrix}
\begin{bmatrix}
\rho_1 \\
\rho_2 \\
\vdots \\
\rho_{k-1} \\
\rho_k
\end{bmatrix}
= \begin{bmatrix}
q_k^T r_0 \\
q_2^T r_0 \\
\vdots \\
q_{k-1}^T r_0 \\
q_k^T r_0
\end{bmatrix}.
\]

Since \( L_{k-1} D_{k-1} p_{k-1} = Q_{k-1}^T r_0 \), it follows that

\[
p_k = \begin{bmatrix}
p_{k-1} \\
\rho_k
\end{bmatrix}
\]

where

\[
\rho_k = (q_k^T r_0 - \mu_{k-1} d_{k-1} \rho_{k-1}) / d_k
\]

and thus,

\[
x_k = x_0 + C_k p_k = x_0 + C_{k-1} p_{k-1} + \rho_k c_k = x_{k-1} + \rho_k c_k.
\]

This is precisely the kind of recursive formula for \( x_k \) that we need. Together with (9.3.6) and (9.3.7) it enables us to make the transition from \((q_{k-1}, c_{k-1}, x_{k-1})\) to \((q_k, c_k, x_k)\) with a minimal work and storage.

A further simplification results if we set \( q_1 \) to be a unit vector in the direction of the initial residual \( r_0 = b - Ax_0 \). With this choice for a Lanczos starting vector, \( q_k^T r_0 = 0 \) for \( k \geq 2 \). It follows from (9.3.3) that

\[
b - Ax_k = b - A(x_0 + Q_k y_k) = r_0 - (Q_k T_k + r_k e_k^T) y_k
\]

\[
= r_0 - Q_k e_k^T r_0 - r_k e_k^T y = -r_k e_k^T y.
\]
Thus, if $\beta_k = \| r_k \|_2 = 0$ in the Lanczos iteration, then $Ax_k = b$. Moreover, $\| Ax_k - b \|_2 = \beta_k e_k^T y_k$ and so estimates of the current residual can be obtained as a by-product of the iteration. Overall, we have the following procedure.

Algorithm 9.3.1 If $A \in \mathbb{R}^{n \times n}$ is symmetric positive definite, $b \in \mathbb{R}^n$, and $x_0 \in \mathbb{R}^n$ is an initial guess ($Ax_0 \approx b$), then this algorithm computes the solution to $Ax = b$.

\[
\begin{align*}
  r_0 &= b - Ax_0 \\
  \beta_0 &= \| r_0 \|_2 \\
  q_0 &= 0 \\
  k &= 0 \\
  \text{while } \beta_k \neq 0 \\
  q_{k+1} &= r_k / \beta_k \\
  k &= k + 1 \\
  \alpha_k &= q_k^T A q_k \\
  r_k &= (A - \alpha_k I) q_k - \beta_{k-1} q_{k-1} \\
  \beta_k &= \| r_k \|_2 \\
  \text{if } k = 1 \\
  d_1 &= \alpha_1 \\
  c_1 &= q_1 \\
  \rho_1 &= \beta_0 / \alpha_1 \\
  x_1 &= \rho_1 q_1 \\
  \text{else} \\
  \mu_{k-1} &= \beta_{k-1} / d_{k-1} \\
  d_k &= \alpha_k - \beta_{k-1} \mu_{k-1} \\
  c_k &= q_k - \mu_{k-1} c_{k-1} \\
  \rho_k &= -\mu_{k-1} d_{k-1} \rho_{k-1} / d_k \\
  x_k &= x_{k-1} + \rho_k c_k \\
  \text{end} \\
  x &= x_k
\end{align*}
\]

This algorithm requires one matrix-vector multiplication and a couple of saxpy operations per iteration. The numerical behavior of Algorithm 9.3.1 is discussed in the next chapter, where it is rederived and identified as the widely known method of conjugate gradients.

### 9.3.2 Symmetric Indefinite Systems

A key feature in the above development is the idea of computing the $LDLT^T$ factorization of the tridiagonal matrices $T_k$. Unfortunately, this is potentially unstable if $A$, and consequently $T_k$, is not positive definite. A way around this difficulty proposed by Paige and Saunders (1975) is to develop
the recursion for \( x_k \) via an “LQ” factorization of \( T_k \). In particular, at the \( k \)th step of the iteration, we have Givens rotations \( J_1, \ldots, J_{k-1} \) such that

\[
T_k J_1 \cdots J_{k-1} = L_k = \begin{bmatrix}
d_1 & 0 & 0 & \cdots & \cdots & \cdots & 0 \\
c_1 & d_2 & 0 & \cdots & \cdots & \cdots & 0 \\
f_1 & e_2 & d_3 & \cdots & \cdots & \cdots & 0 \\
\vdots & \vdots & \vdots & \ddots & \ddots & \ddots & \vdots \\
0 & 0 & 0 & \cdots & f_{k-2} & e_{k-1} & \tilde{d}_k
\end{bmatrix}.
\]

Note that with this factorization \( x_k \) is given by

\[
x_k = x_0 + Q_k y_k = Q_k T_k^{-1} Q_k^T b = W_k s_k
\]

where

\[
W_k = Q_k J_1 \cdots J_{k-1} \in \mathbb{R}^{n \times k}
\]

and \( s_k \in \mathbb{R}^k \) solves

\[
L_k s_k = Q_k^T b.
\]

Scrutiny of these equations enables one to develop a formula for computing \( x_k \) from \( x_{k-1} \) and an easily computed multiple of \( w_k \), the last column of \( W_k \). This defines the SYMMLQ method set forth in Paige and Saunders (1975).

A different idea is to notice from (9.3.3) and the definition \( \beta_k q_{k+1} = r_k \) that

\[
AQ_k = Q_k T_k + \beta_k q_{k+1} e_k^T = Q_{k+1} H_k
\]

where

\[
H_k = \begin{bmatrix}
T_k \\
\beta_k e_k^T
\end{bmatrix}.
\]

This \((k + 1)\)-by-\( k \) matrix is upper Hessenberg and figures in the MINRES method of Paige and Saunders (1975). In this technique \( x_k \) minimizes \( \| Ax - b \|_2 \) over the set \( x_0 + \text{span}\{q_1, \ldots, q_k\} \). Note that

\[
\| A(x_0 + Q_k y) - b \|_2 = \| AQ_k y - (b - A x_0) \|_2 \\
= \| Q_{k+1} H_k y - (b - A x_0) \|_2 = \| H_k y - \beta_0 e_1 \|_2
\]

where it is assumed that \( q_1 = (b - A x_0) / \beta_0 \) is a unit vector. As in SYMMLQ, it is possible to develop recursions that permit the efficient computation of \( x_k \) from its predecessor \( x_{k-1} \). The QR factorization of \( H_k \) is involved.

The behavior of the conjugate gradient method is detailed in the next chapter. The convergence of SYMMLQ and MINRES is more complicated and is discussed in Paige, Parlett, and Van Der Vorst (1995).
9.3.3 Bidiagonalization and the SVD

Suppose $U^T A V = B$ represents the bidiagonalization of $A \in \mathbb{R}^{m \times n}$ with

$$
U = \begin{bmatrix} u_1, \ldots, u_m \end{bmatrix} \quad U^T U = I_m
$$

$$
V = \begin{bmatrix} v_1, \ldots, v_n \end{bmatrix} \quad V^T V = I_n
$$

and

$$
B = \begin{bmatrix}
\alpha_1 & \beta_1 & \cdots & 0 \\
0 & \alpha_2 & \cdots & \vdots \\
& \ddots & \ddots & \ddots \\
& & \ddots & \beta_{n-1} \\
0 & \cdots & 0 & \alpha_n
\end{bmatrix} \quad (9.3.8)
$$

Recall from §5.4.3 that this factorization may be computed using Householder transformations and that it serves as a front end for the SVD algorithm.

Unfortunately, if $A$ is large and sparse, then we can expect large, dense submatrices to arise during the Householder bidiagonalization. Consequently, it would be nice to develop a means for computing $B$ directly without any orthogonal updates of the matrix $A$.

Proceeding just as we did in §9.1.2 we compare columns in the equations $AV = UB$ and $A^T U = V B^T$ for $k = 1:n$ and obtain

$$
A v_k = \alpha_k u_k + \beta_{k-1} u_{k-1}, \quad \beta_0 u_0 \equiv 0
$$

$$
A^T u_k = \alpha_k v_k + \beta_k v_{k+1}, \quad \beta_n v_{n+1} \equiv 0 \quad (9.3.9)
$$

Defining

$$
r_k = A v_k - \beta_{k-1} u_{k-1}
$$

$$
p_k = A^T u_k - \alpha_k v_k
$$

we may conclude from orthonormality that $\alpha_k = \pm \| r_k \|_2$, $u_k = r_k / \alpha_k$, $\beta_k = \pm \| p_k \|_2$, and $v_{k+1} = p_k / \beta_k$. Properly sequenced, these equations define the Lanczos method for bidiagonalizing a rectangular matrix:

$v_1$ = given unit 2-norm $n$-vector

$p_0 = v_1$; $\beta_0 = 1$; $k = 0$; $u_0 = 0$

while $\beta_k \neq 0$

$$
v_{k+1} = p_k / \beta_k
$$

$$
k = k + 1
$$

$$
r_k = A v_k - \beta_{k-1} u_{k-1} \quad (9.3.10)
$$

$$
\alpha_k = \| r_k \|_2
$$

$$
\beta_k = \| p_k \|_2
$$

end
If \( \text{rank}(A) = n \), then we can guarantee that no zero \( \alpha_k \) arise. Indeed, if \( \alpha_k = 0 \) then \( \text{span}\{Av_1, \ldots, Av_k\} \subset \text{span}\{u_1, \ldots, u_{k-1}\} \) which implies rank deficiency.

If \( \beta_k = 0 \), then it is not hard to verify that

\[
A[v_1, \ldots, v_k] = [u_1, \ldots, u_k]B_k
\]

\[
A^T[u_1, \ldots, u_k] = [v_1, \ldots, v_k]B_k^T
\]

where \( B_k = B(1:k, 1:k) \) and \( B \) is prescribed by (9.3.8). Thus, the \( v \) vectors and the \( u \) vectors are singular vectors and \( \sigma(B_k) \subset \sigma(A) \). Lanczos bidiagonalization is discussed in Paige (1974). See also Cullum and Willoughby (1985a, 1985b). It is essentially equivalent to applying the Lanczos tridiagonalization scheme to the symmetric matrix

\[
C = \begin{bmatrix}
0 & A \\
A^T & 0
\end{bmatrix}.
\]

We showed that \( \lambda_i(C) = \sigma_i(A) = -\lambda_{n+m-i+1}(C) \) for \( i = 1:n \) at the beginning of §8.6. Because of this, it is not surprising that the large singular values of the bidiagonal matrix tend to be very good approximations to the large singular values of \( A \). The small singular values of \( A \) correspond to the interior eigenvalues of \( C \) and are not so well approximated. The equivalent of the Kaniel-Paige theory for the Lanczos bidiagonalization may be found in Luk (1978) as well as in Golub, Luk, and Overton (1981). The analytic, algorithmic, and numerical developments of the previous two sections all carry over naturally to the bidiagonalization.

### 9.3.4 Least Squares

The full-rank LS problem \( \min \|Ax - b\|_2 \) can be solved via the bidiagonalization. In particular,

\[
x_{LS} = V y_{LS} = \sum_{i=1}^{n} y_i v_i
\]

where \( y = [y_1, \ldots, y_n]^T \) solves the system \( By = [u_1^Tb, \ldots, u_n^Tb]^T \). Note that because \( B \) is upper bidiagonal, we cannot solve for \( y \) until the bidiagonalization is complete. Moreover, we are required to save the vectors \( v_1, \ldots, v_n \), an unhappy circumstance if \( n \) is large.

The development of a sparse least squares algorithm based on the bidiagonalization can be accomplished more favorably if \( A \) is reduced to lower
bidiagonal form

\[ U^T A V = B = \begin{bmatrix}
\alpha_1 & 0 & \cdots & \cdots & 0 \\
\beta_1 & \alpha_2 & \cdots & \cdots & \vdots \\
\vdots & \ddots & \ddots & \ddots & \vdots \\
\vdots & \ddots & \ddots & \ddots & 0 \\
0 & \cdots & \cdots & \alpha_n & \beta_n \\
0 & \cdots & \cdots & 0 & \beta_n \\
0 & 0 & \cdots & \cdots & 0 \\
0 & 0 & \cdots & \cdots & 0 \\
\end{bmatrix} \]

where \( V = [v_1, \ldots, v_n] \) and \( U = [u_1, \ldots, u_m] \) are orthogonal. Comparing columns in the equations \( A^T U = V B^T \) and \( A V = U B \) we obtain

\[
A^T u_k = \beta_{k-1} v_{k-1} + \alpha_k v_k \quad \beta_0 v_0 \equiv 0 \\
A v_k = \alpha_1 u_k + \beta_k u_{k+1}
\]

It is straightforward to develop a Lanczos procedure from these equations and the resulting algorithm is very similar to (9.3.10), only \( u_1 \) is the starting vector.

Define the matrices \( V_k = [v_1, \ldots, v_k] \), \( U_k = [u_1, \ldots, u_k] \), and \( B_k = B(1:k+1, 1:k) \) and observe that \( A V_k = U_{k+1} B_k \). Our goal is to compute \( x_k \), the minimizer of \( \| A x - b \|_2 \) over all vectors of the form \( x = x_0 + V_k y \), where \( y \in \mathbb{R}^k \) and \( x_0 \in \mathbb{R}^n \) is an initial guess. If \( u_1 = (b - Ax_0) / \| b - Ax_0 \|_2 \), then

\[
A(x_0 + V_k y) - b = U_{k+1} B_k y - \beta_1 U_{k+1} e_1 = U_{k+1} (B_k y - \beta_1 e_1)
\]

where \( e_1 = I_n(:, 1) \). It follows that if \( y_k \) solves the \((k+1)\)-by-\( k \) lower bidiagonal LS problem

\[
\min \| B_{k+1} y - \beta_1 e_1 \|_2
\]

then \( x_k = x_0 + V_k y_k \). Since \( B_k \) is lower bidiagonal, it is easy to compute Givens rotations \( J_1, \ldots, J_k \) such that

\[
J_k \cdots J_1 B_k = \begin{bmatrix}
R_k \\
0 \\
k
1
\end{bmatrix}
\]

is upper bidiagonal. If

\[
J_k \cdots J_1 U_{k+1}^T b = \begin{bmatrix}
d_k \\
u \\
k
1
\end{bmatrix}
\]

then it follows that \( x_k = x_0 + V_k y_k = W_k d_k \) where \( W_k = V_k R_k^{-1} \). Paige and Saunders (1982a) show how \( x_k \) can be obtained from \( x_{k-1} \) via a simple
recursion that involves the last column of \( W_k \). The net result is a sparse LS algorithm referred to as LSQR that requires only a few \( n \)-vectors of storage to implement.

Problems

P9.3.1 Modify Algorithm 9.3.1 so that it implements the indefinite symmetric solver outlined in §9.3.2.

P9.3.2 How many vector workspaces are required to implement efficiently (9.3.10)?

P9.3.3 Suppose \( A \) is rank deficient and \( \alpha_k = 0 \) in (9.3.10). How could \( u_k \) be obtained so that the iteration could continue?

P9.3.4 Work out the lower bidiagonal version of (9.3.10) and detail the least square solver sketched in §9.3.4.

Notes and References for Sec. 9.3

Much of the material in this section has been distilled from the following papers:

See also Cullum and Willoughby (1985a, 1985b) and

9.4 Arnoldi and Unsymmetric Lanczos

If $A$ is not symmetric, then the orthogonal tridiagonalization $Q^T AQ = T$
does not exist in general. There are two ways to proceed. The Arnoldi
approach involves the column-by-column generation of an orthogonal $Q$
such that $Q^T AQ = H$ is the Hessenberg reduction of §7.4. The unsymmetric
Lanczos approach computes the columns of $Q = [q_1, \ldots, q_n]$ and
$P = [p_1, \ldots, p_n]$ so that $P^T AQ = T$ is tridiagonal and $P^T Q = I_n$. Both
methods are interesting as large sparse unsymmetric eigenvalue solvers and
both can be adapted for sparse unsymmetric $Ax = b$ solving. (See §10.4.)

9.4.1 The Basic Arnoldi Iteration

One way to extend the Lanczos process to unsymmetric matrices is due to
Arnoldi (1951) and revolves around the Hessenberg reduction $Q^T AQ = H$.
In particular, if $Q = [q_1, \ldots, q_n]$ and we compare columns in $AQ = QH$,
then

$$ AQ_k = \sum_{i=1}^{k+1} h_{ik} q_i \quad 1 \leq k \leq n - 1. $$

Isolating the last term in the summation gives

$$ h_{k+1,k} q_{k+1} = Aq_k - \sum_{i=1}^{k} h_{ik} q_i = r_k $$

where $h_{ik} = q_i^T A q_k$ for $i = 1:k$. It follows that if $r_k \neq 0$, then $q_{k+1}$ is
specified by

$$ q_{k+1} = r_k / h_{k+1,k} $$

where $h_{k+1,k} = \| r_k \|_2$. These equations define the Arnoldi process and in
strict analogy to the symmetric Lanczos process (9.1.3) we obtain:

\begin{align*}
  r_0 &= q_1 \\
  h_{10} &= 1 \\
  k &= 0 \\
  \text{while } (h_{k+1,k} \neq 0) & \quad q_{k+1} = r_k / h_{k+1,k} \\
  & \quad k = k + 1 \\
  & \quad r_k = Aq_k \\
  \text{for } i = 1:k & \quad h_{ik} = q_i^T w \\
  & \quad r_k = r_k - h_{ik} q_i \\
  \text{end} & \quad h_{k+1,k} = \| r_k \|_2 \\
\end{align*}

end
We assume that \( q_1 \) is a given unit 2-norm starting vector. The \( q_k \) are called the Arnoldi vectors and they define an orthonormal basis for the Krylov subspace \( \mathcal{K}(A, q_1, k) \):

\[
\text{span}\{q_1, \ldots, q_k\} = \text{span}\{q_1, Aq_1, \ldots, A^{k-1}q_1\}. \tag{9.4.2}
\]

The situation after \( k \) steps is summarized by the \( k \)-step Arnoldi factorization

\[
AQ_k = Q_kH_k + r_k e_k^T \tag{9.4.3}
\]

where \( Q_k = [q_1, \ldots, q_k] \), \( e_k = I_k(:, k) \), and

\[
H_k = \begin{bmatrix}
    h_{11} & h_{12} & \cdots & \cdots & h_{1k} \\
    h_{21} & h_{22} & \cdots & \cdots & h_{2k} \\
    0 & h_{32} & \ddots & \cdots & \vdots \\
    \vdots & \ddots & \ddots & \ddots & \vdots \\
    0 & \cdots & \cdots & h_{k,k-1} & h_{kk}
\end{bmatrix}.
\]

If \( r_k = 0 \), then the columns of \( Q_k \) define an invariant subspace and \( \lambda(H_k) \subseteq \lambda(A) \). Otherwise, the focus is on how to extract information about \( A \)'s eigensystem from the Hessenberg matrix \( H_k \) and the matrix \( Q_k \) of Arnoldi vectors.

If \( y \in \mathbb{R}^k \) is a unit 2-norm eigenvector for \( H_k \) and \( H_k y = \lambda y \), then from (9.4.3)

\[
(A - \lambda I)x = (e_k^T y)r_k
\]

where \( x = Q_k y \). We call \( \lambda \) a Ritz value and \( x \) the corresponding Ritz vector. The size of \( |e_k^T y| \| r_k \|_2 \) can be used to obtain error bounds, although the relevant perturbation theorems are not as routine to apply as in the symmetric case.

Some numerical properties of the Arnoldi iteration are discussed in Wilkinson (1965, pp.382). As with the symmetric Lanczos iteration, loss of orthogonality among the \( q_i \) is an issue. But two other features of (9.4.1) must be addressed before a practical Arnoldi eigensolver can be obtained:

- The Arnoldi vectors \( q_1, \ldots, q_k \) are referenced in step \( k \) and the computation of \( H_k(1:k,k) \) involves \( O(kn) \) flops. Thus, there is a steep penalty associated with the generation of long Arnoldi sequences.

- The eigenvalues of \( H_k \) do not approximate the eigenvalues of \( A \) in the style of Kaniel and Paige. This is in contrast to the symmetric case where information about \( A \)'s extremal eigenvalues emerges quickly. With Arnoldi, the early extraction of eigenvalue information depends crucially on the choice of \( q_1 \).

These realities suggest a framework in which we use Arnoldi with repeated, carefully chosen restarts and a controlled iteration maximum. (Recall the s-step Lanczos process of §9.2.7.)
9.4.2 Arnoldi with Restarting

Consider running Arnoldi for \( m \) steps and then restarting the process with a vector \( q_+ \) chosen from the span of the Arnoldi vectors \( q_1, \ldots, q_m \). Because of the Krylov connection (9.4.2), \( q_+ \) has the form

\[
q_+ = p(A)q_1
\]

for some polynomial of degree \( m - 1 \). If \( Av_i = \lambda_i v_i \) for \( i = 1:n \) and \( q_1 \) has the eigenvector expansion

\[
q_1 = a_1 v_1 + \cdots + a_n v_n,
\]

then

\[
q_+ = a_1 p(\lambda_1) v_1 + \cdots + a_n p(\lambda_n) v_n.
\]

Note that \( \mathcal{K}(A, q_+, m) \) is rich in eigenvectors that are emphasized by \( p(\lambda) \). That is, if \( p(\lambda_{\text{wanted}}) \) is large compared to \( p(\lambda_{\text{unwanted}}) \), then the Krylov space \( \mathcal{K}(A, q_+, m) \) will have much better approximations to the eigenvector \( x_{\text{wanted}} \) than to the eigenvector \( x_{\text{unwanted}} \). (It is possible to couch this argument in terms of Schur vectors and invariant subspaces rather than in terms of particular eigenvectors.)

Thus the act of picking a good restart vector \( q_+ \) from \( \mathcal{K}(A, q_1, m) \) is the act of picking a polynomial "filter" that tunes out unwanted portions of the spectrum. Various heuristics for doing this have been developed based on computed Ritz vectors. See Saad (1980, 1984, 1992).

We describe a method due to Sorensen (1992) that determines the restart vector implicitly using the QR iteration with shifts. The restart occurs after every \( m \) steps and we assume that \( m > j \) where \( j \) is the number of sought-after eigenvalues. The choice of the Arnoldi length parameter \( m \) depends on the problem dimension \( n \), the effect of orthogonality loss, and system storage constraints.

After \( m \) steps we have the Arnoldi factorization

\[
AQ_c = Q_c H_c + r_c e_m^T
\]

where \( Q_c \in \mathbb{R}^{n \times m} \) has orthonormal columns, \( H_c \in \mathbb{R}^{m \times m} \) is upper Hessenberg, and \( Q_c^T r_c = 0 \). The subscript "c" stands for "current." The QR iteration with shifts is then applied to \( H_c \):

\[
H^{(1)} = H_c
\]

for \( i = 1:p \)

\[
H^{(i)} - \mu_i I = V_i R_i
\]

\[
H^{(i+1)} = R_i V_i + \mu_i I
\]

end

\[
H_+ = H^{(p+1)}
\]
Here \( p = m - j \) and it is assumed that the implicitly shifted QR process of §7.5.5 is applied. The selection of the shifts will be discussed shortly.

The orthogonal matrix \( V = V_1 \cdots V_p \) has three crucial properties:

1. \( H_+ = V^T H_c V \). This is because \( V_i^T H^{(i)} V_i = H^{(i+1)} \).

2. \( [V]_{mj} = 0 \) for \( i = 1:j-1 \). This is because each \( V_i \) is upper Hessenberg and so \( V \in \mathbb{R}^{m \times m} \) has lower bandwidth \( p = m - j \).

3. The first column of \( V \) has the form
   \[
   Ve_1 = \alpha (H_c - \mu_p I)(H_c - \mu_{p-1} I) \cdots (H_c - \mu_1 I)e_1 \tag{9.4.4}
   \]
   where \( \alpha \) is a scalar.

To be convinced of property (3), consider the \( p = 2 \) case:

\[
VR_2R_1 = V_1(V_2R_2)R_1 = V_1(H^{(2)} - \mu_2 I)R_1 = V_1(V_1^T H^{(1)} V_1 - \mu_2 I)R_1 = (H^{(1)} - \mu_2 I)V_1 R_1 = (H^{(1)} - \mu_2 I)(H^{(1)} - \mu_1 I) = (H_c - \mu_2 I)(H_c - \mu_1 I).
\]

Since \( R_2R_1 \) is upper triangular, the first column of \( V = V_1V_2 \) is a multiple of \( (H_c - \mu_2 I)(H_c - \mu_1 I) \).

We now show how to restart the Arnoldi process using the matrix \( V \) to implicitly select the new starting vector. From (1) we obtain the following transformation of (9.4.3):

\[
AQ_+ = Q_+H_+ + r_ee_m^TV
\]

where \( Q_+ = Q_cV \). This is not a new length-\( m \) Arnoldi factorization because \( e_m^TV \) is not a multiple of \( e_m^T \). However, in view of property (2),

\[
AQ_+(;1:j) = Q_+(;1:j)H_+(1:j,1:j) + v_{mj}r_j e_j^T \tag{9.4.5}
\]

is a length-\( j \) Arnoldi factorization. By “jumping into” the basic Arnoldi iteration at step \( j+1 \) and performing \( p \) steps, we can extend (9.4.5) to a new length-\( m \) Arnoldi factorization. Moreover, using property (3) the associated starting vector \( q_1^{(new)} = Q_+(;1) \) has the following characterization:

\[
Q_+(;1) = Q_cVe_1 = \alpha Q_c(H_c - \mu_p I) \cdots (H_c - \mu_1 I)e_1 = \alpha (A - \mu_p I) \cdots (A_c - \mu_1 I)Q_c e_1 \tag{9.4.6}
\]

The last equation follows from the identity

\[
(A - \mu I)Q_c = Q_c(H_c - \mu I) + re_m^T
\]

and the fact that \( e_m^T f(H_c)e_1 = 0 \) for any polynomial \( f(\cdot) \) of degree \( p - 1 \) or less.
Thus, \( q_1^{(new)} = p(A)q_1 \) where \( p(\lambda) \) is the polynomial
\[
p(\lambda) = (\lambda - \mu_1)(\lambda - \mu_2) \cdots (\lambda - \mu_p).
\]
This shows that the shifts are the zeros of the filtering polynomial. One interesting choice for the shifts is to compute \( \lambda(H_c) \) and to identify the eigenvalues of interest \( \tilde{\lambda}_1, \ldots, \tilde{\lambda}_j \):
\[
\lambda(H_c) = \{ \tilde{\lambda}_1, \ldots, \tilde{\lambda}_j \} \cup \{ \tilde{\lambda}_{j+1}, \ldots, \tilde{\lambda}_m \}.
\]
Setting \( \mu_i = \tilde{\lambda}_{i+j} \) for \( i = 1:p \) is one way of generating a filter polynomial that de-emphasizes the unwanted portion of the spectrum.

We have just presented the rudiments of the implicitly restarted Arnoldi method. It has many attractive attributes. For implementation details and further analysis, see Lehoucq and Sorensen (1996) and Morgan (1996).

### 9.4.3 Unsymmetric Lanczos Tridiagonalization

Another way to extend the symmetric Lanczos process is to reduce \( A \) to tridiagonal form using a general similarity transformation. Suppose \( A \in \mathbb{R}^{n \times n} \) and that a nonsingular matrix \( Q \) exists so
\[
Q^{-1}AQ = T = \begin{bmatrix}
\alpha_1 & \gamma_1 & \cdots & 0 \\
\beta_1 & \alpha_2 & \cdots & 0 \\
& \ddots & \ddots & \ddots \\
& & \ddots & \gamma_{n-1} \\
0 & \cdots & \cdots & \beta_{n-1} & \alpha_n \\
\end{bmatrix}.
\]

With the column partitionings
\[
Q = \begin{bmatrix} q_1, \ldots, q_n \end{bmatrix}, \quad Q^T = P = \begin{bmatrix} p_1, \ldots, p_n \end{bmatrix}
\]
we find upon comparing columns in \( AQ = QT \) and \( A^TP = PT^T \) that
\[
Aq_k = \gamma_{k-1}q_{k-1} + \alpha_kq_k + \beta_kq_{k+1}, \quad \gamma_0q_0 = 0
\]
\[
A^Tp_k = \beta_{k-1}p_{k-1} + \alpha_kp_k + \gamma_kp_{k+1}, \quad \beta_0p_0 = 0
\]
for \( k = 1:n-1 \). These equations together with the biorthogonality condition \( PTQ = I_n \) imply
\[
\alpha_k = p_k^TAq_k
\]
and
\[
\beta_kq_{k+1} = \tau_k = (A - \alpha_kI)q_k - \gamma_{k-1}q_{k-1} \quad \gamma_{k-1}q_{k-1} = \beta_{k-1}p_{k-1}
\]
\[
\beta_kp_{k+1} = s_k = (A - \alpha_kI)^Tp_k - \beta_{k-1}p_{k-1}.
\]
There is some flexibility in choosing the scale factors $\beta_k$ and $\gamma_k$. Note that

$$1 = p_{k+1}^T q_{k+1} = (s_k / \gamma_k)^T (r_k / \beta_k).$$

It follows that once $\beta_k$ is specified $\gamma_k$ is given by

$$\gamma_k = s_k^T r_k / \beta_k.$$

With the "canonical" choice $\beta_k = \| r_k \|_2$ we obtain

$q_1, p_1$ given unit 2-norm vectors with $p_1^T q_1 \neq 0$.
$k = 0$
$q_0 = 0; r_0 = q_1$
$p_0 = 0; s_0 = p_1$
while $(r_k \neq 0) \land (s_k \neq 0) \land (s_k^T r_k \neq 0)$
$$\beta_k = \| r_k \|_2$$
$$\gamma_k = s_k^T r_k / \beta_k$$
$$q_{k+1} = r_k / \beta_k$$
$$p_{k+1} = s_k / \gamma_k$$
$$k = k + 1$$
(9.4.7)
$$\alpha_k = p_k^T A q_k$$
$$r_k = (A - \alpha_k I) q_k - \gamma_{k-1} q_{k-1}$$
$$s_k = (A - \alpha_k I)^T p_k - \beta_{k-1} p_{k-1}$$
end

If

$$T_k = \begin{bmatrix}
\alpha_1 & \gamma_1 & \cdots & 0 \\
\beta_1 & \alpha_2 & \ddots & \vdots \\
& \ddots & \ddots & \ddots \\
0 & \cdots & \cdots & \gamma_{k-1} \\
& \cdots & \cdots & \cdots & \alpha_k
\end{bmatrix},$$

then the situation at the bottom of the loop is summarized by the equations

$$A \begin{bmatrix} q_1, \ldots, q_k \end{bmatrix} = \begin{bmatrix} q_1, \ldots, q_k \end{bmatrix} T_k + r_k e_k^T$$
(9.4.8)
$$A^T \begin{bmatrix} p_1, \ldots, p_k \end{bmatrix} = \begin{bmatrix} p_1, \ldots, p_k \end{bmatrix} T_k^T + s_k e_k^T.$$ (9.4.9)

If $r_k = 0$, then the iteration terminates and span$\{q_1, \ldots, q_k\}$ is an invariant subspace for $A$. If $s_k = 0$, then the iteration also terminates and span$\{p_1, \ldots, p_k\}$ is an invariant subspace for $A^T$. However, if neither of these conditions are true and $s_k^T r_k = 0$, then the tridiagonalization process ends without any invariant subspace information. This is called serious breakdown. See Wilkinson (1965, p.389) for an early discussion of the matter.
9.4.4 The Look-Ahead Idea

It is interesting to look the serious breakdown issue in the block version of (9.4.7). For clarity assume that \( A \in \mathbb{R}^{n \times n} \) with \( n = rp \). Consider the factorization

\[
P^T AQ = \begin{bmatrix}
M_1 & C_1^T & \cdots & 0 \\
B_1 & M_2 & \cdots & \vdots \\
& \ddots & \ddots & \vdots \\
& & \ddots & C_{r-1}^T \\
0 & \cdots & \cdots & B_{r-1} & M_r
\end{bmatrix}
\tag{9.4.10}
\]

where all the blocks are \( p \)-by-\( p \). Let \( Q = [Q_1, \ldots, Q_r] \) and \( P = [P_1, \ldots, P_r] \) be conformable partitionings of \( Q \) and \( P \). Comparing block columns in the equations \( AQ = QT \) and \( A^T P = PT^T \) we obtain

\[
Q_{k+1}B_k = AQ_k - Q_kM_k - Q_{k-1}C_{k-1}^T = R_k
\]

\[
P_{k+1}C_k = A^TP_k - P_kM_k^T - P_{k-1}B_{k-1}^T = S_k
\]

Note that \( M_k = P_k^TAQ_k \). If \( S_k^TR_k \in \mathbb{R}^{p \times p} \) is nonsingular and we compute \( B_k, C_k \in \mathbb{R}^{p \times p} \) so that

\[
C_k^TB_k = S_k^TR_k,
\]

then

\[
Q_{k+1} = R_kB_k^{-1}
\]

\[
P_{k+1} = S_kC_k^{-1}
\tag{9.4.12}
\]

satisfy \( P_{k+1}^TQ_{k+1} = I_p \). Serious breakdown in this setting is associated with having a singular \( S_k^TR_k \).

One way of solving the serious breakdown problem in (9.4.7) is to go after a factorization of the form (9.4.10) in which the block sizes are dynamically determined. Roughly speaking, in this approach matrices \( Q_{k+1} \) and \( P_{k+1} \) are built up column by column with special recursions that culminate in the production of a nonsingular \( P_{k+1}^TQ_{k+1} \). The computations are arranged so that the biorthogonality conditions \( P_i^TQ_{k+1} = 0 \) and \( Q_i^TP_{k+1} = 0 \) hold for \( i = 1:k \).

A method of this form belongs to the family of look-ahead Lanczos methods. The length of a look-ahead step is the width of the \( Q_{k+1} \) and \( P_{k+1} \) that it produces. If that width is one, a conventional block Lanczos step may be taken. Length-2 look-ahead steps are discussed in Parlett, Taylor and Liu (1985). The notion of incurable breakdown is also presented by these authors. Freund, Gutknecht, and Nachtigal (1993) cover the general case along with a host of implementation details. Floating point considerations
require the handling of "near" serious breakdown. In practice, each $M_k$ that is 2-by-2 or larger corresponds to an instance of near serious breakdown.

Problems

P9.4.1 Prove that the Arnoldi vectors in (9.4.1) are mutually orthogonal.

P9.4.2 Prove (9.4.4).

P9.4.3 Prove (9.4.6).

P9.4.4 Give an example of a starting vector for which the unsymmetric Lanczos iteration (9.4.7) breaks down without rendering any invariant subspace information. Use

$$A = \begin{bmatrix} 1 & 6 & 2 \\ 3 & 0 & 2 \\ 1 & 3 & 5 \end{bmatrix}.$$

P9.4.5 Suppose $H \in \mathbb{R}^{n \times n}$ is upper Hessenberg. Discuss the computation of a unit upper triangular matrix $U$ such that $HU = UT$ where $T$ is tridiagonal.

P9.4.6 Show that the QR algorithm for eigenvalues does not preserve tridiagonal structure in the unsymmetric case.

Iterative Methods for Linear Systems

§10.1 The Standard Iterations
§10.2 The Conjugate Gradient Method
§10.3 Preconditioned Conjugate Gradients
§10.4 Other Krylov Subspace Methods

We concluded the previous chapter by showing how the Lanczos iteration could be used to solve various linear equation and least squares problems. The methods developed were suitable for large sparse problems because they did not require the factorization of the underlying matrix. In this section, we continue the discussion of linear equation solvers that have this property.

The first section is a brisk review of the classical iterations: Jacobi, Gauss-Seidel, SOR, Chebyshev semi-iterative, and so on. Our treatment of these methods is brief because our principal aim in this chapter is to highlight the method of conjugate gradients. In §10.2, we carefully develop this important technique in a natural way from the method of steepest descent. Recall that the conjugate gradient method has already been introduced via the Lanczos iteration in §9.3. The reason for deriving the method again is to motivate some of its practical variants, which are the subject of §10.3. Extensions to unsymmetric problems are treated in §10.4.

We warn the reader of an inconsistency in the notation of this chapter. In §10.1, methods are developed at the "(i, j) level" necessitating the use of superscripts: $x_i^{(k)}$ denotes the i-th component of a vector $x^{(k)}$. In the other
sections, however, algorithmic developments can proceed without explicit mention of vector/matrix entries. Hence, in §10.2-§10.4 we dispense with superscripts and denote vector sequences by \( \{x_k\} \).

## 10.1 The Standard Iterations

The linear equation solvers in Chapters 3 and 4 involve the factorization of the coefficient matrix \( A \). Methods of this type are called **direct methods**. Direct methods can be impractical if \( A \) is large and sparse, because the sought-after factors can be dense. An exception to this occurs when \( A \) is banded (cf. §4.3). Yet in many band matrix problems even the band itself is sparse making algorithms such as band Cholesky difficult to implement.

One reason for the great interest in sparse linear equation solvers is the importance of being able to obtain numerical solutions to partial differential equations. Indeed, researchers in computational PDE's have been responsible for many of the sparse matrix techniques that are presently in general use.

Roughly speaking, there are two approaches to the sparse \( Ax = b \) problem. One is to pick an appropriate direct method and adapt it to exploit \( A \)'s sparsity. Typical adaptation strategies involve the intelligent use of data structures and special pivoting strategies that minimize fill-in.

In contrast to the direct methods are the **iterative methods**. These methods generate a sequence of approximate solutions \( \{x^{(k)}\} \) and essentially involve the matrix \( A \) only in the context of matrix-vector multiplication. The evaluation of an iterative method invariably focuses on how quickly the iterates \( x^{(k)} \) converge. In this section, we present some basic iterative methods, discuss their practical implementation, and prove a few representative theorems concerned with their behavior.
10.1.1 The Jacobi and Gauss-Seidel Iterations

Perhaps the simplest iterative scheme is the Jacobi iteration. It is defined for matrices that have nonzero diagonal elements. The method can be motivated by rewriting the 3-by-3 system $Ax = b$ as follows:

\[
\begin{align*}
    x_1 &= (b_1 - a_{12}x_2 - a_{13}x_3)/a_{11} \\
    x_2 &= (b_2 - a_{21}x_1 - a_{23}x_3)/a_{22} \\
    x_3 &= (b_3 - a_{31}x_1 - a_{32}x_2)/a_{33}
\end{align*}
\]

Suppose $x^{(k)}$ is an approximation to $x = A^{-1}b$. A natural way to generate a new approximation $x^{(k+1)}$ is to compute

\[
\begin{align*}
    x_1^{(k+1)} &= (b_1 - a_{12}x_2^{(k)} - a_{13}x_3^{(k)})/a_{11} \\
    x_2^{(k+1)} &= (b_2 - a_{21}x_1^{(k)} - a_{23}x_3^{(k)})/a_{22} \\
    x_3^{(k+1)} &= (b_3 - a_{31}x_1^{(k)} - a_{32}x_2^{(k)})/a_{33}
\end{align*}
\]

(10.1.1)

This defines the Jacobi iteration for the case $n = 3$. For general $n$ we have

for $i = 1:n$

\[
x_i^{(k+1)} = \left( b_i - \sum_{j=1}^{i-1} a_{ij}x_j^{(k)} - \sum_{j=i+1}^{n} a_{ij}x_j^{(k)} \right) / a_{ii} \tag{10.1.2}
\]

end

Note that in the Jacobi iteration one does not use the most recently available information when computing $x_i^{(k+1)}$. For example, $x_1^{(k)}$ is used in the calculation of $x_2^{(k+1)}$ even though component $x_1^{(k+1)}$ is known. If we revise the Jacobi iteration so that we always use the most current estimate of the exact $x_i$ then we obtain

for $i = 1:n$

\[
x_i^{(k+1)} = \left( b_i - \sum_{j=1}^{i-1} a_{ij}x_j^{(k+1)} - \sum_{j=i+1}^{n} a_{ij}x_j^{(k)} \right) / a_{ii} \tag{10.1.3}
\]

end

This defines what is called the Gauss-Seidel iteration.

For both the Jacobi and Gauss-Seidel iterations, the transition from $x^{(k)}$ to $x^{(k+1)}$ can be succinctly described in terms of the matrices $L$, $D$, and $U$ defined by:

\[
L = \begin{bmatrix}
    0 & 0 & \cdots & \cdots & 0 \\
    a_{21} & 0 & \cdots & \vdots & \\
    a_{31} & a_{32} & \ddots & 0 \\
    \vdots & \vdots & 0 & 0 & \\
    a_{n1} & a_{n2} & \cdots & a_{n,n-1} & 0
\end{bmatrix}
\]
\[ D = \text{diag}(a_{11}, \ldots, a_{nn}) \quad (10.1.4) \]

\[
U = \begin{bmatrix}
0 & a_{12} & \cdots & \cdots & a_{1n} \\
0 & 0 & \cdots & \vdots \\
0 & 0 & \cdots & a_{n-2,n} \\
\vdots & & & a_{n-1,n} \\
0 & 0 & \cdots & 0 & 0
\end{bmatrix}
\]

In particular, the Jacobi step has the form \( M_J x^{(k+1)} = N_J x^{(k)} + b \) where \( M_J = D \) and \( N_J = -(L+U) \). On the other hand, Gauss-Seidel is defined by \( M_G x^{(k+1)} = N_G x^{(k)} + b \) with \( M_G = (D + L) \) and \( N_G = -U \).

### 10.1.2 Splittings and Convergence

The Jacobi and Gauss-Seidel procedures are typical members of a large family of iterations that have the form

\[ M x^{(k+1)} = N x^{(k)} + b \quad (10.1.5) \]

where \( A = M - N \) is a splitting of the matrix \( A \). For the iteration (10.1.5) to be practical, it must be "easy" to solve a linear system with \( M \) as the matrix. Note that for Jacobi and Gauss-Seidel, \( M \) is diagonal and lower triangular respectively.

Whether or not (10.1.5) converges to \( x = A^{-1}b \) depends upon the eigenvalues of \( M^{-1}N \). In particular, if the spectral radius of an \( n \times n \) matrix \( G \) is defined by

\[ \rho(G) = \max\{ |\lambda| : \lambda \in \lambda(G) \} , \]

then it is the size of \( \rho(M^{-1}N) \) is critical to the success of (10.1.5).

**Theorem 10.1.1** Suppose \( b \in \mathbb{R}^n \) and \( A = M - N \in \mathbb{R}^{n \times n} \) is nonsingular. If \( M \) is nonsingular and the spectral radius of \( M^{-1}N \) satisfies the inequality \( \rho(M^{-1}N) < 1 \), then the iterates \( x^{(k)} \) defined by \( M x^{(k+1)} = N x^{(k)} + b \) converge to \( x = A^{-1}b \) for any starting vector \( x^{(0)} \).

**Proof.** Let \( e^{(k)} = x^{(k)} - x \) denote the error in the \( k \)th iterate. Since \( M x^{(k)} = N x^{(k)} + b \) it follows that \( M(x^{(k+1)} - x) = N(x^{(k)} - x) \), and thus, the error in \( x^{(k+1)} \) is given by \( e^{(k+1)} = M^{-1}N e^{(k)} = (M^{-1}N)^{k+1} e^{(0)} \). From Lemma 7.3.2 we know that \( (M^{-1}N)^k \to 0 \) iff \( \rho(M^{-1}N) < 1 \).

This result is central to the study of iterative methods where algorithmic development typically proceeds along the following lines:

- A splitting \( A = M - N \) is proposed where linear systems of the form \( M z = b \) are "easy" to solve.
• Classes of matrices are identified for which the iteration matrix \( G = M^{-1}N \) satisfies \( \rho(G) < 1 \).

• Further results about \( \rho(G) \) are established to gain intuition about how the error \( e^{(k)} \) tends to zero.

For example, consider the Jacobi iteration, \( D x^{(k+1)} = -(L + U) x^{(k)} + b \). One condition that guarantees \( \rho(M_J^{-1}N_J) < 1 \) is strict diagonal dominance. Indeed, if \( A \) has that property (defined in §3.4.10), then

\[
\rho(M_J^{-1}N_J) \leq \| D^{-1}(L + U) \|_\infty = \max_{1 \leq i \leq n} \left| \sum_{j=1, j \neq i}^{n} \frac{a_{ij}}{a_{ii}} \right| < 1
\]

Usually, the "more dominant" the diagonal the more rapid the convergence but there are counterexamples. See P10.1.7.

A more complicated spectral radius argument is needed to show that Gauss-Seidel converges for symmetric positive definite \( A \).

**Theorem 10.1.2** If \( A \in \mathbb{R}^{n \times n} \) is symmetric and positive definite, then the Gauss-Seidel iteration (10.1.3) converges for any \( x^{(0)} \).

**Proof.** Write \( A = L + D + L^T \) where \( D = \text{diag}(a_{ii}) \) and \( L \) is strictly lower triangular. In light of Theorem 10.1.1 our task is to show that the matrix \( G = -(D + L)^{-1}L^T \) has eigenvalues that are inside the unit circle. Since \( D \) is positive definite we have \( G_1 \equiv D^{1/2}GD^{-1/2} = -(I + L_1)^{-1}L_1^T \), where \( L_1 = D^{-1/2}LD^{-1/2} \). Since \( G \) and \( G_1 \) have the same eigenvalues, we must verify that \( \rho(G_1) < 1 \). If \( G_1 x = \lambda x \) with \( x^H x = 1 \), then we have \(-L_1^T x = \lambda (I + L_1) x \) and thus, \(-x^H L_1^T x = \lambda (1 + x^H L_1 x) \). Letting \( a + bi = x^H L_1 x \) we have

\[
|\lambda|^2 = \left| \frac{-a + bi}{1 + a + bi} \right|^2 = \frac{a^2 + b^2}{1 + 2a + a^2 + b^2}.
\]

However, since \( D^{-1/2}AD^{-1/2} = I + L_1 + L_1^T \) is positive definite, it is not hard to show that \( 0 < 1 + x^H L_1 x + x^H L_1^T x = 1 + 2a \) implying \( |\lambda| < 1 \).

This result is frequently applicable because many of the matrices that arise from discretized elliptic PDE's are symmetric positive definite. Numerous other results of this flavor appear in the literature.

**10.1.3 Practical Implementation of Gauss-Seidel**

We now focus on some practical details associated with the Gauss-Seidel iteration. With overwriting the Gauss-Seidel step (10.1.3) is particularly simple to implement:
for $i = 1:n$

$$x_i = \left( b_i - \sum_{j=1}^{i-1} a_{ij}x_j - \sum_{j=i+1}^{n} a_{ij}x_j \right) / a_{ii}$$

end

This computation requires about twice as many flops as there are nonzero entries in the matrix $A$. It makes no sense to be more precise about the work involved because the actual implementation depends greatly upon the structure of the problem at hand.

In order to stress this point we consider the application of (10.1.3) to the $NM$-by-$NM$ block tridiagonal system

$$
\begin{bmatrix}
T & -I_N & \cdots & 0 \\
-I_N & T & \cdots & \vdots \\
\vdots & \ddots & \ddots & \vdots \\
0 & \cdots & -I_N & T
\end{bmatrix}
\begin{bmatrix}
g_1 \\
g_2 \\
\vdots \\
g_M
\end{bmatrix}
= 
\begin{bmatrix}
f_1 \\
f_2 \\
\vdots \\
f_M
\end{bmatrix}
$$

(10.1.6)

where

$$
T = 
\begin{bmatrix}
4 & -1 & \cdots & 0 \\
-1 & 4 & \cdots & \vdots \\
\vdots & \ddots & \ddots & \vdots \\
0 & \cdots & -1 & 4
\end{bmatrix},
\quad
g_j = 
\begin{bmatrix}
G(1,j) \\
G(2,j) \\
\vdots \\
G(N,j)
\end{bmatrix},
\quad
f_j = 
\begin{bmatrix}
F(1,j) \\
F(2,j) \\
\vdots \\
F(N,j)
\end{bmatrix}.
$$

This problem arises when the Poisson equation is discretized on a rectangle. It is easy to show that the matrix $A$ is positive definite.

With the convention that $G(i,j) = 0$ whenever $i \in \{0,N+1\}$ or $j \in \{0,M+1\}$ we see that with overwriting the Gauss-Seidel step takes on the form:

for $j = 1:M$

for $i = 1:N$

$$G(i,j) = (F(i,j) + G(i-1,j) + G(i+1,j) + G(i,j-1) + G(i,j+1))/4$$

end

end

Note that in this problem no storage is required for the matrix $A$. 
10.1.4 Successive Over-Relaxation

The Gauss-Seidel iteration is very attractive because of its simplicity. Unfortunately, if the spectral radius of $M_G^{-1}N_G$ is close to unity, then it may be prohibitively slow because the error tends to zero like $\rho(M_G^{-1}N_G)^k$. To rectify this, let $\omega \in \mathbb{R}$ and consider the following modification of the Gauss-Seidel step:

$$
\text{for } i = 1:n
\quad x_i^{(k+1)} = \omega \left( b_i - \sum_{j=1}^{i-1} a_{ij} x_j^{(k+1)} - \sum_{j=i+1}^{n} a_{ij} x_j^{(k)} \right)/a_{ii}
+ (1 - \omega) x_i^{(k)}
$$

(10.1.7)

This defines the method of successive over-relaxation (SOR). Using (10.1.4) we see that in matrix terms, the SOR step is given by

$$
M_\omega x^{(k+1)} = N_\omega x^{(k)} + \omega b
$$

(10.1.8)

where $M_\omega = D + \omega L$ and $N_\omega = (1 - \omega)D - \omega U$. For a few structured (but important) problems such as (10.1.6), the value of the relaxation parameter $\omega$ that minimizes $\rho(M_\omega^{-1}N_\omega)$ is known. Moreover, a significant reduction in $\rho(M_1^{-1}N_1) = \rho(M_G^{-1}N_G)$ can result. In more complicated problems, however, it may be necessary to perform a fairly sophisticated eigenvalue analysis in order to determine an appropriate $\omega$.

10.1.5 The Chebyshev Semi-Iterative Method

Another way to accelerate the convergence of an iterative method makes use of Chebyshev polynomials. Suppose $x^{(1)}, \ldots, x^{(k)}$ have been generated via the iteration $M x^{(j+1)} = N x^{(j)} + b$ and that we wish to determine coefficients $\nu_j(k)$, $j = 0:k$ such that

$$
y^{(k)} = \sum_{j=0}^{k} \nu_j(k) x^{(j)}
$$

(10.1.9)

represents an improvement over $x^{(k)}$. If $x^{(0)} = \cdots = x^{(k)} = x$, then it is reasonable to insist that $y^{(k)} = x$. Hence, we require

$$
\sum_{j=0}^{k} \nu_j(k) = 1.
$$

(10.1.10)

Subject to this constraint, we consider how to choose the $\nu_j(k)$ so that the error in $y^{(k)}$ is minimized.
Recalling from the proof of Theorem 10.1.1 that \( x^{(k)} - x = (M^{-1}N)^k e^{(0)} \) where \( e^{(0)} = x^{(0)} - x \), we see that

\[
y^{(k)} - x = \sum_{j=0}^{k} \nu_j(k)(x^{(j)} - x) = \sum_{j=0}^{k} \nu_j(k)(M^{-1}N)^j e^{(0)}.
\]

Working in the 2-norm we therefore obtain

\[
\| y^{(k)} - x \|_2 \leq \| p_k(G) \|_2 \| e^{(0)} \|_2 \tag{10.1.11}
\]

where \( G = M^{-1}N \) and

\[
p_k(z) = \sum_{j=0}^{k} \nu_j(k)z^j.
\]

Note that the condition (10.1.10) implies \( p_k(1) = 1 \).

At this point we assume that \( G \) is symmetric with eigenvalues \( \lambda_i \) that satisfy \(-1 < \alpha \leq \lambda_n \leq \cdots \leq \lambda_1 \leq \beta < 1\). It follows that

\[
\| p_k(G) \|_2 = \max_{\lambda_i \in \lambda(A)} |p_k(\lambda_i)| \leq \max_{\alpha \leq \lambda \leq \beta} |p_k(\lambda)|.
\]

Thus, to make the norm of \( p_k(G) \) small, we need a polynomial \( p_k(z) \) that is small on \([\alpha, \beta]\) subject to the constraint that \( p_k(1) = 1 \).

Consider the Chebyshev polynomials \( c_j(z) \) generated by the recursion \( c_j(z) = 2zc_{j-1}(z) - c_{j-2}(z) \) where \( c_0(z) = 1 \) and \( c_1(z) = z \). These polynomials satisfy \( |c_j(z)| \leq 1 \) on \([-1, 1]\) but grow rapidly off this interval. As a consequence, the polynomial

\[
p_k(z) = \frac{c_k\left(-1 + 2\frac{z-\alpha}{\beta-\alpha}\right)}{c_k(\mu)}
\]

where

\[
\mu = -1 + 2\frac{1-\alpha}{\beta-\alpha} = 1 + 2\frac{1-\beta}{\beta-\alpha}
\]

satisfies \( p_k(1) = 1 \) and tends to be small on \([\alpha, \beta]\). From the definition of \( p_k(z) \) and equation (10.1.11) we see

\[
\| y^{(k)} - x \|_2 \leq \frac{\| x - x^{(0)} \|_2}{|c_k(\mu)|}.
\]

Thus, the larger \( \mu \) is, the greater the acceleration of convergence.

In order for the above to be a practical acceleration procedure, we need a more efficient method for calculating \( y^{(k)} \) than (10.1.9). We have been
tacitly assuming that \( n \) is large and thus the retrieval of \( x^{(0)}, \ldots, x^{(k)} \) for large \( k \) would be inconvenient or even impossible.

Fortunately, it is possible to derive a three-term recurrence among the \( y^{(k)} \) by exploiting the three-term recurrence among the Chebyshev polynomials. In particular, it can be shown that

\[
\omega_{k+1} = 2 \frac{2 - \beta - \alpha}{\beta - \alpha} \frac{c_k(\mu)}{c_{k+1}(\mu)}
\]

then

\[
y^{(k+1)} = \omega_{k+1}(y^{(k)} - y^{(k-1)} + \gamma z^{(k)}) + y^{(k-1)}
\]

\[
Mz^{(k)} = b - Ay^{(k)}
\]

\[
\gamma = \frac{2}{2 - \alpha - \beta},
\]

where \( y^{(0)} = x^{(0)} \) and \( y^{(1)} = x^{(1)} \). We refer to this scheme as the Chebyshev semi-iterative method associated with \( M y^{(k+1)} = N y^{(k)} + b \). For the acceleration to be effective we need good lower and upper bounds \( \alpha \) and \( \beta \). As in SOR, these parameters may be difficult to ascertain except in a few structured problems.

Chebyshev semi-iterative methods are extensively analyzed in Varga (1962, chapter 5), as well as in Golub and Varga (1961).

### 10.1.6 Symmetric SOR

In deriving the Chebyshev acceleration we assumed that the iteration matrix \( G = M^{-1}N \) was symmetric. Thus, our simple analysis does not apply to the unsymmetric SOR iteration matrix \( M_{\omega}^{-1}N_{\omega} \). However, it is possible to symmetrize the SOR method making it amenable to Chebyshev acceleration. The idea is to couple SOR with the backward SOR scheme

for \( i = n; -1:1 \)

\[
x^{(k+1)} = \omega \left( b_i - \sum_{j=1}^{i-1} a_{ij} x^{(k+1)}_j - \sum_{j=i+1}^{n} a_{ij} x^{(k)}_j \right) / a_{ii}
\]

\[
+ (1 - \omega) x^{(k)}_i
\]

end

This iteration is obtained by updating the unknowns in reverse order in (10.1.7). Backward SOR can be described in matrix terms using (10.1.4). In particular, we have \( \tilde{M}_{\omega} x^{(k+1)} = \tilde{N}_{\omega} x^{(k)} + \omega b \) where

\[
\tilde{M}_{\omega} = D + \omega U \quad \text{and} \quad \tilde{N}_{\omega} = (1 - \omega) D - \omega L.
\]

(10.1.14)
If $A$ is symmetric ($U = L^T$), then $M_\omega = M_\omega^T$ and $N_\omega = N_\omega^T$, and we have the iteration

$$M_\omega x^{(k+1/2)} = N_\omega x^{(k)} + \omega b$$

$$M_\omega^T x^{(k+1)} = N_\omega^T x^{(k+1/2)} + \omega b.$$  \hspace{1cm} (10.1.15)

It is clear that $G = M_\omega^{-T} N_\omega^T M_\omega^{-1} N_\omega$ is the iteration matrix for this method. From the definitions of $M_\omega$ and $N_\omega$, it follows that

$$G = M^{-1} N \equiv (M_\omega D^{-1} M_\omega^T)^{-1} (N_\omega^T D^{-1} N_\omega).$$  \hspace{1cm} (10.1.16)

If $D$ has positive diagonal entries and $KK^T = (N_\omega^T D^{-1} N_\omega)$ is the Cholesky factorization, then $K^T G K^{-T} = K^T (M_\omega D^{-1} M_\omega^T)^{-1} K$. Thus, $G$ is similar to a symmetric matrix and has real eigenvalues.

The iteration (10.1.15) is called the symmetric successive over-relaxation (SSOR) method. It is frequently used in conjunction with the Chebyshev semi-iterative acceleration.

**Problems**

**P10.1.1** Show that the Jacobi iteration can be written in the form $x^{(k+1)} = x^{(k)} + H r^{(k)}$ where $r^{(k)} = b - A x^{(k)}$. Repeat for the Gauss-Seidel iteration.

**P10.1.2** Show that if $A$ is strictly diagonally dominant, then the Gauss-Seidel iteration converges.

**P10.1.3** Show that the Jacobi iteration converges for 2-by-2 symmetric positive definite systems.

**P10.1.4** Show that if $A = M - N$ is singular, then we can never have $\rho(M^{-1} N) < 1$ even if $M$ is nonsingular.

**P10.1.5** Prove (10.1.16).

**P10.1.6** Prove the converse of Theorem 10.1.1. In other words, show that if the iteration $M x^{(k+1)} = N x^{(k)} + b$ always converges, then $\rho(M^{-1} N) < 1$.

**P10.1.7** (Supplied by R.S. Varga) Suppose that

$$A_1 = \begin{bmatrix} 1 & -1/2 \\ -1/2 & 1 \end{bmatrix} \quad A_2 = \begin{bmatrix} 1 & -3/4 \\ -1/12 & 1 \end{bmatrix}.$$  

Let $J_1$ and $J_2$ be the associated Jacobi iteration matrices. Show that $\rho(J_1) > \rho(J_2)$ thereby refuting the claim that greater diagonal dominance implies more rapid Jacobi convergence.

**P10.1.8** The Chebyshev algorithm is defined in terms of parameters

$$\omega_{k+1} = \frac{2c_k(1/\rho)}{\rho c_{k+1}(1/\rho)}$$

where $c_k(\lambda) = \cosh[k \cosh^{-1}(\lambda)]$ with $\lambda > 1$. (a) Show that $1 < \omega_k < 2$ for $k > 1$ whenever $0 < \rho < 1$. (b) Verify that $\omega_{k+1} < \omega_k$. (c) Determine $\lim \omega_k$ as $k \to \infty$.

**P10.1.9** Consider the 2-by-2 matrix

$$A = \begin{bmatrix} 1 & \rho \\ -\rho & 1 \end{bmatrix}.$$
(a) Under what conditions will Gauss-Seidel converge with this matrix? (b) For what range of \( \omega \) will the SOR method converge? What is the optimal choice for this parameter? (c) Repeat (a) and (b) for the matrix

\[
A = \begin{bmatrix}
I_n & S \\
-S^T & I_n
\end{bmatrix}
\]

where \( S \in \mathbb{R}^{n \times n} \). Hint: Use the SVD of \( S \).

P10.1.10 We want to investigate the solution of \( Au = f \) where \( A \neq A^T \). For a model problem, consider the finite difference approximation to

\[-u^{''} + \sigma u' = 0 \quad 0 < x < 1\]

where \( u(0) = 10 \) and \( u(1) = 10 \exp \sigma \). This leads to the difference equation

\[-u_{i-1} + 2u_i - u_{i+1} + R(u_{i+1} - u_{i-1}) = 0 \quad i = 1:n\]

where \( R = \sigma h/2, u_0 = 10 \), and \( u_{n+1} = 10 \exp \sigma \). The number \( R \) should be less than 1. What is the convergence rate for the iteration \( M^{(k+1)}u = N^{(k)}u + f \) where \( M = \begin{pmatrix} A + A^T \end{pmatrix}/2 \) and \( N = \begin{pmatrix} A^T - A \end{pmatrix}/2 \)?

P10.1.11 Consider the iteration

\[y^{(k+1)} = \omega(By^{(k)} + d - y^{(k-1)}) + y^{(k-1)}\]

where \( B \) has Schur decomposition \( Q^T B Q = \text{diag}(\lambda_1, \ldots, \lambda_n) \) with \( \lambda_1 \geq \cdots \geq \lambda_n \). Assume that \( x = Bx + d \). (a) Derive an equation for \( e^{(k)} = y^{(k)} - x \). (b) Assume \( y^{(1)} = By^{(0)} + d \). Show that \( e^{(k)} = p_k(B)e^{(0)} \) where \( p_k \) is an even polynomial if \( k \) is even and an odd polynomial if \( k \) is odd. (c) Write \( f^{(k)} = QT e^{(k)} \). Derive a difference equation for \( f_j^{(k)} \) for \( j = 1:n \). Try to specify the exact solution for general \( f_j^{(0)} \) and \( f_j^{(1)} \). (d) Show how to determine an optimal \( \omega \).

Notes and References for Sec. 10.1

As we mentioned, Young (1971) has the most comprehensive treatment of the SOR method. The object of "SOR theory" is to guide the user in choosing the relaxation parameter \( \omega \). In this setting, the ordering of equations and unknowns is critical. See

An analysis of the Chebyshev semi-iterative method appears in

This work is premised on the assumption that the underlying iteration matrix has real eigenvalues. How to proceed when this is not the case is discussed in

Other unsymmetric methods include

Sometimes it is possible to "symmetrize" an iterative method, thereby simplifying the acceleration process, since all the relevant eigenvalues are real. This is the case for the SSOR method discussed in

The parallel implementation of the classical iterations has received some attention. See

We have seen that the condition \( \kappa(A) \) is an important issue when direct methods are applied to \( Ax = b \). However, the condition of the system also has a bearing on iterative method performance. See

Iterative methods for singular systems are discussed in
10.2 The Conjugate Gradient Method

A difficulty associated with the SOR, Chebyshev semi-iterative, and related methods is that they depend upon parameters that are sometimes hard to choose properly. For example, the Chebyshev acceleration scheme needs good estimates of the largest and smallest eigenvalue of the underlying iteration matrix $M^{-1}N$. Unless this matrix is sufficiently structured, it may be analytically impossible and/or computationally expensive to do this.

In this section, we present a method without this difficulty for the symmetric positive definite $Ax = b$ problem, the well-known Hestenes-Stiefel conjugate gradient method. We derived this method in §9.3.1 from the Lanczos algorithm. The derivation now is from a different point of view and it will set the stage for various important generalizations in §10.3 and §10.4.

10.2.1 Steepest Descent

The starting point in the derivation is to consider how we might go about minimizing the function

$$\phi(x) = \frac{1}{2} x^T A x - x^T b$$

where $b \in \mathbb{R}^n$ and $A \in \mathbb{R}^{n \times n}$ is assumed to be positive definite and symmetric. The minimum value of $\phi(x)$ is $-b^T A^{-1} b / 2$, achieved by setting $x = A^{-1} b$. Thus, minimizing $\phi$ and solving $Ax = b$ are equivalent problems if $A$ is symmetric positive definite.

One of the simplest strategies for minimizing $\phi$ is the method of steepest descent. At a current point $x_c$ the function $\phi$ decreases most rapidly in the direction of the negative gradient: $-\nabla \phi(x_c) = b - Ax_c$. We call

$$r_c = b - Ax_c$$

the residual of $x_c$. If the residual is nonzero, then there exists a positive $\alpha$ such that $\phi(x_c + \alpha r_c) < \phi(x_c)$. In the method of steepest descent (with
exact line search) we set \( \alpha = \frac{r_c^T r_c}{r_c^T A r_c} \) thereby minimizing

\[
\phi(x_c + \alpha r_c) = \phi(x_c) - \alpha r_c^T r_c + \frac{1}{2} \alpha^2 r_c^T A r_c.
\]

This gives

\[
x_0 = \text{initial guess} \\
r_0 = b - Ax_0 \\
k = 0 \\
\text{while } r_k \neq 0 \begin{align*}
\alpha_k &= \frac{r_{k-1}^T r_{k-1}}{r_{k-1}^T A r_{k-1}} \\
x_k &= x_{k-1} + \alpha_k r_{k-1} \\
r_k &= b - A x_k
\end{align*} \tag{10.2.1}
\]

end

It can be shown that

\[
\left( \phi(x_k) + \frac{1}{2} b^T A^{-1} b \right) \leq \left( 1 - \frac{1}{\kappa_2(A)} \right) \left( \phi(x_{k-1}) + \frac{1}{2} b^T A^{-1} b \right) \tag{10.2.2}
\]

which implies global convergence. Unfortunately, the rate of convergence may be prohibitively slow if the condition \( \kappa_2(A) = \lambda_1(A)/\lambda_n(A) \) is large. Geometrically this means that the level curves of \( \phi \) are very elongated hyperellipsoids and minimization corresponds to finding the lowest point in a relatively flat, steep-sided valley. In steepest descent, we are forced to traverse back and forth across the valley rather than down the valley. Stated another way, the gradient directions that arise during the iteration are not different enough.

### 10.2.2 General Search Directions

To avoid the pitfalls of steepest descent, we consider the successive minimization of \( \phi \) along a set of directions \( \{p_1, p_2, \ldots\} \) that do not necessarily correspond to the residuals \( \{r_0, r_1, \ldots\} \). It is easy to show that \( \phi(x_{k-1} + \alpha p_k) \) is minimized by setting

\[
\alpha = \alpha_k = \frac{p_k^T r_{k-1}}{p_k^T A p_k}.
\]

With this choice it can be shown that

\[
\phi(x_{k-1} + \alpha_k p_k) = \phi(x_{k-1}) - \frac{1}{2} \frac{(p_k^T r_{k-1})^2}{p_k^T A p_k}. \tag{10.2.3}
\]

To ensure a reduction in the size of \( \phi \) we insist that \( p_k \) not be orthogonal to \( r_{k-1} \). This leads to the following framework:
\[ x_0 = \text{initial guess} \]
\[ r_0 = b - Ax_0 \]
\[ k = 0 \]
while \( r_k \neq 0 \)
\[ k = k + 1 \]
Choose a direction \( p_k \) such that \( p_k^T r_{k-1} \neq 0 \).
\[ \alpha_k = p_k^T r_{k-1} / p_k^T Ap_k \]
\[ x_k = x_{k-1} + \alpha_k p_k \]
\[ r_k = b - Ax_k \]
end

Note that
\[ x_k \in x_0 + \text{span}\{p_1, \ldots, p_k\} \equiv \{x_0 + \gamma_1 p_1 + \cdots + \gamma_k p_k : \gamma_i \in \mathbb{R}\}. \]

Our goal is to choose the search directions in a way that guarantees convergence without the shortcomings of steepest descent.

### 10.2.3 A-Conjugate Search Directions

If the search directions are linearly independent and \( x_k \) solves the problem

\[ \min_{x \in x_0 + \text{span}\{p_1, \ldots, p_k\}} \phi(x) \]  

for \( k = 1, 2, \ldots \), then convergence is guaranteed in at most \( n \) steps. This is because \( x_n \) minimizes \( \phi \) over \( \mathbb{R}^n \) and therefore satisfies \( Ax_n = b \).

However, for this to be a viable approach the search directions must have the property that it is "easy" to compute \( x_k \) given \( x_{k-1} \). Let us see what this says about the determination of \( p_k \). If

\[ x_k = x_0 + P_{k-1} y + \alpha p_k \]

where \( P_{k-1} = [p_1, \ldots, p_{k-1}] \), \( y \in \mathbb{R}^{k-1} \), and \( \alpha \in \mathbb{R} \), then

\[ \phi(x_k) = \phi(x_0 + P_{k-1} y) + \alpha y^T P_{k-1}^T A p_k + \frac{\alpha^2}{2} p_k^T A p_k - \alpha p_k^T r_0. \]

If \( p_k \in \text{span}\{A p_1, \ldots, A p_{k-1}\}^\perp \), then the cross term \( \alpha y^T P_{k-1}^T A p_k \) is zero and the search for the minimizing \( x_k \) splits into a pair of uncoupled minimizations, one for \( y \) and one for \( \alpha \):

\[ \min_{x_k \in x_0 + \text{span}\{p_1, \ldots, p_k\}} \phi(x_k) = \min_{y, \alpha} \phi(x_0 + P_{k-1} y + \alpha p_k) \]

\[ = \min_{y, \alpha} \left( \phi(x_0 + P_{k-1} y) + \frac{\alpha^2}{2} p_k^T A p_k - \alpha p_k^T r_0 \right) \]
\[ = \min_y \phi(x_0 + P_{k-1}y) + \min_\alpha \left( \frac{\alpha^2}{2} p_k^T A p_k - \alpha p_k^T r_0 \right). \]

Note that if \( y_{k-1} \) solves the first min problem then \( x_{k-1} = x_0 + P_{k-1}y_{k-1} \) minimizes \( \phi \) over \( x_0 + \text{span}\{p_1, \ldots, p_{k-1}\} \). The solution to the \( \alpha \) min problem is given by \( \alpha_k = p_k^T r_0 / p_k^T A p_k \). Note that because of \( A \)-conjugacy,

\[
p_k^T r_{k-1} = p_k^T (b - Ax_{k-1}) = p_k^T (b - A(x_0 + P_{k-1}y_{k-1})) = p_k^T r_0.
\]

With these results it follows that \( x_k = x_{k-1} + \alpha_k p_k \) and we obtain the following instance of (10.2.4):

\[
x_0 = \text{initial guess} \\
k = 0 \\
r_0 = b - Ax_0 \\
\text{while } r_k \neq 0 \\
\quad k = k + 1 \\
\quad \text{Choose } p_k \in \text{span}\{A p_1, \ldots, A p_{k-1}\}^\perp \text{ so } p_k^T r_{k-1} \neq 0. \quad (10.2.6) \\
\quad \alpha_k = p_k^T r_{k-1} / p_k^T A p_k \\
\quad x_k = x_{k-1} + \alpha_k p_k \\
\quad r_k = b - Ax_k \\
\end
\]

end

The following lemma shows that it is possible to find the search directions with the required properties.

**Lemma 10.2.1** If \( r_{k-1} \neq 0 \), then there exists a \( p_k \in \text{span}\{A p_1, \ldots, A p_{k-1}\}^\perp \) such that \( p_k^T r_{k-1} \neq 0 \).

**Proof.** For the case \( k = 1 \), set \( p_1 = r_0 \). If \( k > 1 \), then since \( r_{k-1} \neq 0 \) it follows that

\[
A^{-1}b \notin x_0 + \text{span}\{p_1, \ldots, p_{k-1}\} \implies b \notin Ax_0 + \text{span}\{A p_1, \ldots, A p_{k-1}\} \\
\implies r_0 \notin \text{span}\{A p_1, \ldots, A p_{k-1}\}.
\]

Thus there exists a \( p \in \text{span}\{A p_1, \ldots, A p_{k-1}\}^\perp \) such that \( p^T r_0 \neq 0 \). But \( x_{k-1} \in x_0 + \text{span}\{p_1, \ldots, p_{k-1}\} \) and so \( r_{k-1} \in r_0 + \text{span}\{A p_1, \ldots, A p_{k-1}\} \). It follows that \( p^T r_{k-1} = p^T r_0 \neq 0 \). \( \square \)

The search directions in (10.2.6) are said to be \( A \)-conjugate because \( p_i^T A p_j = 0 \) for all \( i \neq j \). Note that if \( P_k = [p_1, \ldots, p_k] \) is the matrix of these vectors, then

\[ P_k^T A P_k = \text{diag}(p_1^T A p_1, \ldots, p_k^T A p_k) \]

is nonsingular since \( A \) is positive definite and the search directions are nonzero. It follows that \( P_k \) has full column rank. This guarantees convergence in (10.2.6) in at most \( n \) steps because \( x_n \) (if we get that far) minimizes \( \phi(x) \) over \( \text{ran}(P_n) = \mathbb{R}^n \).
10.2.4 Choosing a Best Search Direction

A way to combine the positive aspects of steepest descent and \(A\)-conjugate searching is to choose \(p_k\) in (10.2.6) to be the closest vector to \(r_{k-1}\) that is \(A\)-conjugate to \(p_1, \ldots, p_{k-1}\). This defines "version zero" of the method of conjugate gradients:

\[
x_0 = \text{initial guess} \\
k = 0 \\
r_0 = b - Ax_0 \\
\text{while } r_k \neq 0 \\
\hspace{1em} k = k + 1 \\
\hspace{2em} \text{if } k = 1 \\
\hspace{3em} p_1 = r_0 \\
\hspace{2em} \text{else} \\
\hspace{3em} \text{Let } p_k \text{ minimize } \| p - r_{k-1} \|_2 \text{ over all vectors} \\
\hspace{4em} p \in \text{span}\{Ap_1, \ldots, Ap_{k-1}\}^\perp \\
\hspace{3em} \text{end} \\
\alpha_k = p_k^T r_{k-1}/p_k^T Ap_k \\
x_k = x_{k-1} + \alpha_k p_k \\
r_k = b - Ax_k \\
\text{end} \\
x = x_k
\]

(10.2.7)

To make this an effective sparse \(Ax = b\) solver, we need an efficient method for computing \(p_k\). A considerable amount of analysis is required to develop the final recursions. The first step is to show that \(p_k\) is the minimum residual of a certain least squares problem.

**Lemma 10.2.2** For \(k \geq 2\) the vectors \(p_k\) generated by (10.2.7) satisfy

\[
\begin{align*}
p_k &= r_{k-1} - AP_{k-1} z_{k-1},
\end{align*}
\]

where \(P_{k-1} = [p_1, \ldots, p_{k-1}]\) and \(z_{k-1}\) solves

\[
\min_{z \in \mathbb{R}^{k-1}} \| r_{k-1} - AP_{k-1} z \|_2.
\]

**Proof.** Suppose \(z_{k-1}\) solves the above LS problem and let \(p\) be the associated minimum residual:

\[
p = r_{k-1} - AP_{k-1} z_{k-1}.
\]

It follows that \(p^T AP_{k-1} = 0\). Moreover, \(p = [I - (AP_{k-1})(AP_{k-1})^+] r_{k-1}\) is the orthogonal projection of \(r_{k-1}\) into \(\text{ran}(AP_{k-1})^\perp\) and so it is the closest vector in \(\text{ran}(AP_{k-1})^\perp\) to \(r_{k-1}\). Thus, \(p = p_k\). \(\Box\)
With this result we can establish a number of important relationships between the residuals \( r_k \), the search directions \( p_k \), and the Krylov subspaces

\[
K(r_0, A, k) = \text{span}\{r_0, Ar_0, \ldots, A^{k-1}r_0\}.
\]

**Theorem 10.2.3** After \( k \) iterations in (10.2.7) we have

\[
\begin{align*}
    r_k &= r_{k-1} - \alpha_k Ap_k \quad (10.2.8) \\
    P_k^T r_k &= 0 \quad (10.2.9) \\
    \text{span}\{p_1, \ldots, p_k\} &= \text{span}\{r_0, \ldots, r_{k-1}\} = K(r_0, A, k) \quad (10.2.10)
\end{align*}
\]

and the residuals \( r_0, \ldots, r_k \) are mutually orthogonal.

**Proof.** Equation (10.2.8) follows by applying \( A \) to both sides of \( x_k = x_{k-1} + \alpha_k p_k \) and using the definition of the residual.

To prove (10.2.9), we recall that \( x_k = x_0 + P_k y_k \) where \( y_k \) is the minimizer of

\[
\phi(x_0 + P_k y) = \phi(x_0) + \frac{1}{2} y^T (P_k^T Ap_k) y - y^T P_k (b - Ax_0).
\]

But this means that \( y_k \) solves the linear system \( (P_k^T Ap) y = P_k^T (b - Ax_0) \). Thus

\[
0 = P_k^T (b - Ax_0) - P_k^T Ap_k y_k = P_k^T (b - A(x_0 + P_k y_k)) = P_k^T r_k.
\]

To prove (10.2.10) we note from (10.2.8) that

\[
\{Ap_1, \ldots, Ap_{k-1}\} \subseteq \text{span}\{r_0, \ldots, r_{k-1}\}
\]

and so from Lemma 10.2.2,

\[
p_k = r_{k-1} - [Ap_1, \ldots, Ap_{k-1}] z_{k-1} \in \text{span}\{r_0, \ldots, r_{k-1}\}
\]

It follows that

\[
[p_1, \ldots, p_k] = [r_0, \ldots, r_{k-1}] T
\]

for some upper triangular \( T \). Since the search directions are independent, \( T \) is nonsingular. This shows

\[
\text{span}\{p_1, \ldots, p_k\} = \text{span}\{r_0, \ldots, r_{k-1}\}.
\]

Using (10.2.8) we see that

\[
r_k \in \text{span}\{r_{k-1}, Ap_k\} \subseteq \text{span}\{r_{k-1}, Ar_0, \ldots, Ar_{k-1}\}.
\]

The Krylov space connection in (10.2.10) follows from this by induction.

Finally, to establish the mutual orthogonality of the residuals, we note from (10.2.9) that \( r_k \) is orthogonal to any vector in the range of \( P_k \). But from (10.2.10) this subspace contains \( r_0, \ldots, r_{k-1} \). □

Using these facts we next show that \( p_k \) is a simple linear combination of its predecessor \( p_{k-1} \) and the "current" residual \( r_{k-1} \).
Corollary 10.2.4 The residuals and search directions in (10.2.7) have the property that \( p_k \in \text{span}\{p_{k-1}, r_{k-1}\} \) for \( k \geq 2 \).

Proof. If \( k = 2 \), then from (10.2.10) \( p_2 \in \text{span}\{r_0, r_1\} \). But \( p_1 = r_0 \) and so \( p_2 \) is a linear combination of \( p_1 \) and \( r_1 \).

If \( k > 2 \), then partition the vector \( z_{k-1} \) of Lemma 10.2.2 as

\[
z_{k-1} = \begin{bmatrix} w \\ \mu \end{bmatrix} \begin{bmatrix} k - 2 \\ 1 \end{bmatrix}.
\]

Using the identity \( r_{k-1} = r_{k-2} - \alpha_{k-1} A p_{k-1} \), we see that

\[
p_k = r_{k-1} - A p_{k-1} z_{k-1} = r_{k-1} - A p_{k-2} w - \mu A p_{k-1}
\]

\[
= \left(1 + \frac{\mu}{\alpha_{k-1}}\right) r_{k-1} + s_{k-1}
\]

where

\[
s_{k-1} = -\frac{\mu}{\alpha_{k-1}} r_{k-2} - A p_{k-2} w
\]

\[\in \text{span}\{r_{k-2}, A p_{k-2} w\}\]

\[\subseteq \text{span}\{r_{k-2}, A p_1, \ldots, A p_{k-2}\}\]

\[\subseteq \text{span}\{r_1, \ldots, r_{k-2}\}\]

Because the \( r_i \) are mutually orthogonal, it follows that \( s_{k-1} \) and \( r_{k-1} \) are orthogonal to each other. Thus, the least squares problem of Lemma 10.2.2 boils down to choosing \( \mu \) and \( w \) such that

\[
\| p_k \|_2^2 = \left(1 + \frac{\mu}{\alpha_{k-1}}\right) \| r_{k-1} \|_2^2 + \| s_{k-1} \|_2^2
\]

is minimum. Since the 2-norm of \( r_{k-2} - A p_{k-2} z \) is minimized by \( z_{k-2} \) giving residual \( p_{k-1} \), it follows that \( s_{k-1} \) is a multiple of \( p_{k-1} \). Consequently, \( p_k \in \text{span}\{r_{k-1}, p_{k-1}\} \). \( \square \)

We are now set to derive a very simple expression for \( p_k \). Without loss of generality we may assume from Corollary 10.2.4 that

\[
p_k = r_{k-1} + \beta_k p_{k-1}.
\]

Since \( p_{k-1}^T A p_k = 0 \) it follows that

\[
\beta_k = -\frac{p_{k-1}^T A r_{k-1}}{p_{k-1}^T A p_{k-1}}
\]

This leads us to "version 1" of the conjugate gradient method:
$x_0 =$ initial guess
$k = 0$
$r_0 = b - Ax_0$
while $r_k \neq 0$
\[ k = k + 1 \]
\[ \text{if } k = 1 \]
\[ p_1 = r_0 \]
else
\[ \beta_k = -p_{k-1}^T Ar_{k-1}/p_{k-1}^T A p_{k-1} \]
\[ p_k = r_{k-1} + \beta_k p_{k-1} \] (10.2.11)
end
\[ \alpha_k = p_k^T r_{k-1} / p_k^T A p_k \]
\[ x_k = x_{k-1} + \alpha_k p_k \]
\[ r_k = b - Ax_k \]
end
$x = x_k$

In this implementation, the method requires three separate matrix-vector multiplications per step. However, by computing residuals recursively via
\[ r_k = r_{k-1} - \alpha_k A p_k \]
and substituting
\[ r_{k-1}^T r_{k-1} = -\alpha_{k-1} r_{k-1}^T A p_{k-1} \] (10.2.12)

and
\[ r_{k-2}^T r_{k-2} = \alpha_{k-1} p_{k-1}^T A p_{k-1} \] (10.2.13)
into the formula for $\beta_k$, we obtain the following more efficient version:

Algorithm 10.2.1 [Conjugate Gradients] If $A \in \mathbb{R}^{n \times n}$ is symmetric positive definite, $b \in \mathbb{R}^n$, and $x_0 \in \mathbb{R}^n$ is an initial guess ($Ax_0 \approx b$), then the following algorithm computes $x \in \mathbb{R}^n$ so $Ax = b$.

$k = 0$
$r_0 = b - Ax_0$
while $r_k \neq 0$
\[ k = k + 1 \]
\[ \text{if } k = 1 \]
\[ p_1 = r_0 \]
else
\[ \beta_k = r_{k-1}^T r_{k-1} / r_{k-2}^T r_{k-2} \]
\[ p_k = r_{k-1} + \beta_k p_{k-1} \]
end
\[ \alpha_k = r_{k-1}^T r_{k-1} / p_k^T A p_k \]
\[ x_k = x_{k-1} + \alpha_k p_k \]
\[ r_k = r_{k-1} - \alpha_k A p_k \]
end
$x = x_k$
This procedure is essentially the form of the conjugate gradient algorithm that appears in the original paper by Hestenes and Stiefel (1952). Note that only one matrix-vector multiplication is required per iteration.

10.2.5 The Lanczos Connection

In §9.3.1 we derived the conjugate gradient method from the Lanczos algorithm. Now let us look at the connections between these two algorithms in the reverse direction by "deriving" the Lanczos process from conjugate gradients. Define the matrix of residuals \( R_k \in \mathbb{R}^{n \times k} \) by

\[
R_k = [r_0, \ldots, r_{k-1}]
\]

and the upper bidiagonal matrix \( B_k \in \mathbb{R}^{k \times k} \) by

\[
B_k = \begin{bmatrix}
1 & -\beta_2 & 0 & \cdots & 0 \\
0 & 1 & -\beta_3 & \cdots & \vdots \\
& \ddots & \ddots & \ddots & 0 \\
\vdots & & \ddots & \ddots & -\beta_k \\
0 & \cdots & 0 & 1
\end{bmatrix}
\]

From the equations \( p_i = r_{i-1} + \beta_i p_{i-1} \), \( i = 2:k \), and \( p_1 = r_0 \) it follows that \( R_k = P_k B_k \). Since the columns of \( P_k = [p_1, \ldots, p_k] \) are \( A \)-conjugate, we see that \( R_k^T A R_k = B_k^T \text{diag}(p_1^T A p_1, \ldots, p_k^T A p_k) B_k \) is tridiagonal. From (10.2.10) it follows that if

\[
\Delta = \text{diag}(\rho_0, \ldots, \rho_{k-1}) \quad \rho_i = \| r_i \|_2
\]

then the columns of \( R_k \Delta^{-1} \) form an orthonormal basis for the subspace \( \text{span}\{r_0, Ar_0, \ldots, A^{k-1} r_0\} \). Consequently, the columns of this matrix are essentially the Lanczos vectors of Algorithm 9.3.1, i.e.,

\[
q_i = \pm r_{i-1}/\rho_{i-1} \quad i = 1:k.
\]

Moreover, the tridiagonal matrix associated with these Lanczos vectors is given by

\[
T_k = \Delta^{-1} B_k^T \text{diag}(p_i^T A p_i) B_k \Delta^{-1}.
\]

The diagonal and subdiagonal of this matrix involve quantities that are readily available during the conjugate gradient iteration. Thus, we can obtain good estimates of \( A \)'s extremal eigenvalues (and condition number) as we generate the \( x_k \) in Algorithm 10.2.1.
10.2.6 Some Practical Details

The termination criteria in Algorithm 10.2.1 is unrealistic. Rounding errors lead to a loss of orthogonality among the residuals and finite termination is not mathematically guaranteed. Moreover, when the conjugate gradient method is applied, \( n \) is usually so big that \( O(n) \) iterations represents an unacceptable amount of work. As a consequence of these observations, it is customary to regard the method as a genuinely iterative technique with termination based upon an iteration maximum \( k_{\text{max}} \) and the residual norm. This leads to the following practical version of Algorithm 10.2.1:

\[
\begin{align*}
x &= \text{initial guess} \\
k &= 0 \\
r &= b - Ax_0 \\
\rho_0 &= \|r\|_2^2 \\
\text{while } (\sqrt{\rho_k} > \epsilon \|b\|_2) \land (k < k_{\text{max}}) \\
&\quad k = k + 1 \\
&\quad \text{if } k = 1 \\
&\quad \quad p = r \\
&\quad \text{else} \\
&\quad \quad \beta_k = \rho_{k-1}/\rho_{k-2} \\
&\quad \quad p = r + \beta_k p \\
&\quad \text{end} \\
w &= Ap \\
\alpha_k &= \rho_{k-1}/p^T w \\
x &= x + \alpha_k p \\
r &= r - \alpha_k w \\
\rho_k &= \|r\|_2^2 \\
\text{end}
\]

This algorithm requires one matrix-vector multiplication and 10n flops per iteration. Notice that just four \( n \)-vectors of storage are essential: \( x, r, p, \) and \( w \). The subscripting of the scalars is not necessary and is only done here to facilitate comparison with Algorithm 10.2.1.

It is also possible to base the termination criteria on heuristic estimates of the error \( A^{-1}r_k \) by approximating \( \|A^{-1}\|_2 \) with the reciprocal of the smallest eigenvalue of the tridiagonal matrix \( T_k \) given in (10.2.14).

The idea of regarding conjugate gradients as an iterative method began with Reid (1971). The iterative point of view is useful but then the rate of convergence is central to the method's success.

10.2.7 Convergence Properties

We conclude this section by examining the convergence of the conjugate gradient iterates \( \{x_k\} \). Two results are given and they both say that the
method performs well when $A$ is near the identity either in the sense of a 
low rank perturbation or in the sense of norm.

**Theorem 10.2.5** If $A = I + B$ is an $n$-by-$n$ symmetric positive definite matrix and $\text{rank}(B) = r$ then Algorithm 10.2.1 converges in at most $r + 1$ steps.

**Proof.** The dimension of

$$\text{span}\{r_0, Ar_0, \ldots, A^{k-1}r_0\} = \text{span}\{r_0, Br_0, \ldots, B^{k-1}r_0\}$$

cannot exceed $r + 1$. Since $p_1, \ldots, p_k$ span this subspace and are independent, the iteration cannot progress beyond $r + 1$ steps. $\Box$

An important metatheorem follows from this result:

- If $A$ is close to a rank $r$ correction to the identity, then Algorithm 10.2.1 almost converges after $r + 1$ steps.

We show how this heuristic can be exploited in the next section.

An error bound of a different flavor can be obtained in terms of the $A$-norm which we define as follows:

$$\|w\|_A = \sqrt{w^T A w}.$$

**Theorem 10.2.6** Suppose $A \in \mathbb{R}^{n \times n}$ is symmetric positive definite and $b \in \mathbb{R}$: If Algorithm 10.2.1 produces iterates $\{x_k\}$ and $\kappa = \kappa_2(A)$ then

$$\|x - x_k\|_A \leq \frac{2}{\kappa} \|x - x_0\| \left(\frac{\sqrt{\kappa} - 1}{\sqrt{\kappa} + 1}\right)^k.$$

**Proof.** See Luenberger (1973, p.187). $\Box$

The accuracy of the $\{x_k\}$ is often much better than this theorem predicts. However, a heuristic version of Theorem 10.2.6 turns out to be very useful:

- The conjugate gradient method converges very fast in the $A$-norm if $\kappa_2(A) \approx 1$.

In the next section we show how we can sometimes convert a given $Ax = b$ problem into a related $\tilde{A}\tilde{x} = \tilde{b}$ problem with $\tilde{A}$ being close to the identity.

**Problems**

P10.2.1 Verify that the residuals in (10.2.1) satisfy $r_i^T r_j = 0$ whenever $j = i + 1$.
P10.2.2 Verify (10.2.2).
P10.2.3 Verify (10.2.3).
P10.2.4 Verify (10.2.12) and (10.2.13).
P10.2.5 Give formula for the entries of the tridiagonal matrix $T_k$ in (10.2.14).

P10.2.6 Compare the work and storage requirements associated with the practical implementation of Algorithms 9.3.1 and 10.2.1.

P10.2.7 Show that if $A \in \mathbb{R}^{n \times n}$ is symmetric positive definite and has $k$ distinct eigenvalues, then the conjugate gradient method does not require more than $k + 1$ steps to converge.

P10.2.8 Use Theorem 10.2.6 to verify that

$$\|x_k - A^{-1}b\|_2 \leq 2\sqrt{\kappa} \left(\frac{\sqrt{\kappa} - 1}{\sqrt{\kappa} + 1}\right)^k \|x_0 - A^{-1}b\|_2.$$ 

Notes and References for Sec. 10.2

The conjugate gradient method is a member of a larger class of methods that are referred to as conjugate direction algorithms. In a conjugate direction algorithm the search directions are all $B$-conjugate for some suitably chosen matrix $B$. A discussion of these methods appears in

Some historical and unifying perspectives are offered in

The classic reference for the conjugate gradient method is

An exact arithmetic analysis of the method may be found in chapter 2 of

See also

For a discussion of conjugate gradient convergence behavior, see

Finally, we mention that the method can be used to compute an eigenvector of a large sparse symmetric matrix:

### 10.3 Preconditioned Conjugate Gradients

We concluded the previous section by observing that the method of conjugate gradients works well on matrices that are either well conditioned or have just a few distinct eigenvalues. (The latter being the case when $A$ is a lower rank perturbation of the identity.) In this section we show how to precondition a linear system so that the matrix of coefficients assumes one of these nice forms. Our treatment is quite brief and informal. Golub and Meurant (1983) and Axelsson (1985) have more comprehensive expositions.

#### 10.3.1 Derivation

Consider the $n$-by-$n$ symmetric positive definite linear system $Ax = b$. The idea behind preconditioned conjugate gradients is to apply the "regular" conjugate gradient method to the transformed system

$$
\tilde{A}\tilde{x} = \tilde{b},
$$

where $\tilde{A} = C^{-1}AC^{-1}$, $\tilde{x} = Cx$, $\tilde{b} = C^{-1}b$, and $C$ is symmetric positive definite. In view of our remarks in §10.2.8, we should try to choose $C$...
so that $\tilde{A}$ is well conditioned or a matrix with clustered eigenvalues. For reasons that will soon emerge, the matrix $C^2$ must also be "simple."

If we apply Algorithm 10.2.1 to (10.3.1), then we obtain the iteration

\begin{align*}
    k &= 0 \\
    \tilde{x}_0 &= \text{initial guess } (\tilde{A}\tilde{x}_0 \approx \tilde{b}) \\
    \tilde{r}_0 &= \tilde{b} - \tilde{A}\tilde{x}_0 \\
    \text{while } \tilde{r}_k \neq 0 & \\
    k &= k + 1 \\
    \text{if } k = 1 & \quad \tilde{p}_1 = \tilde{r}_0 \\
    \text{else} & \quad \beta_k = \tilde{r}_{k-1}^T\tilde{r}_{k-1}/\tilde{r}_{k-2}^T\tilde{r}_{k-2} \\
    & \quad \tilde{p}_k = \tilde{r}_{k-1} + \beta_k\tilde{p}_{k-1} \\
    \text{end} \\
    \alpha_k &= \tilde{r}_{k-1}^T\tilde{r}_{k-1}/\tilde{p}_k^T C^{-1}AC^{-1}\tilde{p}_k \\
    \tilde{x}_k &= \tilde{x}_{k-1} + \alpha_k\tilde{p}_k \\
    \tilde{r}_k &= \tilde{r}_{k-1} - \alpha_k C^{-1}AC^{-1}\tilde{p}_k \\
    \text{end} \\
    \tilde{x} &= \tilde{x}_k
\end{align*}

Here, $\tilde{x}_k$ should be regarded as an approximation to $\tilde{x}$ and $\tilde{r}_k$ is the residual in the transformed coordinates, i.e., $\tilde{r}_k = \tilde{b} - \tilde{A}\tilde{x}_k$. Of course, once we have $\tilde{x}$ then we can obtain $x$ via the equation $x = C^{-1}\tilde{x}$. However, it is possible to avoid explicit reference to the matrix $C^{-1}$ by defining $\tilde{p}_k = Cp_k$, $\tilde{x}_k = Cx_k$, and $\tilde{r}_k = C^{-1}r_k$. Indeed, if we substitute these definitions into (10.3.2) and recall that $\tilde{b} = C^{-1}b$ and $\tilde{x} = Cx$, then we obtain

\begin{align*}
    k &= 0 \\
    x_0 &= \text{initial guess } (Ax_0 \approx b) \\
    r_0 &= b - Ax_0 \\
    \text{while } C^{-1}r_k \neq 0 & \\
    k &= k + 1 \\
    \text{if } k = 1 & \quad Cp_1 = C^{-1}r_0 \\
    \text{else} & \quad \beta_k = (C^{-1}r_{k-1})^T(C^{-1}r_{k-1})/(C^{-1}r_{k-2})^T(C^{-1}r_{k-2}) \\
    & \quad Cp_k = C^{-1}r_{k-1} + \beta_kCp_{k-1} \\
    \text{end} \\
    \alpha_k &= (C^{-1}r_{k-1})^T(C^{-1}r_{k-1})/(Cp_k)^T(C^{-1}AC^{-1})(Cp_k) \\
    Cx_k &= Cx_{k-1} + \alpha_kCp_k \\
    C^{-1}r_k &= C^{-1}r_{k-1} - \alpha_k(C^{-1}AC^{-1})Cp_k \\
    \text{end} \\
    Cx &= Cx_k
\end{align*}
If we define the preconditioner $M$ by $M = C^2$ (also positive definite) and let $z_k$ be the solution of the system $Mz_k = r_k$ then (10.3.3) simplifies to

**Algorithm 10.3.1 [Preconditioned Conjugate Gradients]** Given a symmetric positive definite $A \in \mathbb{R}^{n \times n}$, $b \in \mathbb{R}^n$, a symmetric positive definite preconditioner $M$, and an initial guess $x_0$ ($Ax_0 \approx b$), the following algorithm solves the linear system $Ax = b$.

\[
\begin{align*}
    k &= 0 \\
    r_0 &= b - Ax_0 \\
    \textbf{while } (r_k \neq 0) \\
    &\quad \text{Solve } Mz_k = r_k. \\
    &\quad k = k + 1 \\
    &\quad \text{if } k = 1 \\
    &\quad \quad p_1 = z_0 \\
    &\quad \text{else} \\
    &\quad \quad \beta_k = r_{k-1}^T z_{k-1} / r_{k-2}^T z_{k-2} \\
    &\quad \quad p_k = z_{k-1} + \beta_k p_{k-1} \\
    &\quad \end{align*}
\]

\[
\alpha_k = r_{k-1}^T z_{k-1} / p_k^T Ap_k
\]

\[
x_k = x_{k-1} + \alpha_k p_k
\]

\[
r_k = r_{k-1} - \alpha_k Ap_k
\]

\[
x = x_k
\]

A number of important observations should be made about this procedure:

- It can be shown that the residuals and search directions satisfy

\[
    r_j^T M^{-1} r_i = 0 \quad i \neq j
\]  

(10.3.4)

\[
    p_j^T (C^{-1} A C^{-1}) p_i = 0 \quad i \neq j
\]  

(10.3.5)

- The denominators $r_{k-2}^T z_{k-2} = z_{k-2}^T M z_{k-2}$ never vanish because $M$ is positive definite.

- Although the transformation $C$ figured heavily in the derivation of the algorithm, its action is only felt through the preconditioner $M = C^2$.

- For Algorithm 10.3.1 to be an effective sparse matrix technique, linear systems of the form $Mz = r$ must be easily solved and convergence must be rapid.

The choice of a good preconditioner can have a dramatic effect upon the rate of convergence. Some of the possibilities are now discussed.
10.3.2 Incomplete Cholesky Preconditioners

One of the most important preconditioning strategies involves computing an incomplete Cholesky factorization of $A$. The idea behind this approach is to calculate a lower triangular matrix $H$ with the property that $H$ has some tractable sparsity structure and is somehow "close" to $A$'s exact Cholesky factor $G$. The preconditioner is then taken to be $M = HH^T$. To appreciate this choice consider the following facts:

- There exists a unique symmetric positive definite matrix $C$ such that $M = C^2$.
- There exists an orthogonal $Q$ such that $C = QH^T$, i.e., $H^T$ is the upper triangular factor of a QR factorization of $C$.

We therefore obtain the heuristic

$$
\tilde{A} = C^{-1}AC^{-1} = C^{-T}AC^{-1} = (HQ^T)^{-1}A(QH^T)^{-1} = Q(H^{-1}GG^TH^{-T})Q^T \approx I
$$

Thus, the better $H$ approximates $G$ the smaller the condition of $\tilde{A}$, and the better the performance of Algorithm 10.3.1.

An easy but effective way to determine such a simple $H$ that approximates $G$ is to step through the Cholesky reduction setting $h_{ij}$ to zero if the corresponding $a_{ij}$ is zero. Pursuing this with the outer product version of Cholesky we obtain

\[
\text{for } k = 1:n \\
\quad A(k, k) = \sqrt{A(k, k)} \\
\quad \text{for } i = k + 1:n \\
\quad \quad \text{if } A(i, k) \neq 0 \\
\quad \quad \quad A(i, k) = A(i, k)/A(k, k) \\
\quad \text{end} \\
\quad \text{end} \\
\quad \text{for } j = k + 1:n \\
\quad \quad \text{for } i = j:n \\
\quad \quad \quad \text{if } A(i, j) \neq 0 \\
\quad \quad \quad \quad A(i, j) = A(i, j) - A(i, k)A(j, k) \\
\quad \quad \text{end} \\
\quad \text{end} \\
\text{end}
\]

In practice, the matrix $A$ and its incomplete Cholesky factor $H$ would be stored in an appropriate data structure and the looping in the above algorithm would take on a very special appearance.

Unfortunately, (10.3.7) is not always stable. Classes of positive definite matrices for which incomplete Cholesky is stable are identified in Manteuffel (1979). See also Elman (1986).
10.3.3 Incomplete Block Preconditioners

As with just about everything else in this book, the incomplete factorization ideas outlined in the previous subsection have a block analog. We illustrate this by looking at the incomplete block Cholesky factorization of the symmetric, positive definite, block tridiagonal matrix

\[
A = \begin{bmatrix} A_1 & E_1^T & 0 \\ E_1 & A_2 & E_2^T \\ 0 & E_2 & A_3 \end{bmatrix}.
\]

For purposes of illustration, we assume that the \( A_i \) are tridiagonal and the \( E_i \) are diagonal. Matrices with this structure arise from the standard 5-point discretization of self-adjoint elliptic partial differential equations over a two-dimensional domain.

The 3-by-3 case is sufficiently general. Our discussion is based upon Concus, Golub, and Meurant (1985). Let

\[
G = \begin{bmatrix} G_1 & 0 & 0 \\ F_1 & G_2 & 0 \\ 0 & F_2 & G_3 \end{bmatrix}
\]

be the exact block Cholesky factor of \( A \). Although \( G \) is sparse as a block matrix, the individual blocks are dense with the exception of \( G_1 \). This can be seen from the required computations:

\[
\begin{align*}
G_1G_1^T &= B_1 \equiv A_1 \\
F_1 &= E_1G_1^{-1} \\
G_2G_2^T &= B_2 \equiv A_2 - F_1F_1^T = A_2 - E_1B_1^{-1}E_1^T \\
F_2 &= E_2G_2^{-1} \\
G_3G_3^T &= B_3 \equiv A_3 - F_2F_2^T = A_3 - E_2B_2^{-1}E_2^T
\end{align*}
\]

We therefore seek an approximate block Cholesky factor of the form

\[
\tilde{G} = \begin{bmatrix} \tilde{G}_1 & 0 & 0 \\ \tilde{F}_1 & \tilde{G}_2 & 0 \\ 0 & \tilde{F}_2 & \tilde{G}_3 \end{bmatrix}
\]

so that we can easily solve systems that involve the preconditioner \( M = \tilde{G}\tilde{G}^T \). This involves the imposition of sparsity on \( \tilde{G} \)'s blocks and here is a reasonable approach given that the \( A_i \) are tridiagonal and the \( E_i \) are diagonal:
\[
\begin{align*}
\tilde{G}_1 \tilde{G}_1^T &= \tilde{B}_1 \equiv A_1 \\
\tilde{F}_1 &= E_1 \tilde{G}_1^{-1} \\
\tilde{G}_2 \tilde{G}_2^T &= \tilde{B}_2 = A_2 - E_1 \Lambda_1 E_1^T, \quad \Lambda_1 \text{ (tridiagonal)} \approx \tilde{B}_1^{-1} \\
\tilde{F}_2 &= E_2 \tilde{G}_2^{-1} \\
\tilde{G}_3 \tilde{G}_3^T &= \tilde{B}_3 \equiv A_3 - E_2 \Lambda_2 E_2^T, \quad \Lambda_2 \text{ (tridiagonal)} \approx \tilde{B}_2^{-1}
\end{align*}
\]

Note that all the \( \tilde{B}_i \) are tridiagonal. Clearly, the \( \Lambda_i \) must be carefully chosen to ensure that the \( \tilde{B}_i \) are also symmetric and positive definite. It then follows that the \( \tilde{G}_i \) are lower bidiagonal. The \( \tilde{F}_i \) are full, but they need not be explicitly formed. For example, in the course of solving the system \( Mz = r \) we must solve a system of the form

\[
\begin{bmatrix}
\tilde{G}_1 & 0 & 0 \\
\tilde{F}_1 & \tilde{G}_2 & 0 \\
0 & \tilde{F}_2 & \tilde{G}_3
\end{bmatrix}
\begin{bmatrix}
w_1 \\
w_2 \\
w_3
\end{bmatrix} =
\begin{bmatrix}
r_1 \\
r_2 \\
r_3
\end{bmatrix}.
\]

Forward elimination can be used to carry out matrix-vector products that involve the \( \tilde{F}_i = E_i \tilde{G}_i^{-1} \):

\[
\begin{align*}
\tilde{G}_1 w_1 &= r_1 \\
\tilde{G}_2 w_2 &= r_2 - \tilde{F}_1 w_1 = r_2 - E_1 \tilde{G}_1^{-1} w_1 \\
\tilde{G}_3 w_3 &= r_3 - \tilde{F}_2 w_2 = r_3 - E_2 \tilde{G}_2^{-1} w_2
\end{align*}
\]

The choice of \( \Lambda_i \) is delicate as the resulting \( \tilde{B}_i \) must be positive definite. As we have organized the computation, the central issue is how to approximate the inverse of an \( m \)-by-\( m \) symmetric, positive definite, tridiagonal matrix \( T = (t_{ij}) \) with a symmetric tridiagonal matrix \( \Lambda \). There are several reasonable approaches:

- Set \( \Lambda = \text{diag}(1/t_{11}, \ldots, 1/t_{nn}) \).
- Take \( \Lambda \) to be the tridiagonal part of \( T^{-1} \). This can be efficiently computed since there exist \( u, v \in \mathbb{R}^m \) such that the lower triangular part of \( T^{-1} \) is the lower triangular part of \( uv^T \). See Aslund (1959).
- Set \( \Lambda = UTU^T \) where \( U \) is the lower bidiagonal portion of \( G^{-1} \) where \( T = GG^T \) is the Cholesky factorization. This can be found in \( O(m) \) flops.

For a discussion of these approximations and what they imply about the associated preconditioners, see Concus, Golub, and Meurant (1985).
10.3.4 Domain Decomposition Ideas

The numerical solution of elliptic partial differential equations often leads to linear systems of the form

\[
\begin{bmatrix}
A_1 & \cdots & \cdots & B_1 \\
\vdots & A_2 & B_2 & \vdots \\
\vdots & \ddots & \vdots & \vdots \\
B_1^T & \cdots & B_p^T & Q
\end{bmatrix}
\begin{bmatrix}
x_1 \\
x_2 \\
\vdots \\
x_p \\
z
\end{bmatrix}
= 
\begin{bmatrix}
d_1 \\
d_2 \\
\vdots \\
d_p \\
f
\end{bmatrix}
\tag{10.3.8}
\]

if the unknowns are properly sequenced. See Meurant (1984). Here, the \( A_i \) are symmetric positive definite, the \( B_i \) are sparse, and the last block column is generally much narrower than the others.

An example with \( p = 2 \) serves to connect (10.3.8) and its block structure with the underlying problem geometry and the chosen domain decomposition. Suppose we are to solve Poisson’s equation on the following domain:

With the usual discretization, an unknown at a mesh point is coupled only to its “north”, “east”, “south”, and “west” neighbor. There are three “types” of variables: those interior to the top subdomain (aggregated in the subvector \( x_1 \) and associated with the “+” mesh points), those interior to the bottom subdomain (aggregated in the subvector \( x_2 \) and associated with the “x” mesh points), and those on the interface between the two subdomains (aggregated in the subvector \( z \) and associated with the “*” mesh points). Note that the interior unknowns of one subdomain are not coupled to the interior unknowns of another subdomain, which accounts
for the zero blocks in (10.3.8). Also observe that the number of interface unknowns is typically small compared to the overall number of unknowns.

Now let us explore the preconditioning possibilities associated with (10.3.8). We continue with the $p = 2$ case for simplicity. If we set

\[
M = L \begin{bmatrix} M_1^{-1} & 0 & 0 \\ 0 & M_2^{-1} & 0 \\ 0 & 0 & S^{-1} \end{bmatrix} L^T
\]

where

\[
L = \begin{bmatrix} M_1 & 0 & 0 \\ 0 & M_2 & 0 \\ B_1^T & B_2^T & S \end{bmatrix}
\]

then

\[
M = \begin{bmatrix} M_1 & 0 & B_1 \\ 0 & M_2 & B_2 \\ B_1^T & B_2^T & S_* \end{bmatrix}
\]  \hspace{1cm} (10.3.9)

with $S_* = S + B_1^T M_1^{-1} B_1 + B_2^T M_2^{-1} B_2$. Let us consider how we might choose the block parameters $M_1$, $M_2$, and $S$ so as to produce an effective preconditioner.

If we compare (10.3.9) with the $p = 2$ version of (10.3.8) we see that it makes sense for $M_i$ to approximate $A_i$ and for $S_*$ to approximate $Q$. The latter is achieved if $S \approx Q - B_1^T M_1^{-1} B_1 - B_2^T M_2^{-1} B_2$. There are several approaches to selecting $S$ and they all address the fact that we cannot form the dense matrices $B_i M_i^{-1} B_i^T$. For example, as discussed in the previous subsection, tridiagonal approximations of the $M_i^{-1}$ could be used. See Meurant (1989).

If the subdomains are sufficiently regular and it is feasible to solve linear systems that involve the $A_i$ exactly (say by using a fast Poisson solver), then we can set $M_i = A_i$. It follows that $M = A + E$ where the rank($E$) = $m$ with $m$ being the number of interface unknowns. Thus, the preconditioned conjugate gradient algorithm would theoretically converge in $m + 1$ steps.

Regardless of the approximations that must be incorporated in the process, we see that there are significant opportunities for parallelism because the subdomain problems are decoupled. Indeed, the number of subdomains $p$ is usually a function of both the problem geometry and the number of processors that are available for the computation.

### 10.3.5 Polynomial Preconditioners

The vector $z$ defined by the preconditioner system $Mz = r$ should be thought of as an approximate solution to $Az = r$ insofar as $M$ is an approximation of $A$. One way to obtain such an approximate solution is to
apply \( p \) steps of a stationary method \( M_1 z^{(k+1)} = N_1 z^{(k)} + r, \) \( z^{(0)} = 0. \) It follows that if \( G = M_1^{-1} N_1 \) then

\[
z \equiv z^{(p)} = (I + G + \cdots G^{p-1}) M_1^{-1} r.
\]

Thus, if \( M^{-1} = (I + G + \cdots G^{p-1}) M_1^{-1} \) then \( Mz = r \) and we can think of \( M \) as a preconditioner. Of course, it is important that \( M \) be symmetric positive definite and this constrains the choice of \( M_1, N_1, \) and \( p. \) Because \( M \) is a polynomial in \( G \) it is referred to as a polynomial preconditioner. This type of preconditioner is attractive from the vector/parallel point of view and has therefore attracted considerable attention.

### 10.3.6 Another Perspective

The polynomial preconditioner discussion points to an important connection between the classical iterations and the preconditioned conjugate gradient algorithm. Many iterative methods have as their basic step

\[
x_k = x_{k-2} + \omega_k (\gamma_k z_{k-1} + x_{k-1} - x_{k-2})
\]

(10.3.10)

where \( M z_{k-1} = r_{k-1} = b - Ax_{k-1}. \) For example, if we set \( \omega = 1, \) and \( \gamma_k = 1, \) then

\[
x_k = M^{-1} (b - Ax_{k-1}) + x_{k-1},
\]

i.e., \( M x_k = N x_{k-1} + b, \) where \( A = M - N. \) Thus, the Jacobi, Gauss-Seidel, SOR, and SSOR methods of \( \S 10.1 \) have the form (10.3.10). So also does the Chebyshev semi-iterative method (10.1.12).

Following Concus, Golub, and O'Leary (1976), it is also possible to organize Algorithm 10.3.1 with a central step of the form (10.3.10):

\[
x_{-1} = 0; \ x_0 = \text{initial guess}; \ k = 0; \ r_0 = b - Ax_0
\]

while \( r_k \neq 0 \)

\[
\begin{align*}
k &= k + 1 \\
\text{Solve } M z_{k-1} &= r_{k-1} \text{ for } z_{k-1}. \\
\gamma_{k-1} &= z^T_{k-1} M z_{k-1} / z^T_{k-1} A z_{k-1} \\
\text{if } k &= 1 \\
\omega_1 &= 1 \\
\text{else} \\
\omega_k &= \left(1 - \frac{\gamma_{k-1}}{\gamma_{k-2}} \frac{z^T_{k-1} M z_{k-1}}{z^T_{k-2} M z_{k-2}} \frac{1}{\omega_{k-1}} \right)^{-1} \\
x_k &= x_{k-2} + \omega_k (\gamma_{k-1} z_{k-1} + x_{k-1} - x_{k-2}) \\
r_k &= b - Ax_k
\end{align*}
\]

end

\[
x = x_n
\]
Thus, we can think of the scalars $\omega_k$ and $\gamma_k$ in (10.3.11) as acceleration parameters that can be chosen to speed the convergence of the iteration $Mx_k = Nx_{k-1} + b$. Hence, any iterative method based on the splitting $A = M - N$ can be accelerated by the conjugate gradient algorithm as long as $M$ (the preconditioner) is symmetric and positive definite.

Problems

P10.3.1 Detail an incomplete factorization procedure that is based on gaxpy Cholesky, i.e., Algorithm 4.2.1.

P10.3.2 How many $n$-vectors of storage is required by a practical implementation of Algorithm 10.3.1? Ignore workspaces that may be required when $Mx = r$ is solved.

Notes and References for Sec. 10.3

Our discussion of the preconditioned conjugate gradient is drawn from several sources including

Incomplete factorization ideas are detailed in

For information on domain decomposition and other "pde driven" preconditioning ideas, see

Various aspects of polynomial preconditioners are discussed in

Numerous vector/parallel implementations of the cg method have been developed. See

Preconditioners for large Toeplitz systems are discussed in

Finally, we offer an assortment of references concerned with the practical application of the cg method:

10.4 Other Krylov Subspace Methods

The conjugate gradient method presented over the previous two sections is applicable to symmetric positive definite systems. The MINRES and SYMMLQ variants developed in §9.3.2 in connection with the symmetric Lanczos process can handle symmetric indefinite systems. Now we push the generalizations even further in pursuit of iterative methods that are applicable to unsymmetric systems.

The discussion is patterned after the survey article by Freund, Golub, and Nachtigal (1992) and Chapter 9 of Golub and Ortega (1993). We focus on cg-type algorithms that involve optimization over Krylov spaces.
Bear in mind that there is a large gap between our algorithmic specifications and production software. A good place to build an appreciation for this point is the Templates book by Barrett et al (1993). The book by Saad (1996) is also highly recommended.

### 10.4.1 Normal Equation Approaches

The method of normal equations for the least squares problem is appealing because it allows us to use simple “Cholesky technology” instead of more complicated methods that involve orthogonalization. Likewise, in the unsymmetric $Ax = b$ problem it is tempting to solve the equivalent symmetric positive definite system

$$A^T A x = A^T b$$

using existing conjugate gradient technology. Indeed, if we make the substitution $A \leftarrow A^T A$ in Algorithm 10.2.1 and note that a normal equation residual $A^T b - A^T A x_k$ is $A^T$ times the “true” residual $b - A x_k$, then we obtain the Conjugate Gradient Normal Equation Residual method:

Algorithm 10.4.1 [CGNR] If $A \in \mathbb{R}^{n \times n}$ is nonsingular, $b \in \mathbb{R}^n$, and $x_0 \in \mathbb{R}^n$ is an initial guess ($Ax_0 \approx b$), then the following algorithm computes $x \in \mathbb{R}^n$ so $Ax = b$.

\[
\begin{align*}
k &= 0 \\
r_0 &= b - A x_0 \\
\text{while } & r_k \neq 0 \text{ do} \\
& k = k + 1 \\
& \text{if } k = 1 \text{ then} \\
& p_1 = A^T r_0 \\
& \text{else} \\
& \beta_k = (A^T r_{k-1})^T (A^T r_{k-1}) / (A^T r_{k-2})^T (A^T r_{k-2}) \\
& p_k = A^T r_{k-1} + \beta_k p_{k-1} \\
& \text{end} \\
& \alpha_k = (A^T r_{k-1})^T (A^T r_{k-1}) / (A p_k)^T (A p_k) \\
& x_k = x_{k-1} + \alpha_k p_k \\
& r_k = r_{k-1} - \alpha_k A p_k \\
& \text{end} \\
x &= x_k
\end{align*}
\]

Another way to make an unsymmetric $Ax = b$ problem “cg-friendly” is to work with the system

$$A A^T y = b \quad x = A^T y.$$ 

In “$y$ space” the cg algorithm takes on the following form:
\[ k = 0 \]
\[ y_0 = \text{initial guess} \ (AATy_0 = b) \]
\[ r_0 = b - AATy_0 \]
while \( r_k \neq 0 \)
\[ k = k + 1 \]
if \( k = 1 \)
\[ p_1 = r_0 \]
else
\[ \beta_k = r_{k-1}^Tr_{k-1}/r_{k-2}^Tr_{k-2} \]
\[ p_k = r_{k-1} + \beta_k p_{k-1} \]
end
\[ \alpha_k = r_{k-1}^Tr_{k-1}/p_k^TAATp_k \]
\[ y_k = y_{k-1} + \alpha_k p_k \]
\[ r_k = r_{k-1} - \alpha_k AATp_k \]
end
\[ y = y_k \]

Making the substitutions \( x_k \leftarrow A^Ty_k \) and \( p_k \leftarrow A^Tp_k \) and simplifying we obtain the Conjugate Gradient Normal Equation Error method:

**Algorithm 10.4.2 [CGNE]** If \( A \in \mathbb{R}^{n \times n} \) is nonsingular, \( b \in \mathbb{R}^n \), and \( x_0 \in \mathbb{R}^n \) is an initial guess \((Ax_0 \approx b)\), then the following algorithm computes \( x \in \mathbb{R}^n \) so \( Ax = b \).

\[ k = 0 \]
\[ r_0 = b - Ax_0 \]
while \( r_k \neq 0 \)
\[ k = k + 1 \]
if \( k = 1 \)
\[ p_1 = A^Tr_0 \]
else
\[ \beta_k = r_{k-1}^Tr_{k-1}/r_{k-2}^Tr_{k-2} \]
\[ p_k = A^Tr_{k-1} + \beta_k p_{k-1} \]
end
\[ \alpha_k = r_{k-1}^Tr_{k-1}/p_k^TAp_k \]
\[ x_k = x_{k-1} + \alpha_k p_k \]
\[ r_k = r_{k-1} - \alpha_k Ap_k \]
end
\[ x = x_k \]

In general these two normal equation approaches are handicapped by the squaring of the condition number. (Recall Theorem 10.2.6.) However, there are some occasions where they are effective and we refer the reader to Freund, Golub and Nachtigal (1991).
10.4.2 A Note on Objective Functions

Based on what we know about the cg method, the CGNR iterate $x_k$ minimizes

$$\phi_1(x) = \frac{1}{2}x^T(A^TA)x - x^TA^Tb$$

over the set

$$\mathcal{S}_k^{(CGNR)} = x_0 + \mathcal{K}(A^TA, r_0, k).$$

It is easy to show that

$$\frac{1}{2}\| b - Ax \|^2 = \phi_1(x) + \frac{1}{2}b^Tb$$

and so $x_k$ minimizes the residual $\| b - Ax \|_2$ over $\mathcal{S}_k^{(CGNR)}$. The "R" in "CGNR" is there because of the residual-based optimization.

On the other hand, the CGNE (implicit) iterate $y_k$ minimizes

$$\phi_2(y) = \frac{1}{2}y^T(AA^T)y - y^Tb$$

over the set $y_0 + \mathcal{K}(AA^T, b - AA^Ty_0, k)$. With the change of variable $x = A^Ty$ it can be shown that $x_k$ minimizes

$$\frac{1}{2}x^TAx - x^TA^{-1}b = \frac{1}{2}\| x - A^{-1}b \|^2 + \frac{1}{2}\| A^{-1}b \|^2$$

over

$$\mathcal{S}_k^{(CGNE)} = x_0 + \mathcal{K}(A^TA, A^Tr_0, k).$$ (10.4.1)

Thus CGNE minimizes the error at each step and that explains the "E" in "CGNE".

10.4.3 The Conjugate Residual Method

Recall that if $A$ is symmetric positive definite, then it has a symmetric positive definite square root $A^{1/2}$. (See §4.2.10.) Note that in this case $Ax = b$ and

$$A^{1/2}x = A^{-1/2}b$$

are equivalent and that the former is the normal equation version of the latter. If we apply CGNR to this square root system and simplify the results, then we obtain

Algorithm 10.2.3 [Conjugate Residuals] If $A \in \mathbb{R}^{n \times n}$ is symmetric positive definite, $b \in \mathbb{R}^n$, and $x_0 \in \mathbb{R}^n$ is an initial guess ($Ax_0 \approx b$), then the following algorithm computes $x \in \mathbb{R}^n$ so $Ax = b$. 
\[ k = 0 \]
\[ r_0 = b - Ax_0 \]
\textbf{while } r_k \neq 0
\[ k = k + 1 \]
\textbf{if } k = 1
\[ p_1 = r_0 \]
\textbf{else}
\[ \beta_k = r_{k-1}^T A r_{k-1} / r_{k-2}^T A r_{k-2} \]
\[ A p_k = A r_{k-1} + \beta_k A p_{k-1} \]
\textbf{end}
\[ \alpha_k = r_{k-1}^T A r_{k-1} / (A p_k)^T (A p_k) \]
\[ x_k = x_{k-1} + \alpha_k p_k \]
\[ r_k = r_{k-1} - \alpha_k A p_k \]
\textbf{end}
\[ x = x_k \]

It follows from our comments about CGNR that \( \| A^{-1/2}(b - Ax) \|_2 \) is minimized over the set \( x_0 + \mathcal{K}(A, r_0, k) \) during the \( k \)th iteration.

### 10.4.4 GMRES

In §9.3.2 we briefly discussed the Lanczos-based MINRES method for symmetric, possibly indefinite, \( Ax = b \) problems. In that method the iterate \( x_k \) minimizes \( \| b - Ax \|_2 \) over the set
\[ S_k = x_0 + \text{span}\{r_0, A r_0, \ldots, A^{k-1} r_0\} = x_0 + \mathcal{K}(A, r_0, k) \quad (10.4.2) \]

The key idea behind the algorithm is to express \( x_k \) in terms of the Lanczos vectors \( q_1, q_2, \ldots, q_k \) which span \( \mathcal{K}(A, r_0, k) \) if \( q_1 \) is a multiple of the initial residual \( r_0 = b - Ax_0 \).

In the Generalized Minimum Residual (GMRES) method of Saad and Schultz (1986) the same approach is taken except that the iterates are expressed in terms of Arnoldi vectors instead of Lanczos vectors in order to handle unsymmetric \( A \). After \( k \) steps of the Arnoldi iteration (9.4.1) we have the factorization
\[ AQ_k = Q_{k+1} \tilde{H}_k \quad (10.4.3) \]

where the columns of \( Q_{k+1} = [Q_k \; q_{k+1}] \) are the orthonormal Arnoldi vectors and

\[ \tilde{H}_k = \begin{bmatrix}
    h_{11} & h_{12} & \cdots & \cdots & h_{1k} \\
    h_{21} & h_{22} & \cdots & \cdots & h_{2k} \\
    0 & \ddots & \ddots & \ddots & \vdots \\
    \vdots & \ddots & \ddots & \ddots & \vdots \\
    0 & \cdots & h_{k,k-1} & h_{kk} \\
    0 & \cdots & 0 & h_{k+1,k}
\end{bmatrix} \in \mathbb{R}^{k+1 \times k} \]
is upper Hessenberg. In the $k$th step of GMRES, $\| b - Ax_k \|_2$ is minimized subject to the constraint that $x_k$ has the form $x_k = x_0 + Q_k y_k$ for some $y_k \in \mathbb{R}^k$. If $q_1 = r_0 / \rho_0$ where $\rho_0 = \| r_0 \|_2$, then it follows that

$$
\begin{align*}
\| b - A(x_0 + Q_k y_k) \|_2 &= \| r_0 - AQ_k y_k \|_2 \\
&= \| r_0 - Q_{k+1} \tilde{H}_k y_k \|_2 \\
&= \| \rho_0 e_1 - \tilde{H}_k y_k \|_2.
\end{align*}
$$

Thus, $y_k$ is the solution to a $(k + 1)$-by-$k$ least squares problem and the GMRES iterate is given by $x_k = x_0 + Q_k y_k$.

Algorithm 10.4.4 [GMRES] If $A \in \mathbb{R}^{n \times n}$ is nonsingular, $b \in \mathbb{R}^n$, and $x_0 \in \mathbb{R}^n$ is an initial guess ($Ax_0 \approx b$), then the following algorithm computes $x \in \mathbb{R}^n$ so $Ax = b$.

\begin{align*}
r_0 &= b - Ax_0 \\
h_{10} &= \| r_0 \|_2 \\
k &= 0 \\
\text{while} \ (h_{k+1,k} > 0) \\
& \quad q_{k+1} = r_k / h_{k+1,k} \\
& \quad k = k + 1 \\
& \quad r_k = AQ_k \\
& \quad \text{for} \ i = 1:k \\
& \quad \quad h_{ik} = q_i^T r_k \\
& \quad \quad r_k = r_k - h_{ikk} q_i \\
& \quad \text{end} \\
& \quad h_{k+1,k} = \| r_k \|_2 \\
x_k &= x_0 + Q_k y_k \text{ where } \| h_{10} e_1 - \tilde{H}_k y_k \|_2 = \min \\
\end{align*}

end

$x = x_k$

It is easy to verify that

$$
\| b - Ax_k \|_2 = h_{k+1,k}
$$

The upper Hessenberg least square problem can be efficiently solved using Givens rotations. In practice there is no need to form $x_k$ until one is happy with its residual.

The main problem with "unlimited GMRES" is that the $k$th iteration involves $O(kn)$ flops. Thus like Arnoldi, a practical GMRES implementation requires a restart strategy to avoid excessive amounts of computation and memory traffic. For example, if at most $m$ steps are tolerable, then $x_m$ can be used as the initial vector for the next GMRES sequence.
10.4.5  Preconditioning

Preconditioning is the other key to making GMRES effective. Analogous to the development of the preconditioned conjugate gradient method in §10.3, we obtain a nonsingular matrix \( M = M_1 M_2 \) that approximates \( A \) in some sense and then apply GMRES to the system \( A\tilde{x} = \tilde{b} \) where \( \tilde{A} = M_1^{-1} A M_2^{-1}, \tilde{b} = M_1^{-1} b, \) and \( \tilde{x} = M_2 x \). If we write down the GMRES iteration for the tilde system and manipulate the equations to restore the original variables, then the resulting iteration requires the solution of linear systems that involve the preconditioner \( M \). Thus, the act of finding a good preconditioner \( M = M_1 M_2 \) is the act of making \( \tilde{A} = M_1^{-1} A M_2^{-1} \) look as much as possible like the identity subject to the constraint that linear systems with \( M \) are easy to solve.

10.4.6  The Biconjugate Gradient Method

Just as Arnoldi underwrites GMRES, the unsymmetric Lanczos process underwrites the Biconjugate gradient (BiCG) method. The starting point in the development of BiCG is to go back to the Lanczos derivation of the conjugate gradient method in §9.3.1. In terms of Lanczos vectors, the \( k \)th cg iterate is given by \( x_k = x_0 + Q_k y_k \) where \( Q_k \) is the matrix of Lanczos vectors, \( T_k = Q_k^T A Q_k \) is tridiagonal, and \( y_k \) solves \( T_k y_k = Q_k^T r_0 \). Note that

\[
Q_k^T (b - A x_k) = Q_k^T (r_0 - A Q_k y_k) = 0.
\]

Thus, we can characterize \( x_k \) by insisting that it come from \( x_0 + K(A, r_0, k) \) and that it produce a residual that is orthogonal to a given subspace, say \( K(A, r_0, k) \).

In the unsymmetric case we can extend this notion by producing a sequence of iterates \( \{x_k\} \) with the property that \( x_k \) belongs to \( x_0 + K(A, r_0, k) \) and produces a residual that is orthogonal to \( K(A^T, s_0, k) \) for some \( s_0 \in \mathbb{R}^n \). Simplifications occur if the unsymmetric Lanczos process is used to generate bases for the two involved Krylov spaces. In particular, after \( k \) steps of the unsymmetric Lanczos algorithm (9.4.7) we have \( Q_k, P_k \in \mathbb{R}^{n \times k} \) such that \( P_k^T Q_k = I_k \) and a tridiagonal matrix \( T_k = P_k^T A Q_k \) such that

\[
\begin{align*}
A Q_k &= Q_k T_k + r_k e_k^T, & P_k^T r_k &= 0 \\
A^T P_k &= P_k T_k^T + s_k e_k^T, & Q_k^T s_k &= 0
\end{align*}
\]

(10.4.4)

In BiCG we set \( x_k = x_0 + Q_k y_k \) where \( T_k y_k = Q_k^T r_0 \). Note that the Galerkin condition

\[
P_k^T (b - A x_k) = P_k^T (r_0 - A Q_k y_k) = 0
\]

holds.

As might be expected, it is possible to develop recursions so that \( x_k \) can be computed as a simple combination of \( x_{k-1} \) and \( q_{k-1} \), instead of as a linear combination of all the previous \( q \)-vectors.
The BiCG method is subject to serious breakdown because of its dependence on the unsymmetric Lanczos process. However, by relying on a look-ahead Lanczos procedure it is possible to overcome some of these difficulties.

10.4.7 QMR

Another iteration that runs off of the unsymmetric Lanczos process is the quasi-minimum residual (QMR) method of Freund and Nachtigal (1991). As in BiCG the $k$th iterate has the form $x_k = x_0 + Q_k y_k$. It is easy to show that after $k$ steps in (9.4.7) we have the factorization

$$AQ_k = Q_{k+1} \tilde{T}_k$$

where $\tilde{T}_k \in \mathbb{R}^{k+1\times k}$ is tridiagonal. It follows that if $q_1 = \rho(b - Ax_0)$, then

$$b - Ax_k = b - A(x_0 + Q_k y_k) = r_0 - AQ_k y_k = r_0 - Q_{k+1} \tilde{T}_k y_k = Q_{k+1}(\rho e_1 - \tilde{T}_k y_k).$$

If $y_k$ is chosen to minimize the 2-norm of this vector, then in exact arithmetic $x_0 + Q_k y_k$ defines the GMRES iterate. In QMR, $y_k$ is chosen to minimize $\| \rho e_1 - \tilde{T}_k y_k \|_2$.

10.4.8 Summary

The methods that we have presented do not submit to a linear ranking. The choice of a technique is complicated and depends on a host of factors. A particularly cogent assessment of the major algorithms is given in Barrett et al (1993).

Problems

P10.4.1 Analogous to (10.2.16), develop efficient implementations of the CGNR, CGNE, Conjugate residual methods.

P10.4.2 Establish the mathematical equivalence of the CGNR and the LSQR method outlined in §9.3.4.

P10.4.3 Prove (10.4.3).

P10.4.4 Develop an efficient preconditioned GMRES implementation. Proceeding as we did in §10.3 for preconditioned conjugate gradient method. (See (10.3.2) and (10.3.3) in particular.)

P10.4.5 Prove that the GMRES least squares problem has full rank.

Chapter 11

Functions of Matrices

§11.1 Eigenvalue Methods
§11.2 Approximation Methods
§11.3 The Matrix Exponential

Computing a function $f(A)$ of an $n$-by-$n$ matrix $A$ is a frequently occurring problem in control theory and other application areas. Roughly speaking, if the scalar function $f(z)$ is defined on $\lambda(A)$, then $f(A)$ is defined by substituting "$A$" for "$z$" in the "formula" for $f(z)$. For example, if $f(z) = (1 + z)/(1 - z)$ and $1 \notin \lambda(A)$, then $f(A) = (I + A)(I - A)^{-1}$.

The computations get particularly interesting when the function $f$ is transcendental. One approach in this more complicated situation is to compute an eigenvalue decomposition $A = YBY^{-1}$ and use the formula $f(A) = Yf(B)Y^{-1}$. If $B$ is sufficiently simple, then it is often possible to calculate $f(B)$ directly. This is illustrated in §11.1 for the Jordan and Schur decompositions. Not surprisingly, reliance on the latter decomposition results in a more stable $f(A)$ procedure.

Another class of methods for the matrix function problem is to approximate the desired function $f(A)$ with an easy-to-calculate function $g(A)$. For example, $g$ might be a truncated Taylor series approximate to $f$. Error bounds associated with the approximation of matrix functions are given in §11.2.

In the last section we discuss the special and very important problem of computing the matrix exponential $e^A$.

Before You Begin

Chapters 1, 2, 3, 7 and 8 are assumed. Within this chapter there are the following dependencies:
Complementary references include Mirsky (1955), Gantmacher (1959), Bellman (1969), and Horn and Johnson (1991). Some Matlab functions important to this chapter are \texttt{expm}, \texttt{expm1}, \texttt{expm2}, \texttt{expm3}, \texttt{logm}, \texttt{sqrtm}, and \texttt{funm}.

### 11.1 Eigenvalue Methods

Given an \( n \)-by-\( n \) matrix \( A \) and a scalar function \( f(z) \), there are several ways to define the \textit{matrix function} \( f(A) \). A very informal definition might be to substitute "\( A \)" for "\( z \)" in the formula for \( f(z) \). For example, if \( p(z) = 1 + z \) and \( r(z) = (1 - (z/2))^{-1}(1 + (z/2)) \) for \( z \neq 2 \), then it is certainly reasonable to define \( p(A) \) and \( r(A) \) by

\[
p(A) = I + A
\]

and

\[
r(A) = \left(I - \frac{A}{2}\right)^{-1}\left(I + \frac{A}{2}\right) \quad 2 \notin \lambda(A).
\]

"\( A \)-for-\( z \)" substitution also works for transcendental functions, i.e.,

\[
e^A = \sum_{k=0}^{\infty} \frac{A^k}{k!}.
\]

To make subsequent algorithmic developments precise, however, we need a more precise definition of \( f(A) \).

#### 11.1.1 A Definition

There are many ways to establish rigorously the notion of a matrix function. See Rinehart (1955). Perhaps the most elegant approach is in terms of a line integral. Suppose \( f(z) \) is analytic inside on a closed contour \( \Gamma \) which encircles \( \lambda(A) \). We define \( f(A) \) to be the matrix

\[
f(A) = \frac{1}{2\pi i} \oint_{\Gamma} f(z)(zI - A)^{-1}dz.
\]  \hspace{1cm} (11.1.1)

This definition is immediately recognized as a matrix version of the Cauchy integral theorem. The integral is defined on an element-by-element basis:

\[
f(A) = (f_{kj}) \implies f_{kj} = \frac{1}{2\pi i} \oint_{\Gamma} f(z)e_k^T(zI - A)^{-1}e_jdz.
\]

Notice that the entries of \( (zI - A)^{-1} \) are analytic on \( \Gamma \) and that \( f(A) \) is defined whenever \( f(z) \) is analytic in a neighborhood of \( \lambda(A) \).
11.1.2 The Jordan Characterization

Although fairly useless from the computational point of view, the definition (11.1.1) can be used to derive more practical characterizations of \( f(A) \). For example, if \( f(A) \) is defined and

\[
A = XBX^{-1} = X\text{diag}(B_1, \ldots, B_p)X^{-1}, \quad B_i \in \mathbb{C}^{m_i \times n_i}
\]

then it is easy to verify that

\[
f(A) = Xf(B)X^{-1} = X\text{diag}(f(B_1), \ldots, f(B_p))X^{-1}.
\] (11.1.2)

For the case when the \( B_i \) are Jordan blocks we obtain the following:

**Theorem 11.1.1** Let \( X^{-1}AX = \text{diag}(J_1, \ldots, J_p) \) be the Jordan canonical form (JCF) of \( A \in \mathbb{C}^{n \times n} \) with

\[
J_i = \begin{bmatrix}
\lambda_i & 1 & \cdots & \cdots & 0 \\
0 & \lambda_i & 1 & \cdots & \\
\vdots & \ddots & \ddots & \ddots & \\
\vdots & \ddots & \ddots & \ddots & 1 \\
0 & \cdots & \cdots & 0 & \lambda_i
\end{bmatrix}
\]

being an \( m_i \)-by-\( m_i \) Jordan block. If \( f(z) \) is analytic on an open set containing \( \lambda(A) \), then

\[
f(A) = X\text{diag}(f(J_1), \ldots, f(J_p))X^{-1}
\]

where

\[
f(J_i) = \begin{bmatrix}
f(\lambda_i) & f^{(1)}(\lambda_i) & \cdots & \frac{f^{(m_i-1)}(\lambda_i)}{(m_i-1)!} \\
0 & f(\lambda_i) & \ddots & \cdots \\
\vdots & \ddots & \ddots & \ddots \\
\vdots & \ddots & \ddots & f^{(1)}(\lambda_i) \\
0 & \cdots & \cdots & f(\lambda_i)
\end{bmatrix}.
\]

**Proof.** In view of the remarks preceding the statement of the theorem, it suffices to examine \( f(G) \) where

\[
G = \lambda I + E \quad E = (\delta_{i,j-1})
\]

is a \( q \)-by-\( q \) Jordan block. Suppose \((zI - G)\) is nonsingular. Since

\[
(zI - G)^{-1} = \sum_{k=0}^{q-1} \frac{E^k}{(z - \lambda)^{k+1}}
\]
it follows from Cauchy’s integral theorem that
\[
f(G) = \sum_{k=0}^{q-1} \left[ \frac{1}{2\pi i} \oint_{\Gamma} \frac{f(z)}{(z - \lambda)^{k+1}} \, dz \right] E^k = \sum_{k=0}^{q-1} \frac{f^{(k)}(\lambda)}{k!} E^k.
\]
The theorem follows from the observation that \( E^k = (\delta_{i,j-k}). \)

**Corollary 11.1.2** If \( A \in \mathbb{C}^{n \times n} \), \( A = X \text{diag}(\lambda_1, \ldots, \lambda_n) X^{-1} \), and \( f(A) \) is defined, then
\[
f(A) = X \text{diag}(f(\lambda_1), \ldots, f(\lambda_n)) X^{-1}.
\]

**Proof.** The Jordan blocks are all 1-by-1. \( \square \)

These results illustrate the close connection between \( f(A) \) and the eigensystem of \( A \). Unfortunately, the JCF approach to the matrix function problem has dubious computational merit unless \( A \) is diagonalizable with a well-conditioned matrix of eigenvectors. Indeed, rounding errors of order \( \kappa_2(X) \) can be expected to contaminate the computed result, since a linear system involving the matrix \( X \) must be solved. The following example suggests that ill-conditioned similarity transformations should be avoided when computing a function of a matrix.

**Example 11.1.1** If
\[
A = \begin{bmatrix} 1 + 10^{-5} & 1 \\ 0 & 1 - 10^{-5} \end{bmatrix},
\]
then any matrix of eigenvectors is a column scaled version of
\[
X = \begin{bmatrix} 1 & -1 \\ 0 & 2(1 - 10^{-5}) \end{bmatrix}
\]
and has a 2-norm condition number of order 10^5. Using a computer with machine precision \( u \approx 10^{-7} \) we find
\[
f([X^{-1} \text{diag}(\exp(1 + 10^{-5}), \exp(1 - 10^{-5}))] X] = \begin{bmatrix} 2.718307 & 2.750000 \\ 0.000000 & 2.718254 \end{bmatrix}
\]
while
\[
e^A = \begin{bmatrix} 2.718309 & 2.718282 \\ 0.000000 & 2.718255 \end{bmatrix}.
\]

### 11.1.3 A Schur Decomposition Approach

Some of the difficulties associated with the Jordan approach to the matrix function problem can be circumvented by relying upon the Schur decomposition. If \( A = QTQ^H \) is the Schur decomposition of \( A \), then
\[
f(A) = Qf(T)Q^H.
\]

For this to be effective, we need an algorithm for computing functions of upper triangular matrices. Unfortunately, an explicit expression for \( f(T) \) is very complicated as the following theorem shows.
Theorem 11.1.3 Let $T = (t_{ij})$ be an $n$-by-$n$ upper triangular matrix with $\lambda_i = t_{ii}$ and assume $f(T)$ is defined. If $f(T) = (f_{ij})$, then $f_{ij} = 0$ if $i > j$, $f_{ij} = f(\lambda_i)$ for $i = j$, and for all $i < j$ we have

$$f_{ij} = \sum_{(s_0, \ldots, s_k) \in S_{ij}} t_{s_0, s_1} t_{s_1, s_2} \cdots t_{s_{k-1}, s_k} f[\lambda_{s_0}, \ldots, \lambda_{s_k}],$$

where $S_{ij}$ is the set of all strictly increasing sequences of integers that start at $i$ and end at $j$ and $f[\lambda_{s_0}, \ldots, \lambda_{s_k}]$ is the $k$th order divided difference of $f$ at $\{\lambda_{s_0}, \ldots, \lambda_{s_k}\}$.

Proof. See Descloix (1963), Davis (1973), or Van Loan (1975). □

Computing $f(T)$ via Theorem 11.1.3 would require $O(2^n)$ flops. Fortunately, Parlett (1974) has derived an elegant recursive method for determining the strictly upper triangular portion of the matrix $F = f(T)$. It requires only $2n^3/3$ flops and can be derived from the following commutivity result:

$$FT = TF. \quad (11.1.3)$$

Indeed, by comparing $(i, j)$ entries in this equation, we find

$$\sum_{k=i}^{j} f_{ik} t_{kj} = \sum_{k=i}^{j} t_{ik} f_{kj} \quad j > i$$

and thus, if $t_{ii}$ and $t_{jj}$ are distinct,

$$f_{ij} = t_{ij} \frac{f_{jj} - f_{ii}}{t_{jj} - t_{ii}} + \sum_{k=i+1}^{j-1} \frac{t_{ik} f_{kj} - f_{ik} t_{kj}}{t_{jj} - t_{ii}}. \quad (11.1.4)$$

From this we conclude that $f_{ij}$ is a linear combination of its neighbors to its left and below in the matrix $F$. For example, the entry $f_{25}$ depends upon $f_{22}, f_{23}, f_{24}, f_{55}, f_{45},$ and $f_{35}$. Because of this, the entire upper triangular portion of $F$ can be computed one superdiagonal at a time beginning with the diagonal, $f(t_{11}), \ldots, f(t_{nn})$. The complete procedure is as follows:

Algorithm 11.1.1 This algorithm computes the matrix function $F = f(T)$ where $T$ is upper triangular with distinct eigenvalues and $f$ is defined on $\lambda(T)$.

for $i = 1:n$

$$f_{ii} = f(t_{ii})$$

end
for \( p = 1:n-1 \)
for \( i = 1:n-p \)
\[
\begin{align*}
&j = i + p \\
&s = t_{ij}(f_{jj} - f_{ii}) \\
&\text{for } k = i + 1:j - 1 \\
&\quad s = s + t_{ik}f_{kj} - f_{ik}t_{kj}
\end{align*}
\]
end
\[
 f_{ij} = s/(t_{jj} - t_{ii})
\]
end

This algorithm requires \( 2n^3/3 \) flops. Assuming that \( T = QAQ^H \) is the Schur form of \( A \), \( f(A) = QFQ^H \) where \( F = f(T) \). Clearly, most of the work in computing \( f(A) \) by this approach is in the computation of the Schur decomposition, unless \( f \) is extremely expensive to evaluate.

**Example 11.1.2** If

\[
T = \begin{bmatrix} 1 & 2 & 3 \\ 0 & 3 & 4 \\ 0 & 0 & 5 \end{bmatrix}
\]

and \( f(z) = (1 + z)/z \) then \( F = (f_{ij}) = f(T) \) is defined by

\[
\begin{align*}
 f_{11} &= (1 + 1)/1 = 2 \\
f_{22} &= (1 + 3)/3 = 4/3 \\
f_{33} &= (1 + 5)/5 = 6/5 \\
f_{12} &= t_{12}(f_{22} - f_{11})/(t_{22} - t_{11}) = -2/3 \\
f_{23} &= t_{23}(f_{33} - f_{22})/(t_{33} - t_{22}) = -4/15 \\
f_{13} &= [t_{13}(f_{33} - f_{11}) + (t_{12}f_{23} - f_{12}t_{23})]/(t_{33} - t_{11}) = -1/15.
\end{align*}
\]

### 11.1.4 A Block Schur Approach

If \( A \) has close or multiple eigenvalues, then Algorithm 11.1.1 leads to poor results. In this case, it is advisable to use a block version of Algorithm 11.1.1. We outline such a procedure due to Parlett (1974a). The first step is to choose \( Q \) in the Schur decomposition such that close or multiple eigenvalues are clustered in blocks \( T_{11}, \ldots, T_{pp} \) along the diagonal of \( T \). In particular, we must compute a partitioning

\[
T = \begin{bmatrix} T_{11} & T_{12} & \cdots & T_{1p} \\ 0 & T_{22} & \cdots & T_{2p} \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & T_{pp} \end{bmatrix} \quad F = \begin{bmatrix} F_{11} & F_{12} & \cdots & F_{1p} \\ 0 & F_{22} & \cdots & F_{2p} \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & F_{pp} \end{bmatrix}
\]

where \( \lambda(T_{ii}) \cap \lambda(T_{jj}) \neq \emptyset, i \neq j \). The actual determination of the block sizes can be done using the methods of §7.6.
Next, we compute the submatrices $F_{ii} = f(T_{ii})$ for $i = 1:p$. Since the eigenvalues of $T_{ii}$ are presumably close, these calculations require special methods. (Some possibilities are discussed in the next two sections.) Once the diagonal blocks of $F$ are known, the blocks in the strict upper triangle of $F$ can be found recursively, as in the scalar case. To derive the governing equations, we equate $(i,j)$ blocks in $FT = TF$ for $i < j$ and obtain the following generalization of (11.1.4):

$$F_{ij}T_{jj} - T_{ii}F_{ij} = T_{ij}F_{jj} - F_{ii}T_{ij} + \sum_{k=i+1}^{j-1} (T_{ik}F_{kj} - F_{tk}T_{kj}). \quad (11.1.5)$$

This is a linear system whose unknowns are the elements of the block $F_{ij}$ and whose right-hand side is "known" if we compute the $F_{ij}$ one block super-diagonal at a time. We can solve (11.1.5) using the Bartels-Stewart algorithm (Algorithm 7.6.2).

The block Schur approach described here is useful when computing real functions of real matrices. After computing the real Schur form $A = QTQ^T$, the block algorithm can be invoked in order to handle the 2-by-2 bumps along the diagonal of $T$.

Problems

P11.1.1 Using the definition (11.1.1) show that (a) $Af(A) = f(A)A$, (b) $f(A)$ is upper triangular if $A$ is upper triangular, and (c) $f(A)$ is Hermitian if $A$ is Hermitian.

P11.1.2 Rewrite Algorithm 11.1.1 so that $f(T)$ is computed column by column.

P11.1.3 Suppose $A = X\text{diag}(\lambda_i)X^{-1}$ where $X = [x_1, \ldots, x_n]$ and $X^{-1} = [y_1, \ldots, y_n]^H$. Show that if $f(A)$ is defined, then

$$f(A) = \sum_{k=1}^{n} f(\lambda_i) x_i y_i^H.$$ 

P11.1.4 Show that

$$T = \begin{bmatrix} T_{11} & T_{12} \\ 0 & T_{22} \end{bmatrix} \begin{bmatrix} p \\ q \end{bmatrix} \Rightarrow f(T) = \begin{bmatrix} F_{11} & F_{12} \\ 0 & F_{22} \end{bmatrix} \begin{bmatrix} p \\ q \end{bmatrix}$$

where $F_{11} = f(T_{11})$ and $F_{22} = f(T_{22})$. Assume $f(T)$ is defined.

Notes and References for Sec. 11.1

The contour integral representation of $f(A)$ given in the text is useful in functional analysis because of its generality. See

As we discussed, other definitions of $f(A)$ are possible. However, for the matrix functions typically encountered in practice, all these definitions are equivalent. See

Various aspects of the Jordan representation are detailed in

The following are concerned with the Schur decomposition and its relationship to the \( f(A) \) problem:

Algorithm 11.1.1 and the various computational difficulties that arise when it is applied to a matrix having close or repeated eigenvalues are discussed in

A compromise between the Jordan and Schur approaches to the \( f(A) \) problem results if \( A \) is reduced to block diagonal form as described in §7.6.3. See

The sensitivity of matrix functions to perturbation is discussed in

A theme in this chapter is that if \( A \) is nonnormal, then there is more to computing \( f(A) \) than just computing \( f(z) \) on \( \lambda(A) \). The pseudo-eigenvalue concept is a way of understanding this phenomena. See

More details are offered in §11.3.4.

## 11.2 Approximation Methods

We now consider a class of methods for computing matrix functions which at first glance do not appear to involve eigenvalues. These techniques are based on the idea that if \( g(z) \) approximates \( f(z) \) on \( \lambda(A) \), then \( f(A) \) approximates \( g(A) \), e.g.,

\[
e^A \approx I + A + \frac{A^2}{2!} + \cdots + \frac{A^q}{q!}.
\]
We begin by bounding $\| f(A) - g(A) \|$ using the Jordan and Schur matrix function representations. We follow this discussion with some comments on the evaluation of matrix polynomials.

### 11.2.1 A Jordan Analysis

The Jordan representation of matrix functions (Theorem 11.1.1) can be used to bound the error in an approximant $g(A)$ of $f(A)$.

**Theorem 11.2.1** Let $X^{-1}AX = \text{diag}(J_1, \ldots, J_p)$ be the JCF of $A \in \mathbb{C}^{n \times n}$ with

$$
J_i = \begin{bmatrix}
\lambda_i & 1 & \cdots & \cdots & 0 \\
0 & \lambda_i & 1 & \cdots & \\
\vdots & \vdots & \ddots & \ddots & \vdots \\
\vdots & \vdots & \ddots & \ddots & 1 \\
0 & \cdots & \cdots & \cdots & \lambda_i
\end{bmatrix}
$$

being an $m_i$-by-$m_i$ Jordan block. If $f(z)$ and $g(z)$ are analytic on an open set containing $\lambda(A)$, then

$$
\| f(A) - g(A) \|_2 \leq \kappa_2(X) \max_{0 \leq r \leq m_i - 1} \frac{|f^{(r)}(\lambda_i) - g^{(r)}(\lambda_i)|}{r!}.
$$

**Proof.** Defining $h(z) = f(z) - g(z)$ we have

$$
\| f(A) - g(A) \|_2 = \| X \text{diag}(h(J_1), \ldots, h(J_p))X^{-1} \|_2 \\
\leq \kappa_2(X) \max_{1 \leq i \leq p} \| h(J_i) \|_2.
$$

Using Theorem 11.1.1 and equation (2.3.8) we conclude that

$$
\| h(J_i) \|_2 \leq m_i \max_{0 \leq r \leq m_i - 1} \frac{|h^{(r)}(\lambda_i)|}{r!}
$$

thereby proving the theorem. □

### 11.2.2 A Schur Analysis

If we rely on the Schur instead of the Jordan decomposition we obtain an alternative bound.
Theorem 11.2.2 Let $Q^H A Q = T = \text{diag}(\lambda_i) + N$ be the Schur decomposition of $A \in \mathbb{C}^{n \times n}$, with $N$ being the strictly upper triangular portion of $T$. If $f(z)$ and $g(z)$ are analytic on a closed convex set $\Omega$ whose interior contains $\lambda(A)$, then

$$
\| f(A) - g(A) \|_F \leq \sum_{r=0}^{n-1} \delta_r \frac{\| N^r \|_F}{r!}
$$

where

$$
\delta_r = \sup_{z \in \Omega} |f^{(r)}(z) - g^{(r)}(z)|.
$$

Proof. Let $h(z) = f(z) - g(z)$ and set $H = (h_{ij}) = h(A)$. Let $S^{(r)}_{ij}$ denote the set of strictly increasing integer sequences $(s_0, \ldots, s_r)$ with the property that $s_0 = i$ and $s_r = j$. Notice that

$$
S_{ij} = \bigcup_{r=1}^{j-i} S^{(r)}_{ij}
$$

and so from Theorem 11.1.3, we obtain the following for all $i < j$:

$$
h_{ij} = \sum_{r=1}^{j-1} \sum_{s \in S^{(r)}_{ij}} n_{s_0, s_1} n_{s_1, s_2} \cdots n_{s_{r-1}, s_r} h[\lambda_{s_0}, \ldots, \lambda_{s_r}].
$$

Now since $\Omega$ is convex and $h$ analytic, we have

$$
|h[\lambda_{s_0}, \ldots, \lambda_{s_r}]| \leq \sup_{z \in \Omega} \frac{|h^{(r)}(z)|}{r!} = \frac{\delta_r}{r!}.
$$

(11.2.1)

Furthermore if $|N|^r = (n_{ij}^{(r)})$ for $r \geq 1$, then it can be shown that

$$
n^{(r)}_{ij} = \begin{cases} 
0 & j < i + r \\
\sum_{s \in S^{(r)}_{ij}} |n_{s_0, s_1} n_{s_1, s_2} \cdots n_{s_{r-1}, s_r}| & j \geq i + r
\end{cases}
$$

(11.2.2)

The theorem now follows by taking absolute values in the expression for $h_{ij}$ and then using (11.2.1) and (11.2.2). □

The bounds in the above theorems suggest that there is more to approximating $f(A)$ than just approximating $f(z)$ on the spectrum of $A$. In particular, we see that if the eigensystem of $A$ is ill-conditioned and/or $A$'s departure
from normality is large, then the discrepancy between \( f(A) \) and \( g(A) \) may be considerably larger than the maximum of \( |f(z) - g(z)| \) on \( \lambda(A) \). Thus, even though approximation methods avoid eigenvalue computations, they appear to be influenced by the structure of \( A \)'s eigensystem, a point that we pursue further in the next section.

Example 11.2.1 Suppose

\[
A = \begin{bmatrix} -0.1 & 1 & 1 \\ 0 & 0 & 1 \\ 0 & 0 & 0.01 \end{bmatrix}.
\]

If \( f(z) = e^z \) and \( g(z) = 1 + z + z^2/2 \), then \( \| f(A) - g(A) \| \approx 10^{-5} \) in either the Frobenius norm or the 2-norm. Since \( \kappa_2(X) \approx 10^7 \), the error predicted by Theorem 11.2.1 is \( O(1) \), rather pessimistic. On the other hand, the error predicted by the Schur decomposition approach is \( O(10^{-2}) \).

11.2.3 Taylor Approximants

A popular way of approximating a matrix function such as \( e^A \) is through the truncation of its Taylor series. The conditions under which a matrix function \( f(A) \) has a Taylor series representation are easily established.

Theorem 11.2.3 If \( f(z) \) has a power series representation

\[
f(z) = \sum_{k=0}^{\infty} c_k z^k
\]
on an open disk containing \( \lambda(A) \), then

\[
f(A) = \sum_{k=0}^{\infty} c_k A^k.
\]

Proof. We prove the theorem for the case when \( A \) is diagonalizable. In P11.2.1, we give a hint as to how to proceed without this assumption. Suppose \( X^{-1}AX = D = \text{diag}(\lambda_1, \ldots, \lambda_n) \). Using Corollary 11.1.2, we have

\[
f(A) = X \text{diag}(f(\lambda_1), \ldots, f(\lambda_n)) X^{-1}
\]

\[
= X \text{diag} \left( \sum_{k=0}^{\infty} c_k \lambda_1^k, \ldots, \sum_{k=0}^{\infty} c_k \lambda_n^k \right) X^{-1}
\]

\[
= X \left( \sum_{k=0}^{\infty} c_k D^k \right) X^{-1} = \sum_{k=0}^{\infty} c_k (XD^{-1})^k = \sum_{k=0}^{\infty} c_k A^k. \quad \square
\]
Several important transcendental matrix functions have particularly simple series representations:

\[
\log(I - A) = \sum_{k=1}^{\infty} \frac{A^k}{k} \quad |\lambda| < 1, \lambda \in \lambda(A)
\]

\[
\sin(A) = \sum_{k=0}^{\infty} (-1)^k \frac{A^{2k+1}}{(2k+1)!}
\]

\[
\cos(A) = \sum_{k=0}^{\infty} (-1)^k \frac{A^{2k}}{(2k)!}.
\]

The following theorem bounds the errors that arise when matrix functions such as these are approximated via truncated Taylor series.

**Theorem 11.2.4** If \( f(z) \) has the Taylor series

\[
f(z) = \sum_{k=0}^{\infty} \alpha_k z^k
\]

on an open disk containing the eigenvalues of \( A \in \mathbb{C}^{n \times n} \), then

\[
\| f(A) - \sum_{k=0}^{q} \alpha_k A^k \|_2 \leq \frac{n}{(q + 1)!} \max_{0 \leq s \leq 1} \| A^{q+1} f^{(q+1)}(As) \|_2.
\]

**Proof.** Define the matrix \( E(s) \) by

\[
f(As) = \sum_{k=0}^{q} \alpha_k (As)^k + E(s) \quad 0 \leq s \leq 1.
\]  

(11.2.3)

If \( f_{ij} \) is the \((i, j)\) entry of \( f(As) \), then it is necessarily analytic and so

\[
f_{ij}(s) = \left( \sum_{k=0}^{q} \frac{f_{ij}^{(k)}(0)}{k!} s^k \right) + \frac{f_{ij}^{(q+1)}(\varepsilon_{ij})}{(q + 1)!} s^{q+1}
\]  

(11.2.4)

where \( \varepsilon_{ij} \) satisfies \( 0 \leq \varepsilon_{ij} \leq s \leq 1 \).

By comparing powers of \( s \) in (11.2.3) and (11.2.4) we conclude that \( e_{ij}(s) \), the \((i, j)\) entry of \( E(s) \), has the form

\[
e_{ij}(s) = \frac{f_{ij}^{(q+1)}(\varepsilon_{ij})}{(q + 1)!} s^{q+1}.
\]
Now $f^{(q+1)}_{ij}(s)$ is the $(i,j)$ entry of $A^{q+1} f^{(q+1)}(As)$ and therefore

$$
|e_{ij}(s)| \leq \max_{0 \leq s \leq 1} \frac{f^{(q+1)}_{ij}(s)}{(q+1)!} \leq \max_{0 \leq s \leq 1} \frac{\|A^{q+1} f^{(q+1)}(As)\|_2}{(q+1)!}.
$$

The theorem now follows by applying (2.3.8). □

Example 11.2.2 If

$$
A = \begin{bmatrix} -49 & 24 \\ -64 & 31 \end{bmatrix},
$$

then

$$
e^A = \begin{bmatrix} -0.735759 & 0.0551819 \\ -1.471518 & 1.103638 \end{bmatrix}.
$$

For $q = 59$, Theorem 11.2.4 predicts that

$$
\| e^A - \sum_{k=0}^{59} \frac{A^k}{k!} \|_2 \leq \frac{n}{(q+1)!} \max_{0 \leq s \leq 1} \| A^{q+1} e^{As} \|_2 \leq 10^{-60}.
$$

However, if $u \approx 10^{-7}$, then we find

$$
\{l \left( \sum_{k=0}^{59} \frac{A^k}{k!} \right) \} = \begin{bmatrix} -22.25880 & -1.4322766 \\ -61.49931 & -3.474280 \end{bmatrix}.
$$

The problem is that some of the partial sums have large elements. For example, $I + \cdots + A^{17}/17!$ has entries of order $10^7$. Since the machine precision is approximately $10^{-7}$, rounding errors larger than the norm of the solution are sustained.

Example 11.2.2 highlights a shortcoming of truncated Taylor series approximation: It tends to be worthwhile only near the origin. The problem can sometimes be circumvented through a change of scale. For example, by repeated application of the double angle formulae:

$$
\cos(2A) = 2\cos(A)^2 - I \quad \sin(2A) = 2\sin(A)\cos(A)
$$

it is possible to "build up" the sine and cosine of a matrix from suitably truncated Taylor series approximates:

$$
S_0 = \text{Taylor approximate to } \sin(A/2^0) \\
C_0 = \text{Taylor approximate to } \cos(A/2^0) \\
\text{for } j = 1:k \\
S_j = 2S_{j-1}C_{j-1} \\
C_j = 2C_{j-1}^2 - I \\
\text{end}
$$

Here $k$ is a positive integer chosen so that, say, $\| A \|_\infty \approx 2^k$. See Serlin and Blalock (1979).
11.2.4 Evaluating Matrix Polynomials

Since the approximation of transcendental matrix functions so often involves the evaluation of polynomials, it is worthwhile to look at the details of computing

\[ p(A) = b_0 I + b_1 A + \ldots + b_q A^q \]

where the scalars \( b_0, \ldots, b_q \in \mathbb{R} \) are given. The most obvious approach is to invoke Horner's scheme:

**Algorithm 11.2.1** Given a matrix \( A \) and \( b(0:q) \), the following algorithm computes \( F = b_q A^q + \ldots + b_1 A + b_0 I \).

\[
\begin{align*}
F &= b_q A + b_{q-1} I \\
\text{for } k &= q - 2: -1:0 \\
F &= AF + b_k I \\
\end{align*}
\]

This requires \( q - 1 \) matrix multiplications. However, unlike the scalar case, this summation process is not optimal. To see why, suppose \( q = 9 \) and observe that

\[
p(A) = A^3 (A^3 (b_9 A^3 + (b_8 A^2 + b_7 A + b_6 I)) + (b_5 A^2 + b_4 A + b_3 I)) + b_2 A^2 + b_1 A + b_0 I.
\]

Thus, \( F = p(A) \) can be evaluated with only four matrix multiplies:

\[
\begin{align*}
A_2 &= A^2 \\
A_3 &= A A_2 \\
F_1 &= b_9 A_3 + b_8 A_2 + b_7 A + b_6 I \\
F_2 &= A_3 F_1 + b_5 A_2 + b_4 A + b_3 I \\
F &= A_3 F_2 + b_2 A_2 + b_1 A + b_0 I.
\end{align*}
\]

In general, if \( s \) is any integer satisfying \( 1 \leq s \leq \sqrt{q} \) then

\[
p(A) = \sum_{k=0}^{r} B_k (A^s)^k \quad \text{if } r = \text{floor}(q/s) \quad (11.2.5)
\]

where

\[
B_k = \begin{cases} 
    b_{sk+s-1} A^{s-1} + \cdots + b_{sk+1} A + b_{sk} I & k = 0:r - 1 \\
    b_q A^{q-sr} + \cdots + b_{sr+1} A + b_k I & k = r.
\end{cases}
\]

Once \( A^2, \ldots, A^s \) are computed, Horner's rule can be applied to (11.2.5) and the net result is that \( p(A) \) can be computed with \( s + r - 1 \) matrix
multiplies. By choosing \( s = \text{floor}(\sqrt{q}) \), the number of matrix multiplies is approximately minimized. This technique is discussed in Paterson and Stockmeyer (1973). Van Loan (1978) shows how the procedure can be implemented without storage arrays for \( A^2, \ldots, A^s \).

### 11.2.5 Computing Powers of a Matrix

The problem of raising a matrix to a given power deserves special mention. Suppose it is required to compute \( A^{13} \). Noting that \( A^4 = (A^2)^2 \), \( A^8 = (A^4)^2 \) and \( A^{13} = A^8A^4A \), we see that this can be accomplished with just 5 matrix multiplications. In general we have

**Algorithm 11.2.2 (Binary Powering)** Given a positive integer \( s \) and \( A \in \mathbb{R}^{n \times n} \), the following algorithm computes \( F = A^s \) where \( s \) is a positive integer and \( A \in \mathbb{R}^{n \times n} \).

\[
\begin{align*}
\text{Let } s &= \sum_{k=0}^{t} \beta_k 2^k \text{ be the binary expansion of } s \text{ with } \beta_t \neq 0. \\
Z &= A; \quad q = 0 \\
\text{while } \beta_q &= 0 \\
Z &= Z^2; \quad q = q + 1 \\
\text{end} \\
F &= Z \\
\text{for } k &= q + 1:t \\
Z &= Z^2 \\
\text{if } \beta_k \neq 0 \\
F &= FZ \\
\text{end} \\
\text{end}
\end{align*}
\]

This algorithm requires at most \( 2 \cdot \text{floor} [\log_2(s)] \) matrix multiplies. If \( s \) is a power of 2, then only \( \log_2(s) \) matrix multiplies are needed.

### 11.2.6 Integrating Matrix Functions

We conclude this section with some remarks on the integration of matrix functions. Suppose \( f(At) \) is defined for all \( t \in [a, b] \) and that we wish to compute

\[
F = \int_a^b f(At)dt.
\]

As in (11.1.1) the integration is on an element-by-element basis.
Ordinary quadrature rules can be applied to $F$. For example, with Simpson's rule, we have

$$ F \approx \tilde{F} = \frac{h}{3} \sum_{k=0}^{m} w_k f(A(a + kh)) $$  

(11.2.6)

where $m$ is even, $h = (b - a)/m$ and

$$ w_k = \begin{cases} 1 & k = 0, m \\ 4 & k \text{ odd} \\ 2 & k \text{ even}, k \neq 0, m. \end{cases} $$

If $(d^4/dz^4)f(zt) = f^{(4)}(zt)$ is continuous for $t \in [a, b]$ and if $f^{(4)}(At)$ is defined on this same interval, then it can be shown that $\tilde{F} = F + E$ where

$$ \| E \|_2 \leq \frac{nh^4(b - a)}{180} \max_{a \leq t \leq b} \| f^{(4)}(At) \|_2. $$  

(11.2.7)

Let $f_{ij}$ and $e_{ij}$ denote the $(i, j)$ entries of $F$ and $E$, respectively. Under the above assumptions we can apply the standard error bounds for Simpson's rule and obtain

$$ |e_{ij}| \leq \frac{h^4(b - a)}{180} \max_{a \leq t \leq b} |e_i^T f^{(4)}(At)e_j|. $$

The inequality (11.2.7) now follows since $\| E \|_2 \leq n \max |e_{ij}|$ and

$$ \max_{a \leq t \leq b} |e_i^T f^{(4)}(At)e_j| \leq \max_{a \leq t \leq b} \| f^{(4)}(At) \|_2. $$

Of course, in the practical application of (11.2.6), the function evaluations $f(A(a + kh))$ normally have to be approximated. Thus, the overall error involves the error in approximating $f(A(a + kh))$ as well as the Simpson rule error.

**Problems**

P11.2.1 (a) Suppose $G = \lambda I + E$ is a $p$-by-$p$ Jordan block, where $E = (\delta_{i,j} - 1)$. Show that

$$ (\lambda I + E)^k = \sum_{j=0}^{\min(p-1,k)} \binom{k}{j} \lambda^{k-j} E^j. $$

(b) Use (a) and Theorem 11.1.1 to prove Theorem 11.2.3.

P11.2.2 Verify (11.2.2).

P11.2.3 Show that if $\| A \|_2 < 1$, then $\log(I + A)$ exists and satisfies the bound
11.2. Approximation Methods

\[ \| \log(I + A) \|_2 \leq \| A \|_2/(1 - \| A \|_2). \]

P11.2.4 Let \( A \) be an \( n \)-by-\( n \) symmetric positive definite matrix. (a) Show that there exists a unique symmetric positive definite \( X \) such that \( A = X^2 \). (b) Show that if \( X_0 = I \) and \( X_{k+1} = (X_k + AX_k^{-1})/2 \) then \( X_k \rightarrow \sqrt{A} \) quadratically where \( \sqrt{A} \) denotes the matrix \( X \) in part (a).

P11.2.5 Specialize Algorithm 11.2.1 to the case when \( A \) is symmetric. Repeat for the case when \( A \) is upper triangular. In both instances, give the associated flop counts.

P11.2.6 Show that \( X(t) = C_1 \cos(t\sqrt{A}) + C_2 \sqrt{A}^{-1}\sin(t\sqrt{A}) \) solves the initial value problem \( \dot{X}(t) = -AX(t), X(0) = C_1, \dot{X}(0) = C_2 \). Assume that \( A \) is symmetric positive definite.

P11.2.7 Using Theorem 11.2.4, bound the error in the approximations:

\[ \sin(A) \approx \sum_{k=0}^{q} (-1)^k \frac{A^{2k+1}}{(2k + 1)!} \quad \cos(A) \approx \sum_{k=0}^{q} (-1)^k \frac{A^{2k}}{(2k)!}. \]

P11.2.8 Suppose \( A \in \mathbb{R}^{n \times n} \) is nonsingular and \( X_0 \in \mathbb{R}^{n \times n} \) is given. The iteration defined by

\[ X_{k+1} = X_k(2I - AX_k) \]

is the matrix analog of Newton's method applied to the function \( f(x) = a - (1/x) \). Use the SVD to analyze this iteration. Do the iterates converge to \( A^{-1} \)? Discuss the choice of \( X_0 \).

Notes and References for Sec. 11.2

The optimality of Horner's rule for polynomial evaluation is discussed in

The Horner evaluation of matrix polynomials is analyzed in

Other aspects of matrix function computation are discussed in

The Newton and Language representations for \( f(A) \) and their relationship to other matrix function definitions is discussed in

The "double angle" method for computing the cosine of matrix is analyzed in

The square root is a particularly important matrix function. See §4.2.10. Several approaches are possible:

### 11.3 The Matrix Exponential

One of the most frequently computed matrix functions is the exponential

\[ e^{At} = \sum_{k=0}^{\infty} \frac{(At)^k}{k!} . \]

Numerous algorithms for computing \( e^{At} \) have been proposed, but most of them are of dubious numerical quality, as is pointed out in the survey article by Moler and Van Loan (1978). In order to illustrate what the computational difficulties are, we present a "scaling and squaring" method based upon Padé approximation. A brief analysis of the method follows that involves some \( e^{At} \) perturbation theory and comments about the shortcomings of eigenanalysis in settings where non-normality prevails.

#### 11.3.1 A Padé Approximation Method

Following the discussion in §11.2, if \( g(z) \approx e^z \), then \( g(A) \approx e^A \). A very useful class of approximants for this purpose are the Padé functions defined by

\[ R_{pq}(z) = D_{pq}(z)^{-1} N_{pq}(z), \]

where

\[ N_{pq}(z) = \sum_{k=0}^{p} \frac{(p + q - k)!p!}{(p + q)!k!(p - k)!} z^k \]

and

\[ D_{pq}(z) = \sum_{k=0}^{q} \frac{(p + q - k)!q!}{(p + q)!k!(q - k)!} (-z)^k . \]

Notice that \( R_{p0}(z) = 1 + z + \cdots + z^p/p! \) is the \( p \)th order Taylor polynomial.
11.3. The Matrix Exponential

Unfortunately, the Padé approximants are good only near the origin, as the following identity reveals:

\[
e^{A} = R_{pq}(A) + \frac{(-1)^{q}}{(p+q)!} A^{p+q+1} D_{pq}(A)^{-1} \int_{0}^{1} u^{p}(1-u)^{q} e^{A(1-u)} du. \tag{11.3.1}
\]

However, this problem can be overcome by exploiting the fact that \(e^{A} = (e^{A/m})^{m}\). In particular, we can scale \(A\) by \(m\) such that \(F_{pq} = R_{pq}(A/m)\) is a suitably accurate approximation to \(e^{A/m}\). We then compute \(F_{pq}^{m}\) using Algorithm 11.2.2. If \(m\) is a power of two, then this amounts to repeated squaring and so is very efficient. The success of the overall procedure depends on the accuracy of the approximant

\[
F_{pq} = \left( R_{pq} \left( \frac{A}{2^{j}} \right) \right)^{2^{j}}.
\]

In Moler and Van Loan (1978) it is shown that if

\[
\frac{\| A \|_{\infty}}{2^{j}} \leq \frac{1}{2},
\]

then there exists an \(E \in \mathbb{R}^{n \times n}\) such that

\[
\begin{align*}
F_{pq} &= e^{A+E} \\
AE &= EA \\
\| E \|_{\infty} &\leq \varepsilon(p,q) \| A \|_{\infty} \\
\varepsilon(p,q) &= 2^{3\alpha(p+q)} \frac{p!q!}{(p+q)!(p+q+1)!}. 
\end{align*}
\]

These results form the basis of an effective \(e^{A}\) procedure with error control. Using the above formulae it is easy to establish the inequality:

\[
\frac{\| e^{A} - F_{pq} \|_{\infty}}{\| e^{A} \|_{\infty}} \leq \varepsilon(p,q) \| A \|_{\infty} \varepsilon(p,q) \| A \|_{\infty}.
\]

The parameters \(p\) and \(q\) can be determined according to some relative error tolerance. Note that since \(F_{pq}\) requires about \(j + \max(p,q)\) matrix multiplies it makes sense to set \(p = q\) as this choice minimizes \(\varepsilon(p,q)\) for a given amount of work. Encapsulating these ideas we obtain

**Algorithm 11.3.1** Given \(\delta > 0\) and \(A \in \mathbb{R}^{n \times n}\), the following algorithm computes \(F = e^{A+E}\) where \(\| E \|_{\infty} \leq \delta \| A \|_{\infty}\)

\[
j = \max(0, 1 + \text{floor}(\log_{2}(\| A \|_{\infty})))
\]

\[
A = A/2^{j}
\]

Let \(q\) be the smallest non-negative integer such that \(\varepsilon(q,q) \leq \delta\).
\[ D = I; \ N = I; \ X = I; \ c = 1 \]

for \( k = 1:q \)
\[ c = c(q - k + 1)/[(2q - k + 1)k] \]
\[ X = AX; \ N = N + cX; \ D = D + (-1)^k cX \]
end

Solve \( DF = N \) for \( F \) using Gaussian elimination.

for \( k = 1:j \)
\[ F = F^2 \]
end

This algorithm requires about \( 2(q + j + 1/3)n^3 \) flops. The roundoff error properties of have essentially been analyzed by Ward (1977).

The special Horner techniques of §11.2 can be applied to quicken the computation of \( D = D_{qq}(A) \) and \( N = N_{qq}(A) \). For example, if \( q = 8 \) we have \( N_{qq}(A) = U + AV \) and \( D_{qq}(A) = U - AV \) where
\[ U = c_0 I + c_2 A^2 + (c_4 I + c_6 A^2 + c_8 A^4)A^4 \]
and
\[ V = c_1 I + c_3 A^2 + (c_5 I + c_7 A^2)A^4. \]

Clearly, \( N \) and \( D \) can be found in 5 matrix multiplies rather than the 7 required by Algorithm 11.3.1.

### 11.3.2 Perturbation Theory

Is Algorithm 11.3.1 stable in the presence of roundoff error? To answer this question we need to understand the sensitivity of the matrix exponential to perturbations in \( A \). The starting point in the discussion is the initial value problem
\[ \dot{X}(t) = AX(t) \quad X(0) = I \]

where \( A, X(t) \in \mathbb{R}^{n \times n} \). This has the unique solution \( X(t) = e^{At} \), a characterization of the matrix exponential that can be used to establish the identity
\[ e^{(A+E)t} - e^{At} = \int_0^t e^{A(t-s)}E e^{(A+E)s} ds. \]

From this it follows that
\[ \frac{\| e^{(A+E)t} - e^{At} \|_2}{\| e^{At} \|_2} \leq \frac{\| E \|_2}{\| e^{At} \|_2} \int_0^t \| e^{A(t-s)} \|_2 \| e^{(A+E)s} \|_2 ds. \]

Further simplifications result if we bound the norms of the exponentials that appear in the integrand. One way of doing this is through the Schur decomposition. If \( Q^H AQ = \text{diag}(\lambda_i) + N \) is the Schur decomposition of \( A \in \mathbb{C}^{n \times n} \), then it can be shown that
\[ \| e^{At} \|_2 \leq e^{\alpha(A)t}M_S(t), \quad (11.3.2) \]
where
\[ \alpha(A) = \max \{ \text{Re}(\lambda) : \lambda \in \lambda(A) \} \] (11.3.3)
and
\[ M_S(t) = \sum_{k=0}^{n-1} \frac{\| N^k t \|_2}{k!} . \]

The quantity \( \alpha(A) \) is called the spectral abscissa and with a little manipulation it can be shown that
\[ \frac{\| e^{(A+E)t} - e^{At} \|_2}{\| e^{At} \|_2} \leq t \| E \|_2 M_S(t)^2 \exp(tM_S(t) \| E \|_2) . \]

Notice that \( M_S(t) \equiv 1 \) if and only if \( A \) is normal, suggesting that the matrix exponential problem is "well behaved" if \( A \) is normal. This observation is confirmed by the behavior of the matrix exponential condition number \( \nu(A, t) \), defined by
\[ \nu(A, t) = \max_{\| E \|_2 \leq 1} \left\| \int_0^t e^{A(t-s)} E e^{As} \, ds \right\|_2 \frac{\| A \|_2}{\| e^{At} \|_2} . \]

This quantity, discussed in Van Loan (1977), measures the sensitivity of the map \( A \rightarrow e^{At} \) in that for a given \( t \), there is a matrix \( E \) for which
\[ \frac{\| e^{(A+E)t} - e^{At} \|_2}{\| e^{At} \|_2} \approx \nu(A, t) \frac{\| E \|_2}{\| A \|_2} . \]

Thus, if \( \nu(A, t) \) is large, small changes in \( A \) can induce relatively large changes in \( e^{At} \). Unfortunately, it is difficult to characterize precisely those \( A \) for which \( \nu(A, t) \) is large. (This is in contrast to the linear equation problem \( Ax = b \), where the ill-conditioned \( A \) are neatly described in terms of SVD.) One thing we can say, however, is that \( \nu(A, t) \geq t \| A \|_2 \), with equality holding for all non-negative \( t \) if and only if \( A \) is normal.

Dwelling a little more on the effect of non-normality, we know from the analysis of §11.2 that approximating \( e^{At} \) involves more than just approximating \( e^{zt} \) on \( \lambda(A) \). Another clue that eigenvalues do not "tell the whole story" in the \( e^{At} \) problem has to do with the inability of the spectral abscissa (11.3.3) to predict the size of \( \| e^{At} \|_2 \) as a function of time. If \( A \) is normal, then
\[ \| e^{At} \|_2 = e^{\alpha(A)t} \] (11.3.4)

Thus, there is uniform decay if the eigenvalues of \( A \) are in the open left half plane. But if \( A \) is non-normal, then \( e^{At} \) can grow before decay "sets in." The 2-by-2 example
\[ A = \begin{bmatrix} -1 & M \\ 0 & -1 \end{bmatrix} \iff e^{At} = e^{-t} \begin{bmatrix} 1 & tM \\ 0 & 1 \end{bmatrix} \]
plainly illustrates this point.
11.3.3 Some Stability Issues

With this discussion we are ready to begin thinking about the stability of Algorithm 11.3.1. A potential difficulty arises during the squaring process if \( A \) is a matrix whose exponential grows before it decays. If

\[
G = R_{qq} \left( \frac{A}{2^j} \right) \approx e^{A/2^j},
\]

then it can be shown that rounding errors of order

\[
\gamma = u \| G^2 \|_2 \| G^4 \|_2 \| G^8 \|_2 \cdots \| G^{2^{j-1}} \|_2
\]

can be expected to contaminate the computed \( G^{2^j} \). If \( \| e^{At} \|_2 \) has a substantial initial growth, then it may be the case that

\[
\gamma \gg u \| G^{2^j} \|_2 \approx u \| e^A \|_2
\]

thus ruling out the possibility of small relative errors.

If \( A \) is normal, then so is the matrix \( G \) and therefore \( \| G^m \|_2 = \| G \|_2^m \) for all positive integers \( m \). Thus, \( \gamma \approx u \| G^{2^j} \|_2 \approx u \| e^A \|_2 \) and so the initial growth problems disappear. The algorithm can essentially be guaranteed to produce small relative error when \( A \) is normal. On the other hand, it is more difficult to draw conclusions about the method when \( A \) is non-normal because the connection between \( \nu(A, t) \) and the initial growth phenomena is unclear. However, numerical experiments suggest that Algorithm 11.3.1 fails to produce a relatively accurate \( e^A \) only when \( \nu(A, 1) \) is correspondingly large.

11.3.4 Eigenvalues and Pseudo-Eigenvalues

We closed §7.1 with a comment that the eigenvalues of a matrix are generally not good “informers” when it comes to measuring nearness to singularity, unless the matrix is normal. It is the singular values that shed light on \( Ax = b \) sensitivity. Our discussion of the matrix exponential is another warning to the same effect. The spectrum of a non-normal \( A \) does not completely describe \( e^{At} \) behavior.

In many applications, the eigenvalues of a matrix “say something” about an underlying phenomenon that is being modeled. If the eigenvalues are extremely sensitive to perturbation, then what they say can be misleading. This has prompted the development of the idea of pseudospectra. For \( \epsilon \geq 0 \), the \( \epsilon \)-pseudospectrum of a matrix \( A \) is a subset of the complex plane defined by

\[
\lambda_\epsilon(A) = \left\{ z \in \mathbb{C} : \| (zI - A)^{-1} \|_2 \geq \frac{1}{\epsilon} \right\} \quad (11.3.5)
\]

Qualitatively, \( z \) is a pseudo-eigenvalue of \( A \) if \( zI - A \) is sufficiently close to singular. By convention we set \( \lambda_0(A) = \lambda(A) \). Here are some pseudospectra properties:
1. If $\epsilon_1 \leq \epsilon_2$, then $\lambda_{\epsilon_1}(A) \subseteq \lambda_{\epsilon_2}(A)$.

2. $\lambda_\epsilon(A) = \{ z \in \mathbb{C} : \sigma_{\min}(zI - A) \leq \epsilon \}$.

3. $\lambda_\epsilon(A) = \{ z \in \mathbb{C} : z \in \lambda(A + E), \text{ for some } E \text{ with } \|E\|_2 \leq \epsilon \}$.

Plotting the pseudospectra of a non-normal matrix $A$ can provide insight into behavior. Here "behavior" can mean anything from the mathematical behavior of an iteration to solve $Ax = b$ to the physical behavior predicted by a model that involves $A$. See Higham and Trefethen (1993), Nachtigal, Reddy, and Trefethen (1992), and Trefethen, Trefethen, Reddy, and Driscoll (1993).

Problems

P11.3.1 Show that $e^{(A+B)t} = e^{At}e^{Bt}$ for all $t$ if and only if $AB = BA$. (Hint: Express both sides as a power series in $t$ and compare the coefficient of $t$.)

P11.3.2 Suppose that $A$ is skew-symmetric. Show that both $e^A$ and the $(1,1)$ Padé approximate $R_{11}(A)$ are orthogonal. Are there any other values of $p$ and $q$ for which $R_{pq}(A)$ is orthogonal?

P11.3.3 Show that if $A$ is nonsingular, then there exists a matrix $X$ such that $A = e^X$. Is $X$ unique?

P11.3.4 Show that if

$$
\exp \left( \begin{bmatrix} -A^T & P \\ 0 & A \end{bmatrix} z \right) = \begin{bmatrix} F_{11} & F_{12} \\ 0 & F_{22} \end{bmatrix} \frac{z^n}{n}
$$

then

$$
F_{11}^t F_{12} = \int_0^z e^{A^T \tau} P e^{A\tau} d\tau.
$$

P11.3.5 Give an algorithm for computing $e^A$ when $A = uv^T$, $u, v \in \mathbb{R}^n$.

P11.3.6 Suppose $A \in \mathbb{R}^{n \times n}$ and that $v \in \mathbb{R}^n$ has unit 2-norm. Define the function $\phi(t) = \|e^{At}v\|_2^2/2$ and show that

$$
\dot{\phi}(t) \leq \mu(A)\phi(t)
$$

where $\mu(A) = \lambda_1((A + A^T)/2)$. Conclude that $\|e^{At}\|_2 \leq e^{\mu(A)t}$ where $t \geq 0$.

P11.3.7 Prove the three pseudospectra properties given in the text.

Notes and References for Sec. 11.3

Much of what appears in this section and an extensive bibliography may be found in the following survey article:

Scaling and squaring with Padé approximants (Algorithm 11.3.1) and a careful implementation of Parlett's Schur decomposition method (Algorithm 11.1.1) were found to be among the less dubious of the nineteen methods scrutinized. Various aspects of Padé
approximation of the matrix exponential are discussed in

A proof of equation (11.3.1) for the scalar case appears in

There are many applications in control theory calling for the computation of the matrix exponential. In the linear optimal regular problem, for example, various integrals involving the matrix exponential are required. See

An understanding of the map $A \rightarrow \exp(At)$ and its sensitivity is helpful when assessing the performance of algorithms for computing the matrix exponential. Work in this direction includes

The computation of a logarithm of a matrix is an important area demanding much more work. These calculations arise in various "system identification" problems. See

§12.2 Subset Selection Using the SVD
§12.3 Total Least Squares
§12.4 Computing Subspaces with the SVD
§12.5 Updating Matrix Factorizations
§12.6 Modified/Structured Eigenproblems

In this final chapter we discuss an assortment of problems that represent important applications of the singular value, QR, and Schur decompositions. We first consider least squares minimization with constraints. Two types of constraints are considered in §12.1, quadratic inequality and linear equality. The next two sections are also concerned with variations on the standard LS problem. In §12.2 we consider how the vector of observations $b$ might be approximated by some subset of $A$'s columns, a course of action that is sometimes appropriate if $A$ is rank-deficient. In §12.3 we consider a variation of ordinary regression known as total least squares that has appeal when $A$ is contaminated with error. More applications of the SVD are considered in §12.4, where various subspace calculations are considered. In §12.5 we investigate the updating of orthogonal factorizations when the matrix $A$ undergoes a low-rank perturbation. Some variations of the basic eigenvalue problem are discussed in §12.6.

Before You Begin

Because of the topical nature of this chapter, it doesn't make sense to have a chapter-wide, before-you-begin advisory. Instead, each section will begin with pointers to earlier portions of the book, and, if appropriate, pointers to LAPACK and other texts.
12.1 Constrained Least Squares

In the least squares setting it is sometimes natural to minimize $\| Ax - b \|_2$ over a proper subset of $\mathbb{R}^n$. For example, we may wish to predict $b$ as best we can with $Ax$ subject to the constraint that $x$ is a unit vector. Or, perhaps the solution defines a fitting function $f(t)$ which is to have prescribed values at a finite number of points. This can lead to an equality constrained least squares problem. In this section we show how these problems can be solved using the QR factorization and the SVD.

Chapter 5 and §8.7 should be understood before reading this section. LAPACK connections include:

12.1.1 The Problem LSQI

Least squares minimization with a quadratic inequality constraint—the LSQI problem—is a technique that can be used whenever the solution to the ordinary LS problem needs to be regularized. A simple LSQI problem that arises when attempting to fit a function to noisy data is

$$\text{minimize } \| Ax - b \|_2 \quad \text{subject to } \| Bx \|_2 \leq \alpha \quad \text{(12.1.1)}$$

where $A \in \mathbb{R}^{m \times n}$, $b \in \mathbb{R}^m$, $B \in \mathbb{R}^{n \times n}$ (nonsingular), and $\alpha \geq 0$. The constraint defines a hyperellipsoid in $\mathbb{R}^n$ and is usually chosen to damp out excessive oscillation in the fitting function. This can be done, for example, if $B$ is a discretized second derivative operator.

More generally, we have the problem

$$\text{minimize } \| Ax - b \|_2 \quad \text{subject to } \| Bx - d \|_2 \leq \alpha \quad \text{(12.1.2)}$$

where $A \in \mathbb{R}^{m \times n}$ ($m \geq n$), $b \in \mathbb{R}^m$, $B \in \mathbb{R}^{p \times n}$, $d \in \mathbb{R}^p$, and $\alpha \geq 0$. The generalized singular value decomposition of §8.7.3 sheds light on the solvability of (12.1.2). Indeed, if

$$U^T A X = \text{diag}(\alpha_1, \ldots, \alpha_n) \quad U^T U = I_m$$
$$V^T B X = \text{diag}(\beta_1, \ldots, \beta_q) \quad V^T V = I_p, \quad q = \min\{p, n\}$$

(12.1.3)
is the generalized singular value decomposition of $A$ and $B$, then (12.1.2) transforms to

$$\text{minimize } \| D_A y - \tilde{b} \|_2 \quad \text{subject to } \| D_B y - \tilde{d} \|_2 \leq \alpha$$

where $\tilde{b} = U^T b$, $\tilde{d} = V^T d$, and $y = X^{-1} x$. The simple form of the objective function

$$\| D_A y - \tilde{b} \|_2^2 = \sum_{i=1}^{n} (\alpha_i y_i - \tilde{b}_i)^2 + \sum_{i=n+1}^{m} \tilde{b}_i^2 \quad (12.1.4)$$

and the constraint equation

$$\| D_B y - \tilde{d} \|_2^2 = \sum_{i=1}^{r} (\beta_i y_i - \tilde{d}_i)^2 + \sum_{i=r+1}^{p} \tilde{d}_i^2 \leq \alpha^2 \quad (12.1.5)$$

facilitate the analysis of the LSQI problem. Here, $r = \text{rank}(B)$ and we assume that $\beta_{r+1} = \cdots = \beta_q = 0$.

To begin with, the problem has a solution if and only if

$$\sum_{i=r+1}^{p} \tilde{d}_i^2 \leq \alpha^2.$$ 

If we have equality in this expression then consideration of (12.1.4) and (12.1.5) shows that the vector defined by

$$y_i = \begin{cases} 
\tilde{d}_i / \beta_i & i = 1:r \\
\tilde{b}_i / \alpha_i & i = r + 1:n, \alpha_i \neq 0 \\
0 & i = r + 1:n, \alpha_i = 0 
\end{cases} \quad (12.1.6)$$

solves the LSQI problem. Otherwise

$$\sum_{i=r+1}^{p} \tilde{d}_i^2 < \alpha^2. \quad (12.1.7)$$

and we have more alternatives to pursue. The vector $y \in \mathbb{R}^n$, defined by

$$y_i = \begin{cases} 
\tilde{b}_i / \alpha_i & \alpha_i \neq 0 \\
\tilde{d}_i / \beta_i & \alpha_i = 0 
\end{cases} \quad i = 1:n$$

is a minimizer of $\| D_A y - \tilde{b} \|_2$. If this vector is also feasible, then we have a solution to (12.1.2). (This is not necessarily the solution of minimum 2-norm, however.) We therefore assume that

$$\sum_{\alpha_i \neq 0}^{q} \left( \frac{\beta_i \tilde{b}_i}{\alpha_i} - \tilde{d}_i \right)^2 + \sum_{i=q+1}^{p} \tilde{d}_i^2 > \alpha^2. \quad (12.1.8)$$
This implies that the solution to the LSQI problem occurs on the boundary of the feasible set. Thus, our remaining goal is to

\[
\text{minimize } \| D_A y - \bar{b} \|_2 \quad \text{subject to } \| D_B y - \bar{d} \|_2 = \alpha.
\]

To solve this problem, we use the method of Lagrange multipliers. Defining

\[
h(\lambda, y) = \| D_A y - \bar{b} \|_2^2 + \lambda \left( \| D_B y - \bar{d} \|_2^2 - \alpha^2 \right)
\]

we see that the equations \(0 = \partial h / \partial y_i, \ i = 1:n\), lead to the linear system

\[
(D_A^T D_A + \lambda D_B^T D_B)y = D_A^T \bar{b} + \lambda D_B^T \bar{d}.
\]

Assuming that the matrix of coefficients is nonsingular, this has a solution \(y(\lambda)\) where

\[
y_i(\lambda) = \begin{cases} \frac{\alpha_i \bar{b}_i + \lambda \beta_i \bar{d}_i}{\alpha_i^2 + \lambda \beta_i^2} & i = 1:q \\ \frac{\bar{b}_i}{\alpha_i} & i = q + 1:n \end{cases}
\]

To determine the Lagrange parameter we define

\[
\phi(\lambda) \equiv \| D_B y(\lambda) - \bar{d} \|_2^2 = \sum_{i=1}^{r} \left( \frac{\alpha_i \beta_i \bar{b}_i - \alpha_i \bar{d}_i}{\alpha_i^2 + \lambda \beta_i^2} \right)^2 + \sum_{i=r+1}^{p} \bar{d}_i^2
\]

and seek a solution to \(\phi(\lambda) = \alpha^2\). Equations of this type are referred to as secular equations and we encountered them earlier in §8.5.3. From (12.1.8) we see that \(\phi(0) > \alpha^2\). Now \(\phi(\lambda)\) is monotone decreasing for \(\lambda > 0\), and (12.1.8) therefore implies the existence of a unique positive \(\lambda^*\) for which \(\phi(\lambda^*) = \alpha^2\). It is easy to show that this is the desired root. It can be found through the application of any standard root-finding technique, such as Newton's method. The solution of the original LSQI problem is then \(x = X y(\lambda^*)\).

### 12.1.2 LS Minimization Over a Sphere

For the important case of minimization over a sphere \((B = I_n, \ d = 0)\), we have the following procedure:

**Algorithm 12.1.1** Given \(A \in \mathbb{R}^{m \times n}\) with \(m \geq n\), \(b \in \mathbb{R}^m\), and \(\alpha > 0\), the following algorithm computes a vector \(x \in \mathbb{R}^n\) such that \(\| Ax - b \|_2\) is minimum, subject to the constraint that \(\| x \|_2 \leq \alpha\).

Compute the SVD \(A = U \Sigma V^T\), save \(V = [v_1, \ldots, v_n]\), and form \(b = U^T b\).

\[r = \text{rank}(A)\]
if \( \sum_{i=1}^{r} \left( \frac{b_i}{\sigma_i} \right)^2 > \alpha^2 \)

Find \( \lambda^* \) such that \( \sum_{i=1}^{r} \left( \frac{\sigma_i b_i}{\sigma_i^2 + \lambda^*} \right)^2 = \alpha^2 \).

\[ x = \sum_{i=1}^{r} \left( \frac{\sigma_i b_i}{\sigma_i^2 + \lambda^*} \right) v_i \]

else

\[ x = \sum_{i=1}^{r} \left( \frac{b_i}{\sigma_i} \right) v_i \]

end

The SVD is the dominant computation in this algorithm.

Example 12.1.1 The secular equation for the problem

\[ \min_{\| x \|_2 = 1} \left\| \begin{bmatrix} 2 & 0 \\ 0 & 1 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} - \begin{bmatrix} 4 \\ 2 \\ 3 \end{bmatrix} \right\|_2 \]

is given by

\[ \left( \frac{8}{\lambda + 4} \right)^2 + \left( \frac{2}{\lambda + 1} \right)^2 = 1. \]

For this problem we find \( \lambda^* = 4.57132 \) and \( x = [.93334 \ .35898]^T \).

12.1.3 Ridge Regression

The problem solved by Algorithm 12.1.1 is equivalent to the Lagrange multiplier problem of determining \( \lambda > 0 \) such that

\[ (A^T A + \lambda I)x = A^T b \] (12.1.9)

and \( \| x \|_2 = \alpha \). This equation is precisely the normal equation formulation for the ridge regression problem

\[ \min_{x} \left\| \sqrt{\lambda} I \right\| x - \begin{bmatrix} b \\ 0 \end{bmatrix} \right\|_2^2 = \min_{x} \| A x - b \|_2^2 + \lambda \| x \|_2^2. \]

In the general ridge regression problem one has some criteria for selecting the ridge parameter \( \lambda \), e.g., \( \| x(\lambda) \|_2 = \alpha \) for some given \( \alpha \). We describe a \( \lambda \)-selection procedure that is discussed in Golub, Heath, and Wahba (1979).

Set \( D_k = I - e_k e_k^T = \text{diag}(1, \ldots, 1, 0, 1, \ldots, 1) \in \mathbb{R}^{m \times m} \) and let \( x_k(\lambda) \) solve

\[ \min_{x} \| D_k (A x - b) \|_2^2 + \lambda \| x \|_2^2. \] (12.1.10)
Thus, \( x_k(\lambda) \) is the solution to the ridge regression problem with the \( k \)th row of \( A \) and \( k \)th component of \( b \) deleted, i.e., the \( k \)th experiment is ignored. Now consider choosing \( \lambda \) so as to minimize the cross-validation weighted square error \( C(\lambda) \) defined by

\[
C(\lambda) = \frac{1}{m} \sum_{k=1}^{m} w_k (a_k^T x_k(\lambda) - b_k)^2 .
\]

Here, \( w_1, \ldots, w_m \) are non-negative weights and \( a_k^T \) is the \( k \)th row of \( A \). Noting that

\[
\| Ax_k(\lambda) - b \|_2^2 = \| D_k(Ax_k(\lambda) - b) \|_2^2 + (a_k^T x_k(\lambda) - b_k)^2
\]

we see that \( (a_k^T x_k(\lambda) - b_k)^2 \) is the increase in the sum of squares resulting when the \( k \)th row is “reinstated.” Minimizing \( C(\lambda) \) is tantamount to choosing \( \lambda \) such that the final model is not overly dependent on any one experiment.

A more rigorous analysis can make this statement precise and also suggest a method for minimizing \( C(\lambda) \). Assuming that \( \lambda > 0 \), an algebraic manipulation shows that

\[
x_k(\lambda) = x(\lambda) + \frac{a_k^T x(\lambda) - b_k}{1 - z_k^T a_k} z_k
\]

(12.1.11)

where \( z_k = (A^T A + \lambda I)^{-1} a_k \) and \( x(\lambda) = (A^T A + \lambda I)^{-1} A^T b \). Applying \( -a_k^T \) to (12.1.11) and then adding \( b_k \) to each side of the resulting equation gives

\[
b_k - a_k^T x_k(\lambda) = \frac{e_k^T (I - A(A^T A + \lambda I)^{-1} A^T) b}{e_k^T (I - A(A^T A + \lambda I)^{-1} A^T) e_k} .
\]

(12.1.12)

Noting that the residual \( r = (r_1, \ldots, r_m)^T = b - Ax(\lambda) \) is given by the formula \( r = [I - A(A^T A + \lambda I)^{-1} A^T] b \), we see that

\[
C(\lambda) = \frac{1}{m} \sum_{k=1}^{m} w_k \left( \frac{r_k}{\partial r_k/\partial b_k} \right)^2 .
\]

The quotient \( r_k/\partial r_k/\partial b_k \) may be regarded as an inverse measure of the “impact” of the \( k \)th observation \( b_k \) on the model. When \( \partial r_k/\partial b_k \) is small, this says that the error in the model’s prediction of \( b_k \) is somewhat independent of \( b_k \). The tendency for this to be true is lessened by basing the model on the \( \lambda^* \) that minimizes \( C(\lambda) \).

The actual determination of \( \lambda^* \) is simplified by computing the SVD of \( A \). Indeed, if \( U^T A V = \text{diag}(\sigma_1, \ldots, \sigma_n) \) with \( \sigma_1 \geq \ldots \geq \sigma_n \) and \( \bar{b} = U^T b \),
then it can be shown from (12.1.12) that

\[ C(\lambda) = \frac{1}{m} \sum_{k=1}^{m} w_k \left( \frac{\hat{b}_k - \sum_{j=1}^{r} u_{kj} \hat{b}_j \left( \frac{\sigma_j^2}{\sigma_j^2 + \lambda} \right)}{1 - \sum_{j=1}^{r} u_{kj}^2 \left( \frac{\sigma_j^2}{\sigma_j^2 + \lambda} \right)} \right)^2. \]

The minimization of this expression is discussed in Golub, Heath, and Wahba (1979).

### 12.1.4 Equality Constrained Least Squares

We conclude the section by considering the least squares problem with linear equality constraints:

\[
\min_{Bx=d} \| Ax - b \|_2 \tag{12.1.13}
\]

Here \( A \in \mathbb{R}^{m \times n} \), \( B \in \mathbb{R}^{p \times n} \), \( b \in \mathbb{R}^m \), \( d \in \mathbb{R}^p \), and \( \text{rank}(B) = p \). We refer to (12.1.13) as the LSE problem. By setting \( \alpha = 0 \) in (12.1.2) we see that the LSE problem is a special case of the LSQI problem. However, it is simpler to approach the LSE problem directly rather than through Lagrange multipliers.

Assume for clarity that both \( A \) and \( B \) have full rank. Let

\[ Q^T B^T = \begin{bmatrix} R & 0 \\ 0 & n-p \end{bmatrix} \]

be the QR factorization of \( B^T \) and set

\[ AQ = \begin{bmatrix} A_1 & A_2 \\ p & n-p \end{bmatrix}, \quad Q^T x = \begin{bmatrix} y \\ z \end{bmatrix}_{n-p}. \]

It is clear that with these transformations (12.1.13) becomes

\[
\min_{R^T y = d} \| A_1 y + A_2 z - b \|_2.
\]

Thus, \( y \) is determined from the constraint equation \( R^T y = d \) and the vector \( z \) is obtained by solving the unconstrained LS problem

\[
\min_z \| A_2 z - (b - A_1 y) \|_2.
\]
Combining the above, we see that \( x = Q \begin{bmatrix} y \\ z \end{bmatrix} \) solves (12.1.13).

**Algorithm 12.1.2** Suppose \( A \in \mathbb{R}^{m \times n} \), \( B \in \mathbb{R}^{p \times n} \), \( b \in \mathbb{R}^m \), and \( d \in \mathbb{R}^p \). If \( \text{rank}(A) = n \) and \( \text{rank}(B) = p \), then the following algorithm minimizes \( \| Ax - b \|_2 \) subject to the constraint \( Bx = d \).

\[
B^T = QR \quad (\text{QR factorization})
\]

Solve \( R(1:p,1:p)^Ty = d \) for \( y \).

\[ A = AQ \]

Find \( z \) so \( \| A(:,p+1:n)z - (b - A(:,1:p)y) \|_2 \) is minimized.

\[ x = Q(:,1:p)y + Q(:,p+1:n)z \]

Note that this approach to the LSE problem involves two factorizations and a matrix multiplication.

### 12.1.5 The Method of Weighting

An interesting way to obtain an approximate solution to (12.1.13) is to solve the unconstrained LS problem

\[
\min_x \left\| \begin{bmatrix} A \\ \lambda B \end{bmatrix} x - \begin{bmatrix} b \\ \lambda d \end{bmatrix} \right\|_2 \tag{12.1.14}
\]

for large \( \lambda \). The generalized singular value decomposition of §8.7.3 sheds light on the quality of the approximation. Let

\[
U^TAX = \text{diag}(\alpha_1, \ldots, \alpha_n) = D_A \in \mathbb{R}^{m \times n}
\]

\[
V^TBX = \text{diag}(\beta_1, \ldots, \beta_p) = D_B \in \mathbb{R}^{p \times n}
\]

be the GSVD of \((A, B)\) and assume that both matrices have full rank for clarity. If \( U = [u_1, \ldots, u_m] \), \( V = [v_1, \ldots, v_p] \), and \( X = [x_1, \ldots, x_n] \), then it is easy to show that

\[
x = \sum_{i=1}^p \frac{v_i^T d}{\beta_i} x_i + \sum_{i=p+1}^n \frac{u_i^T b}{\alpha_i} x_i \tag{12.1.15}
\]

is the exact solution to (12.1.13), while

\[
x(\lambda) = \sum_{i=1}^p \frac{\alpha_i u_i^T b + \lambda^2 \beta_i^2 v_i^T d}{\alpha_i^2 + \lambda^2 \beta_i^2} x_i + \sum_{i=p+1}^n \frac{u_i^T b}{\alpha_i} x_i \tag{12.1.16}
\]

solves (12.1.14). Since

\[
x(\lambda) - x = \sum_{i=1}^p \frac{\alpha_i (\beta_i u_i^T b - \alpha_i v_i^T d)}{\beta_i (\alpha_i^2 + \lambda^2 \beta_i^2)} x_i \tag{12.1.17}
\]
it follows that \( x(\lambda) \rightarrow x \) as \( \lambda \rightarrow \infty \).

The appeal of this approach to the LSE problem is that no special subroutines are required: an ordinary LS solver will do. However, for large values of \( \lambda \) numerical problems can arise and it is necessary to take precautions. See Powell and Reid (1968) and Van Loan (1982a).

Example 12.1.2 The problem

\[
\min_{x_1=x_2} \left\| \begin{bmatrix} 1 & 2 \\ 3 & 4 \\ 5 & 6 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} - \begin{bmatrix} 7 \\ 1 \\ 3 \end{bmatrix} \right\|_2
\]

has solution \( x = [3.407821, .3407821]^T \). This can be approximated by solving

\[
\min \left\| \begin{bmatrix} 1 & 2 \\ 3 & 4 \\ 5 & 6 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} - \begin{bmatrix} 7 \\ 1 \\ 3 \end{bmatrix} \right\|_2
\]

which has solution \( x = [3.407810, .3407829]^T \).

Problems

P 12.1.1 (a) Show that if \( \text{null}(A) \cap \text{null}(B) \neq \{0\} \), then (12.1.2) cannot have a unique solution. (b) Give an example which shows that the converse is not true. (Hint: \( A^+b \) feasible.)

P 12.1.2 Let \( p_0(x), \ldots, p_n(x) \) be given polynomials and \( (x_0, y_0), \ldots, (x_m, y_m) \) a given set of coordinate pairs with \( x_i \in [a, b] \). It is desired to find a polynomial \( p(x) = \sum_{k=0}^{n} a_k p_k(x) \) such that \( \sum_{i=0}^{m} (p(x_i) - y_i)^2 \) is minimized subject to the constraint that

\[
\int_a^b [p''(x)]^2 dx \approx h \sum_{i=0}^{N} \left( \frac{p(z_{i-1}) - 2p(z_i) + p(z_{i+1})}{h^2} \right)^2 \leq \alpha^2
\]

where \( z_i = a + ih \) and \( b = a + Nh \). Show that this leads to an LSQI problem of the form (12.1.1).

P 12.1.3 Suppose \( Y = [y_1, \ldots, y_k] \in \mathbb{R}^{m \times k} \) has the property that

\[
Y^T Y = \text{diag}(d_1, \ldots, d_k) \quad d_1 \geq d_2 \geq \cdots \geq d_k > 0.
\]

Show that if \( Y = QR \) is the QR factorization of \( Y \), then \( R \) is diagonal with \( |r_{ii}| = d_i \).

P 12.1.4 (a) Show that if \( (A^T A + \lambda I) x = A^T b, \ \lambda > 0, \) and \( \| x \|_2 = \alpha \), then \( z = (Ax - b) / \lambda \) solves the dual equations \( (A A^T + \lambda I) z = -b \) with \( \| A z \|_2 = \alpha \). (b) Show that if \( (A A^T + \lambda I) z = -b, \ \| A z \|_2 = \alpha \), then \( z = -A^T z \) satisfies \( (A^T A + \lambda I) x = A^T b, \ \| x \|_2 = \alpha \).

P 12.1.5 Suppose \( A \) is the \( m \)-by-1 matrix of ones and let \( b \in \mathbb{R}^m \). Show that the cross-validation technique with unit weights prescribes an optimal \( \lambda \) given by

\[
\lambda = \left( \frac{(\bar{b})^2}{s} - \frac{1}{m} \right)^{-1}
\]

where \( \bar{b} = (b_1 + \cdots + b_m) / m \) and \( s = \sum_{i=1}^{m} (b_i - \bar{b})^2 / (m - 1) \).
P12.1.6 Establish equations (12.1.15), (12.1.16), and (12.1.17).

P12.1.7 Develop an SVD version of Algorithm 12.1.2 that can handle rank deficiency in $A$ and $B$.

P12.1.8 Suppose

$$A = \begin{bmatrix} A_1 \\ A_2 \end{bmatrix}$$

where $A_1 \in \mathbb{R}^{m \times n}$ is nonsingular and $A_2 \in \mathbb{R}^{(m-n) \times n}$. Show that

$$\sigma_{\min}(A) \geq \sqrt{1 + \sigma_{\min}(A_2 A_1^{-1})^2 \sigma_{\min}(A_1)}.$$

P12.1.9 Consider the problem

$$\min_{\begin{array}{c} z^T B z = \beta^2 \\
                        z^T C z = \gamma^2 \end{array}} \| A z - b \|_2 \quad A \in \mathbb{R}^{m \times n}, \; b \in \mathbb{R}^m, \; B, C \in \mathbb{R}^{n \times n}$$

Assume that $B$ and $C$ are positive definite and that $Z \in \mathbb{R}^{n \times n}$ is a nonsingular matrix with the property that $Z^T B Z = \text{diag}(\lambda_1, \ldots, \lambda_n)$ and $Z^T C Z = I_n$. Assume that

$$\lambda_1 \geq \cdots \geq \lambda_n.$$ 

(a) Show that the set of feasible $x$ is empty unless $\lambda_n \leq \beta^2 / \gamma^2 \leq \lambda_1$.

(b) Using $Z$, show how the two constraint problem can be converted to a single constraint problem of the form

$$\min_{\begin{array}{c} y^T W y = \beta^2 - \lambda_n \gamma^2 \end{array}} \| \tilde{A} z - b \|_2$$

where $W = \text{diag}(\lambda_1, \ldots, \lambda_n) - \lambda_n I$.

P12.1.10 Suppose $p \geq m \geq n$ and that $A \in \mathbb{R}^{m \times n}$ and $B \in \mathbb{R}^{m \times p}$ Show how to compute orthogonal $Q \in \mathbb{R}^{m \times m}$ and orthogonal $V \in \mathbb{R}^{n \times n}$ so that

$$Q^T A = \begin{bmatrix} R \\ 0 \end{bmatrix}, \quad Q^T B V = [0, S]$$

where $R \in \mathbb{R}^{n \times n}$ and $S \in \mathbb{R}^{m \times m}$ are upper triangular.

P12.1.11 Suppose $r \in \mathbb{R}^m$, $y \in \mathbb{R}^n$, and $\delta > 0$. Show how to solve the problem

$$\min_{\| E \|_F \leq \delta} \| E y - r \|_2$$

Repeat with "min" replaced by "max".

Notes and References for Sec. 12.1

Roughly speaking, regularization is a technique for transforming a poorly conditioned problem into a stable one. Quadratically constrained least squares is an important example. See

Other computational aspects of the LSQR problem involve updating and the handling of banded and sparse problems. See

Various aspects of the LSE problem are discussed and analyzed in

Generalized factorizations have an important bearing on generalized least squares problems.

### 12.2 Subset Selection Using the SVD

As described in §5.5, the rank-deficient LS problem \( \min \| Ax - b \|_2 \) can be approached by approximating the minimum norm solution

\[
x_{LS} = \sum_{i=1}^{r} \frac{u_i^T b}{\sigma_i} v_i \quad r = \text{rank}(A)
\]

with

\[
x_\tilde{r} = \sum_{i=1}^{\tilde{r}} \frac{u_i^T b}{\sigma_i} v_i \quad \tilde{r} \leq r
\]

where

\[
A = U\Sigma V^T = \sum_{i=1}^{r} \sigma_i u_i v_i^T
\]

is the SVD of \( A \) and \( \tilde{r} \) is some numerically determined estimate of \( r \). Note that \( x_\tilde{r} \) minimizes \( \| A_{\tilde{r}} x - b \|_2 \) where

\[
A_{\tilde{r}} = \sum_{i=1}^{\tilde{r}} \sigma_i u_i v_i^T
\]

is the closest matrix to \( A \) that has rank \( \tilde{r} \). See Theorem 2.5.3.

Replacing \( A \) by \( A_{\tilde{r}} \) in the LS problem amounts to filtering the small singular values and can make a great deal of sense in those situations where \( A \) is derived from noisy data. In other applications, however, rank deficiency implies redundancy among the factors that comprise the underlying model. In this case, the model-builder may not be interested in a predictor such as \( A_{\tilde{r}} x_\tilde{r} \) that involves all \( n \) redundant factors. Instead, a predictor \( Ay \) may be sought where \( y \) has at most \( \tilde{r} \) nonzero components. The position of the nonzero entries determines which columns of \( A \), i.e., which factors in the model, are to be used in approximating the observation vector \( b \). How to pick these columns is the problem of *subset selection* and is the subject of this section.

The contents of this section depends heavily upon §2.6 and Chapter 5.
12.2.1 QR with Column Pivoting

QR with column pivoting can be regarded as a method for selecting an independent subset of $A$'s columns from which $b$ might be predicted. Suppose we apply Algorithm 5.4.1 to $A \in \mathbb{R}^{m \times n}$ and compute an orthogonal $Q$ and a permutation $\Pi$ such that $R = Q^T A \Pi$ is upper triangular. If $R(1: \tilde{r}, 1: \tilde{r}) z = \tilde{b}(1: \tilde{r})$ where $\tilde{b} = Q^T b$ and we set

$$y = \Pi \begin{bmatrix} z \\ 0 \end{bmatrix},$$

then $A y$ is an approximate LS predictor of $b$ that involves the first $\tilde{r}$ columns of $A \Pi$.

12.2.2 Using the SVD

Although QR with column pivoting is a fairly reliable way to handle near rank deficiency, the SVD is sometimes preferable for reasons discussed in §5.5. We therefore describe an SVD-based subset selection procedure due to Golub, Klemm, and Stewart (1976) that proceeds as follows:

- Compute the SVD $A = U \Sigma V^T$ and use it to determine a rank estimate $\tilde{r}$.

- Calculate a permutation matrix $P$ such that the columns of the matrix $B_1 \in \mathbb{R}^{m \times \tilde{r}}$ in $A P = [B_1 \ B_2]$ are "sufficiently independent."

- Predict $b$ with the vector $A y$ where $y = P \begin{bmatrix} z \\ 0 \end{bmatrix}$ and $z \in \mathbb{R}^{\tilde{r}}$ minimizes $\| B_1 z - b \|_2$

The second step is key. Since

$$\min_{z \in \mathbb{R}^{\tilde{r}}} \| B_1 z - b \|_2 = \| A y - b \|_2 \geq \min_{x \in \mathbb{R}^n} \| A x - b \|_2$$

it can be argued that the permutation $P$ should be chosen to make the residual $(I - B_1 B_1^+) b$ as small as possible. Unfortunately, such a solution procedure can be unstable. For example, if

$$A = \begin{bmatrix} 1 & 1 & 0 \\ 1 & 1 + \epsilon & 1 \\ 0 & 0 & 1 \end{bmatrix}, \quad b = \begin{bmatrix} 1 \\ -1 \\ 0 \end{bmatrix},$$

$\tilde{r} = 2$, and $P = I$, then $\min \| B_1 z - b \|_2 = 0$, but $\| B_1^+ b \|_2 = O(1/\epsilon)$. On the other hand, any proper subset involving the third column of $A$ is strongly independent but renders a much worse residual.
This example shows that there can be a trade-off between the independence of the chosen columns and the norm of the residual that they render. How to proceed in the face of this trade-off requires additional mathematical machinery in the form of useful bounds on \( \sigma_\tilde{r}(B_1) \), the smallest singular value of \( B_1 \).

**Theorem 12.2.1** Let the SVD of \( A \in \mathbb{R}^{m \times n} \) be given by (12.2.1), and define the matrix \( B_1 \in \mathbb{R}^{\tilde{r} \times \tilde{r}} \), \( \tilde{r} \leq \text{rank}(A) \), by

\[
AP = \begin{bmatrix} B_1 & B_2 \\ \tilde{r} & n - \tilde{r} \end{bmatrix}
\]

where \( P \in \mathbb{R}^{n \times n} \) is a permutation. If

\[
P^T V = \begin{bmatrix} \tilde{V}_{11} & \tilde{V}_{12} \\ \tilde{V}_{21} & \tilde{V}_{22} \end{bmatrix} \begin{bmatrix} \tilde{r} \\ n - \tilde{r} \end{bmatrix}
\]

and \( \tilde{V}_{11} \) is nonsingular, then

\[
\frac{\sigma_\tilde{r}(A)}{\| \tilde{V}_{11}^{-1} \|_2} \leq \sigma_\tilde{r}(B_1) \leq \sigma_\tilde{r}(A).
\]

**Proof.** The upper bound follows from the minimax characterization of singular values given in §8.6.1.

To establish the lower bound, partition the diagonal matrix of singular values as follows:

\[
\Sigma = \begin{bmatrix} \Sigma_1 & 0 \\ 0 & \Sigma_2 \end{bmatrix} \begin{bmatrix} \tilde{r} \\ m - \tilde{r} \end{bmatrix}
\]

If \( w \in \mathbb{R}^{\tilde{r}} \) is a unit vector with the property that \( \| B_1 w \|_2 = \sigma_\tilde{r}(B_1) \), then

\[
\sigma_\tilde{r}(B_1)^2 = \| B_1 w \|_2^2 = \left\| U \Sigma V^T P \begin{bmatrix} w \\ 0 \end{bmatrix} \right\|_2^2
\]

\[= \| \Sigma_1 \tilde{V}_{11}^T w \|_2^2 + \| \Sigma_2 \tilde{V}_{12}^T w \|_2^2. \]

The theorem now follows because \( \| \Sigma_1 \tilde{V}_{11}^T w \|_2 \geq \sigma_\tilde{r}(A)/\| \tilde{V}_{11}^{-1} \|_2. \)

This result suggests that in the interest of obtaining a sufficiently independent subset of columns, we choose the permutation \( P \) such that the resulting \( \tilde{V}_{11} \) submatrix is as well-conditioned as possible. A heuristic solution to this problem can be obtained by computing the QR with column-pivoting factorization of the matrix \([ V_{11}^T \ V_{21}^T \]), where

\[
V = \begin{bmatrix} V_{11} & V_{12} \\ V_{21} & V_{22} \end{bmatrix} \begin{bmatrix} \tilde{r} \\ n - \tilde{r} \end{bmatrix}
\]
is a partitioning of the matrix $V$ in (12.2.1). In particular, if we apply QR with column pivoting (Algorithm 5.4.1) to compute

$$Q^T [V_{11}^T \ V_{21}^T ]P = \begin{bmatrix} R_{11} & R_{12} \\ \tilde{r} & n-\tilde{r} \end{bmatrix}$$

where $Q$ is orthogonal, $P$ is a permutation matrix, and $R_{11}$ is upper triangular, then (12.2.2) implies:

$$\begin{bmatrix} \tilde{V}_{11} \\ \tilde{V}_{21} \end{bmatrix} = P^T \begin{bmatrix} V_{11} \\ V_{21} \end{bmatrix} = \begin{bmatrix} R_{11}^T Q^T \\ R_{12}^T Q^T \end{bmatrix}.$$  

Note that $R_{11}$ is nonsingular and that $\| \tilde{V}_{11}^{-1} \|_2 = \| R_{11}^{-1} \|_2$. Heuristically, column pivoting tends to produce a well-conditioned $\tilde{R}_{11}$, and so the overall process tends to produce a well-conditioned $\tilde{V}_{11}$. Thus we obtain

**Algorithm 12.2.1** Given $A \in \mathbb{R}^{m \times n}$ and $b \in \mathbb{R}^m$ the following algorithm computes a permutation $P$, a rank estimate $\tilde{r}$, and a vector $z \in \mathbb{R}^{\tilde{r}}$ such that the first $\tilde{r}$ columns of $B = AP$ are independent and such that $\| B(:,\, 1:\tilde{r})z - b \|_2$ is minimized.

1. Compute the SVD $U^T AV = \text{diag}(\sigma_1, \ldots, \sigma_n)$ and save $V$.
2. Determine $\tilde{r} \leq \text{rank}(A)$.
3. Apply QR with column pivoting: $Q^T V(:,\, 1:\tilde{r})^T P = [ R_{11} \ R_{12} ]$ and set $AP = [ B_1 \ B_2 ]$ with $B_1 \in \mathbb{R}^{m \times \tilde{r}}$ and $B_2 \in \mathbb{R}^{m \times (n-\tilde{r})}$.
4. Determine $z \in \mathbb{R}^{\tilde{r}}$ such that $\| b - B_1 z \|_2 = \text{min}$.

**Example 12.2.1** Let

$$A = \begin{bmatrix} 3 & 4 & 1.0001 \\ 7 & 4 & -3.0002 \\ 2 & 5 & 2.9999 \\ -1 & 4 & 5.0003 \end{bmatrix}, \quad b = \begin{bmatrix} 1 \\ 1 \\ 1 \\ 1 \end{bmatrix}.$$  

$A$ is close to being rank 2 in the sense that $\sigma_3(A) \approx .0001$. Setting $\tilde{r} = 2$ in Algorithm 12.2.1 leads to $x = [0 \ 0.2360 \ -0.0085]^T$ with $\| Ax - b \|_2 = .1966$. (The permutation $P$ is given by $P = [e_3 \ e_2 \ e_1]$.) Note that $x_{LS} = [828.1056 \ -827.8569 \ 828.0536]^T$ with minimum residual $\| Ax_{LS} - b \|_2 = 0.0343$.

**12.2.3 More on Column Independence vs. Residual**

We return to the discussion of the trade-off between column independence and norm of the residual. In particular, to assess the above method of subset selection, we need to examine the residual of the vector $y$ that it produces $r_y = b - Ay = b - B_1 z = (I - B_1 B_1^+) b$. Here, $B_1 = B(:,\, 1:\tilde{r})$ with
\[ B = AP. \] To this end, it is appropriate to compare \( r_y \) with \( r_{x_\tilde{r}} = b - Ax_{\tilde{r}} \) since we are regarding \( A \) as a rank-\( \tilde{r} \) matrix and since \( x_{\tilde{r}} \) solves the nearest rank-\( \tilde{r} \) LS problem, namely, \( \min \| A_{\tilde{r}}x - b \|_2 \).

**Theorem 12.2.2** If \( r_y \) and \( r_{x_\tilde{r}} \) are defined as above and if \( \tilde{V}_{11} \) is the leading \( r \)-by-\( r \) principal submatrix of \( P^T V \), then

\[
\| r_{x_\tilde{r}} - r_y \|_2 \leq \frac{\sigma_{\tilde{r}+1}(A)}{\sigma_{\tilde{r}}(A)} \| \tilde{V}_{11}^{-1} \|_2 \| b \|_2
\]

**Proof.** Note that \( r_{x_\tilde{r}} = (I - U_1 U_1^T)b \) and \( r_y = (I - Q_1 Q_1^T)b \) where

\[
U = \begin{bmatrix} U_1 & U_2 \\ \tilde{r} & m - \tilde{r} \end{bmatrix}
\]

is a partitioning of the matrix \( U \) in (12.2.1) and where \( Q_1 = B_1(B_1^T B_1)^{-1/2} \).

Using Theorem 2.6.1 we obtain

\[
\| r_{x_\tilde{r}} - r_y \|_2 \leq \| U_1 U_1^T - Q_1 Q_1^T \|_2 \| b \|_2 = \| U_2^T Q_1 \|_2 \| B_1(B_1^T B_1)^{-1/2} \|_2 \leq \sigma_{\tilde{r}+1}(A) \frac{1}{\sigma_{\tilde{r}}(B_1)}
\]

while Theorem 12.2.1 permits us to conclude that

\[
\| U_2^T Q_1 \|_2 \leq \| U_2^T B_1 \|_2 \| (B_1^T B_1)^{-1/2} \|_2 \leq \frac{\sigma_{\tilde{r}+1}(A)}{\sigma_{\tilde{r}}(A)} \| \tilde{V}_{11}^{-1} \|_2.
\]

Noting that

\[
\| r_{x_\tilde{r}} - r_y \|_2 = \left\| B_1 y - \sum_{i=1}^r (u_i^T b) u_i \right\|_2
\]

we see that Theorem 12.2.2 sheds light on how well \( B_1 y \) can predict the "stable" component of \( b \), i.e., \( U_1^T b \). Any attempt to approximate \( U_2^T b \) can lead to a large norm solution. Moreover, the theorem says that if \( \sigma_{\tilde{r}+1}(A) \ll \sigma_{\tilde{r}}(A) \), then any reasonably independent subset of columns produces essentially the same-sized residual. On the other hand, if there is no well-defined gap in the singular values, then the determination of \( \tilde{r} \) becomes difficult and the entire subset selection problem more complicated.

**Problems**

**P12.2.1** Suppose \( A \in \mathbb{R}^{m \times n} \) and that \( \| u^T A \|_2 = \sigma \) with \( u^T u = 1 \). Show that if \( u^T (Ax - b) = 0 \) for \( x \in \mathbb{R}^m \) and \( b \in \mathbb{R}^m \), then \( \| x \|_2 \geq |u^T b|/\sigma \).

**P12.2.2** Show that if \( B_1 \in \mathbb{R}^{m \times k} \) is comprised of \( k \) columns from \( A \in \mathbb{R}^{m \times n} \) then \( \sigma_k(B_1) \leq \sigma_k(A) \).

**P12.2.3** In equation (12.2.2) we know that the matrix

\[
P^T V = \begin{bmatrix} \tilde{V}_{11} & \tilde{V}_{12} \\ \tilde{V}_{21} & \tilde{V}_{22} \end{bmatrix} \begin{bmatrix} \tilde{r} \\ n - \tilde{r} \end{bmatrix}
\]
is orthogonal. Thus, \( \| \tilde{V}_{11}^{-1} \|_2 = \| \tilde{V}_{22}^{-1} \|_2 \) from the CS decomposition (Theorem 2.6.3). Show how to compute \( P \) by applying the QR with column pivoting algorithm to \( [\tilde{V}_{22}^T \; \tilde{V}_{12}^T] \). (For \( r > n/2 \), this procedure would be more economical than the technique discussed in the text.) Incorporate this observation in Algorithm 12.2.1.

Notes and References for Sec. 12.2

The material in this section is derived from

A subset selection procedure based upon the total least squares fitting technique of §12.3 is given in

The literature on subset selection is vast and we refer the reader to

### 12.3 Total Least Squares

The problem of minimizing \( \| D(Ax - b) \|_2 \) where \( A \in \mathbb{R}^{m \times n} \), and \( D = \text{diag}(d_1, \ldots, d_m) \) is nonsingular can be recast as follows:

\[
\min_{b+r \in \text{range}(A)} \| Dr \|_2, \quad r \in \mathbb{R}^m. \tag{12.3.1}
\]

In this problem, there is a tacit assumption that the errors are confined to the "observation" \( b \). When error is also present in the "data" \( A \), then it may be more natural to consider the problem

\[
\min_{b+r \in \text{range}(A+E)} \| D[E, r^T]_F \|, \quad E \in \mathbb{R}^{m \times n}, \; r \in \mathbb{R}^m \tag{12.3.2}
\]

where \( D = \text{diag}(d_1, \ldots, d_m) \) and \( T = \text{diag}(t_1, \ldots, t_{n+1}) \) are nonsingular. This problem, discussed in Golub and Van Loan (1980), is referred to as the total least squares (TLS) problem.

If a minimizing \( [E_0, \; r_0] \) can be found for (12.3.2), then any \( x \) satisfying \((A + E_0)x = b + r_0\) is called a TLS solution. However, it should be realized that (12.3.2) may fail to have a solution altogether. For example, if

\[
A = \begin{bmatrix} 1 & 0 \\ 0 & 0 \\ 0 & 0 \end{bmatrix}, \quad b = \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix}, \quad D = I_3, \; T = I_3, \; \text{and} \; E_\varepsilon = \begin{bmatrix} 0 & 0 \\ 0 & \varepsilon \\ 0 & \varepsilon \end{bmatrix}
\]
then for all $\epsilon > 0$, $b \in \text{ran}(A + E\epsilon)$. However, there is no smallest value of $\| [E, \; r] \|_F$ for which $b + r \in \text{ran}(A + E)$.

A generalization of (12.3.2) results if we allow multiple right-hand sides. In particular, if $B \in \mathbb{R}^{m \times k}$, then we have the problem

$$
\min_{\text{range}(B+R) \subseteq \text{range}(A+E)} \| D[ E, \; R ] T \|_F
$$

(12.3.3)

where $E \in \mathbb{R}^{m \times n}$ and $R \in \mathbb{R}^{m \times k}$ and the matrices $D = \text{diag}(d_1, \ldots, d_m)$ and $T = \text{diag}(t_1, \ldots, t_{n+k})$ are nonsingular. If $[E_0, R_0]$ solves (12.3.3), then any $X \in \mathbb{R}^{n \times k}$ that satisfies $(A + E_0)X = (B + R_0)$ is said to be a TLS solution to (12.3.3).

In this section we discuss some of the mathematical properties of the total least squares problem and show how it can be solved using the SVD. Chapter 5 is the only prerequisite. A very detailed treatment of the TLS problem is given in the monograph by Van Huffel and Vanderwalle (1991).

### 12.3.1 Mathematical Background

The following theorem gives conditions for the uniqueness and existence of a TLS solution to the multiple right-hand side problem.

**Theorem 12.3.1** Let $A$, $B$, $D$, and $T$ be as above and assume $m \geq n + k$. Let

$$
C = D[A, \; B] T = \begin{bmatrix} C_1 & C_2 \\ n & k \end{bmatrix}
$$

have SVD $U^T CV = \text{diag}(\sigma_1, \ldots, \sigma_{n+k}) = \Sigma$ where $U$, $V$, and $\Sigma$ are partitioned as follows:

$$
U = \begin{bmatrix} U_1 & U_2 \\ n & k \end{bmatrix}, \quad V = \begin{bmatrix} V_{11} & V_{12} \\ V_{21} & V_{22} \\ n & k \end{bmatrix},
$$

$$
\Sigma = \begin{bmatrix} \Sigma_1 & 0 \\ 0 & \Sigma_2 \end{bmatrix}.
$$

If $\sigma_n(C_1) > \sigma_{n+1}(C)$, then the matrix $[E_0, R_0]$ defined by

$$
D[E_0, \; R_0] T = -U_2 \Sigma_2 [V_{12}^T, \; V_{22}^T]
$$

(12.3.4)

solves (12.3.3). If $T_1 = \text{diag}(t_1, \ldots, t_n)$ and $T_2 = \text{diag}(t_{n+1}, \ldots, t_{n+k})$ then the matrix

$$
X_{\text{TLS}} = -T_1 V_{12} V_{22}^{-1} T_2^{-1}
$$

exists and is the unique solution to $(A + E_0)X = B + R_0$. 
Proof. We first establish two results that follow from the assumption \( \sigma_n(C_1) > \sigma_{n+1}(C) \). From the equation \( CV = U \Sigma \) we have \( C_1 V_{12} + C_2 V_{22} = U_2 \Sigma_2 \). We wish to show that \( V_{22} \) is nonsingular. Suppose \( V_{22} x = 0 \) for some unit 2-norm \( x \). It follows from \( V_{12}^T V_{12} + V_{22}^T V_{22} = I \) that \( \| V_{12} x \|_2 = 1 \). But then

\[
\sigma_{n+1}(C) \geq \| U_2 \Sigma_2 x \|_2 = \| C_1 V_{12} x \|_2 \geq \sigma_n(C_1),
\]
a contradiction. Thus, the submatrix \( V_{22} \) is nonsingular.

The other fact that follows from \( \sigma_n(C_1) > \sigma_{n+1}(C) \) concerns the strict separation of \( \sigma_n(C) \) and \( \sigma_{n+1}(C) \). From Corollary 8.3.3, we have \( \sigma_n(C) \geq \sigma_n(C_1) \) and so \( \sigma_n(C) \geq \sigma_n(C_1) > \sigma_{n+1}(C) \).

Now we are set to prove the theorem. If \( \text{ran}(B + R) \subset \text{ran}(A + E) \), then there is an \( X \) (\( n \)-by-\( k \)) so \( (A + E)X = B + R \), i.e.,

\[
\{ D[A, B]T + D[E, R]T \} T^{-1} \begin{bmatrix} X \\ -I_k \end{bmatrix} = 0. \tag{12.3.5}
\]

Thus, the matrix in curly brackets has, at most, rank \( n \). By following the argument in Theorem 2.5.3, it can be shown that

\[
\| D[E, R]T \|_F \geq \sum_{i=n+1}^{n+k} \sigma_i(C)^2
\]

and that the lower bound is realized by setting \([ E, R ] = [ E_0, R_0 ] \). The inequality \( \sigma_n(C) > \sigma_{n+1}(C) \) ensures that \([ E_0, R_0 ] \) is the unique minimizer. The null space of

\[
\{ D[A, B]T + D[E_0, R_0]T \} = U_1 \Sigma_1 [ V_{11}^T V_{21}^T ]
\]

is the range of \( \begin{bmatrix} V_{12} \\ V_{22} \end{bmatrix} \). Thus, from (12.3.5)

\[
T^{-1} \begin{bmatrix} X \\ -I_k \end{bmatrix} = \begin{bmatrix} V_{12} \\ V_{22} \end{bmatrix} S
\]

for some \( k \)-by-\( k \) matrix \( S \). From the equations \( T_1^{-1} X = V_{12} S \) and \( -T_2^{-1} = V_{22} S \) we see that \( S = -V_{22}^{-1} T_2^{-1} \). Thus, we must have

\[
X = T_1 V_{12} S = -T_1 V_{12} V_{22}^{-1} T_2^{-1} = X_{T_{LS}}. \quad \square
\]

If \( \sigma_n(C) = \sigma_{n+1}(C) \), then the TLS problem may still have a solution, although it may not be unique. In this case, it may be desirable to single out a "minimal norm" solution. To this end, consider the \( \tau \)-norm defined on \( \mathbb{R}^{n \times k} \) by \( \| Z \|_{\tau} = \| T_1^{-1} Z T_2 \|_2 \). If \( X \) is given by (12.3.5), then from the CS decomposition (Theorem 2.6.3) we have

\[
\| X \|_{\tau}^2 = \| V_{12} V_{22}^{-1} \|_2^2 = \frac{1 - \sigma_k(V_{22})^2}{\sigma_k(V_{22})^2}.
\]

This suggests choosing \( V \) in Theorem 12.3.1 so that \( \sigma_k(V_{22}) \) is maximized.
12.3.2 Computation for the \(k=1\) Case

We show how to maximize \(V_{22}\) in the important \(k = 1\) case. Suppose the singular values of \(C\) satisfy \(\sigma_{n-p} > \sigma_{n-p+1} = \cdots = \sigma_{n+1}\) and let \(V = [v_1, \ldots, v_{n+1}]\) be a column partitioning of \(V\). If \(\tilde{Q}\) is a Householder matrix such that

\[
V(:,n+1-p:n+1)\tilde{Q} = \begin{bmatrix} W & z \\ 0 & \alpha \end{bmatrix}
\]

then \(\begin{bmatrix} z \\ \alpha \end{bmatrix}\) has the largest \((n+1)\)-st component of all the vectors in \(\text{span}\{v_{n+1-p}, \ldots, v_{n+1}\}\). If \(\alpha = 0\), the TLS problem has no solution. Otherwise \(x_{TLS} = -T_1 z/(t_{n+1} \alpha)\). Moreover,

\[
\begin{bmatrix} I_{n-1} & 0 \\ 0 & Q \end{bmatrix} U^T(D[A, b]T) V \begin{bmatrix} I_{n-p} & 0 \\ 0 & \tilde{Q} \end{bmatrix} = \Sigma
\]

and so

\[
D[E_0, r_0]T = -D[A, b]T \begin{bmatrix} z \\ \alpha \end{bmatrix} [z^T \alpha].
\]

Overall, we have the following algorithm:

**Algorithm 12.3.1** Given \(A \in \mathbb{R}^{m \times n} (m > n)\), \(b \in \mathbb{R}^m\), and nonsingular \(D = \text{diag}(d_1, \ldots, d_m)\) and \(T = \text{diag}(t_1, \ldots, t_{n+1})\), the following algorithm computes (if possible) a vector \(x_{TLS} \in \mathbb{R}^n\) such that \((A + E_0)x = (b + r_0)\) and \(\|D[E_0, r_0]T\|_F\) is minimal.

1. Compute the SVD \(U^T(D[A, b]T)V = \text{diag}(\sigma_1, \ldots, \sigma_{n+1})\). Save \(V\).
2. Determine \(p\) such that \(\sigma_1 \geq \cdots \geq \sigma_{n-p} > \sigma_{n-p+1} = \cdots = \sigma_{n+1}\).
3. Compute a Householder matrix \(P\) such that if \(\tilde{V} = VP\), then \(\tilde{V}(n+1, n-p+1:n) = 0\)

\[
\text{if } \tilde{v}_{n+1,n+1} \neq 0 \\
\quad \text{for } i = 1:n \\
\quad \quad x_i = -t_i \tilde{v}_{i,n+1}/(t_{n+1} \tilde{v}_{n+1,n+1})
\]

end

This algorithm requires about \(2mn^2 + 12n^3\) flops and most of these are associated with the SVD computation.

**Example 12.3.1** The TLS problem \(\min_{(x,e)=b+r} \| [e, r] \|_F\) where \(a = [1, 2, 3, 4]^T\) and \(b = [2.01, 3.99, 5.80, 8.30]^T\) has solution \(x_{TLS} = 2.0212, e = [-0.0045, -0.0209, -1.048, 0.0855]^T\), and \(r = [0.0022, 0.0103, 0.0519, -0.0423]^T\). Note that for this data \(x_{LS} = 2.0197\).
12.3.3 Geometric Interpretation

It can be shown that the TLS solution $x_{TLS}$ minimizes

$$
\psi(x) = \sum_{i=1}^{m} d_i^2 \frac{|a_i^T x - b_i|^2}{x^T T_1^{-2} x + t_{n+1}^{-2}}
$$

where $a_i^T$ is $i$th row of $A$ and $b_i$ is the $i$th component of $b$. A geometrical interpretation of the TLS problem is made possible by this observation. Indeed,

$$
\frac{|a_i^T x - b_i|^2}{x^T T_1^{-2} x + t_{n+1}^{-2}}
$$

is the square of the distance from $\begin{bmatrix} a_i \\ b_i \end{bmatrix} \in \mathbb{R}^{n+1}$ to the nearest point in the subspace

$$
P_z = \left\{ \begin{bmatrix} a \\ b \end{bmatrix} : a \in \mathbb{R}^n, \ b \in \mathbb{R}, \ b = x^T a \right\}
$$

where distance in $\mathbb{R}^{n+1}$ is measured by the norm $\| z \| = \| Tz \|_2$. A great deal has been written about this kind of fitting. See Pearson (1901) and Madansky (1959).

Problems

P12.3.1 Consider the TLS problem (12.3.2) with nonsingular $D$ and $T$. (a) Show that if $\text{rank}(A) < n$, then (12.3.2) has a solution if and only if $b \in \text{ran}(A)$. (b) Show that if $\text{rank}(A) = n$, then (12.3.2) has no solution if $A^T D^2 b = 0$ and $|t_{n+1}| \| Db \|_2 \geq \sigma_n(DAT_1)$ where $T_1 = \text{diag}(t_1, \ldots, t_n)$.

P12.3.2 Show that if $C = D[A, b]T = [A_1, d]$ and $\sigma_n(C) > \sigma_{n+1}(C)$, then the TLS solution $x$ satisfies $(A_1^T A_1 - \sigma_{n+1}(C)^2 I)x = A_1^T d$.

P12.3.3 Show how to solve (12.3.2) with the added constraint that the first $p$ columns of the minimizing $E$ are zero.

Notes and References for Sec. 12.3

This section is based upon

The bearing of the SVD on the TLS problem is set forth in

The most detailed study of the TLS problem is

If some of the columns of $A$ are known exactly then it is sensible to force the TLS perturbation matrix $E$ to be zero in the same columns. Aspects of this constrained TLS problem are discussed in

Other references concerned with least squares fitting when there are errors in the data matrix include

12.4 Computing Subspaces with the SVD

It is sometimes necessary to investigate the relationship between two given subspaces. How close are they? Do they intersect? Can one be "rotated" into the other? And so on. In this section we show how questions like these can be answered using the singular value decomposition. Knowledge of Chapter 5 and §8.6 are assumed.

12.4.1 Rotation of Subspaces

Suppose $A \in \mathbb{R}^{m \times p}$ is a data matrix obtained by performing a certain set of experiments. If the same set of experiments is performed again, then a different data matrix, $B \in \mathbb{R}^{n \times p}$, is obtained. In the orthogonal Procrustes problem the possibility that $B$ can be rotated into $A$ is explored by solving the following problem:

$$\text{minimize } \| A - BQ \|_F \quad \text{subject to } Q^TQ = I_p. \quad (12.4.1)$$

Recall that the trace of a matrix is the sum of its diagonal entries and thus, $\text{tr}(C^TC) = \| C \|_F^2$. It follows that if $Q \in \mathbb{R}^{p \times p}$ is orthogonal, then

$$\| A - BQ \|_F^2 = \text{tr}(A^TA) + \text{tr}(B^TB) - 2\text{tr}(Q^TB^TA).$$

Thus, (12.4.1) is equivalent to the problem of maximizing $\text{tr}(Q^TB^TA)$.

The maximizing $Q$ can be found by calculating the SVD of $B^TA$. Indeed, if $U^T(B^TA)V = \Sigma = \text{diag}(\sigma_1, \ldots, \sigma_p)$ is the SVD of this matrix and we define the orthogonal matrix $Z$ by $Z = V^TQ^TU$, then

$$\text{tr}(Q^TB^TA) = \text{tr}(Q^TU\Sigma V^T) = \text{tr}(Z\Sigma) = \sum_{i=1}^p z_{ii}\sigma_i \leq \sum_{i=1}^p \sigma_i.$$ 

Clearly, the upper bound is attained by setting $Q = UV^T$ for then $Z = I_p$. This gives the following algorithm:

Algorithm 12.4.1 Given $A$ and $B$ in $\mathbb{R}^{m \times p}$, the following algorithm finds an orthogonal $Q \in \mathbb{R}^{p \times p}$ such that $\| A - BQ \|_F$ is minimum.

- $C = B^TA$
- Compute the SVD $U^TCV = \Sigma$. Save $U$ and $V$.
- $Q = UV^T$.

The solution matrix $Q$ is the orthogonal polar factor of $B^TA$. See §4.2.10.

Example 12.4.1

$$Q = \begin{bmatrix} .9999 & -.0126 \\ .0126 & .9999 \end{bmatrix} \text{ minimizes } \left\| \begin{bmatrix} 1 & 2 \\ 3 & 4 \\ 5 & 6 \\ 7 & 8 \end{bmatrix} Q - \begin{bmatrix} 1.2 & 2.1 \\ 2.9 & 4.3 \\ 5.2 & 6.1 \\ 6.8 & 8.1 \end{bmatrix} \right\|_F.$$
12.4.2 Intersection of Null Spaces

Let \( A \in \mathbb{R}^{m \times n} \) and \( B \in \mathbb{R}^{p \times n} \) be given, and consider the problem of finding an orthonormal basis for \( \text{null}(A) \cap \text{null}(B) \). One approach is to compute the null space of the matrix

\[
C = \begin{bmatrix} A \\ B \end{bmatrix}
\]

since \( Cx = 0 \iff x \in \text{null}(A) \cap \text{null}(B) \). However, a more economical procedure results if we exploit the following theorem.

**Theorem 12.4.1** Suppose \( A \in \mathbb{R}^{m \times n} \) and let \( \{z_1, \ldots, z_t\} \) be an orthonormal basis for \( \text{null}(A) \). Define \( Z = [z_1, \ldots, z_t] \) and let \( \{w_1, \ldots, w_q\} \) be an orthonormal basis for \( \text{null}(BZ) \) where \( B \in \mathbb{R}^{p \times n} \). If \( W = [w_1, \ldots, w_q] \), then the columns of \( ZW \) form an orthonormal basis for \( \text{null}(A) \cap \text{null}(B) \).

**Proof.** Since \( AZ = 0 \) and \( (BZ)W = 0 \), we clearly have \( \text{ran}(ZW) \subseteq \text{null}(A) \cap \text{null}(B) \). Now suppose \( x \) is in both \( \text{null}(A) \) and \( \text{null}(B) \). It follows that \( x = Za \) for some \( 0 \neq a \in \mathbb{R}^t \). But since \( 0 = Bx = BZa \), we must have \( a = Wb \) for some \( b \in \mathbb{R}^q \). Thus, \( x = ZWb \in \text{ran}(ZW) \). \( \square \)

When the SVD is used to compute the orthonormal bases in this theorem we obtain the following procedure:

**Algorithm 12.4.2** Given \( A \in \mathbb{R}^{m \times n} \) and \( B \in \mathbb{R}^{p \times n} \), the following algorithm computes and integer \( s \) and a matrix \( Y = [y_1, \ldots, y_s] \) having orthonormal columns which span \( \text{null}(A) \cap \text{null}(B) \). If the intersection is trivial then \( s = 0 \).

Compute the SVD \( U^T_AAV_A = \text{diag}(\sigma_i) \). Save \( V_A \) and set \( r = \text{rank}(A) \).

if \( r < n \)
\[
C = BV_A(:, r + 1:n)
\]
Compute the SVD \( U^T_CCV_C = \text{diag}(\gamma_i) \). Save \( V_C \) and set \( q = \text{rank}(C) \).

if \( q < n - r \)
\[
s = n - r - q \\
Y = V_A(:, r + 1:n)V_C(:, q + 1:n - r)
\]
else
\[
s = 0
\]
end
else
\[
s = 0
\]
end
The amount of work required by this algorithm depends upon the relative sizes of \( m, \, n, \, p, \) and \( r. \)

We mention that a practical implementation of this algorithm requires a means for deciding when a computed singular value \( \hat{\sigma}_i \) is negligible. The use of a tolerance \( \delta \) for this purpose (e.g. \( \hat{\sigma}_i < \delta \Rightarrow \hat{\sigma}_i = 0 \)) implies that the columns of the computed \( \tilde{Y} \) "almost" define a common null space of \( A \) and \( B \) in the sense that \( \| A\tilde{Y} \|_2 \approx \| B\tilde{Y} \|_2 \approx \delta. \)

**Example 12.4.2** If

\[
A = \begin{bmatrix} 1 & -1 & 1 \\ 1 & -1 & 1 \\ 1 & -1 & 1 \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} 4 & 2 & 0 \\ 2 & 1 & 0 \\ 6 & 3 & 0 \end{bmatrix}
\]

then \( \text{null}(A) \cap \text{null}(B) = \text{span}\{x\}, \) where \( x = [1 \, -2 \, -3]^T. \) Applying Algorithm 12.4.2 we find

\[
V_{2A}V_{2C} = \begin{bmatrix} -0.8165 & 0.0000 & -0.3273 \\ -0.4082 & 0.7071 & -0.5345 \\ 0.4082 & 0.7071 & -0.8018 \end{bmatrix} \approx \begin{bmatrix} 0.2673 \\ -0.5345 \\ -0.8018 \end{bmatrix} \approx 0.2673 \begin{bmatrix} 1 \\ -2 \\ -3 \end{bmatrix}.
\]

### 12.4.3 Angles Between Subspaces

Let \( F \) and \( G \) be subspaces in \( \mathbb{R}^m \) whose dimensions satisfy

\[ p = \dim(F) \geq \dim(G) = q \geq 1. \]

The **principal angles** \( \theta_1, \ldots, \theta_q \in [0, \pi/2] \) between \( F \) and \( G \) are defined recursively by

\[
\cos(\theta_k) = \max_{u \in F} \max_{v \in G} u^Tv = u_k^T v_k
\]

subject to:

\[
\| u \| = \| v \| = 1, \\
u_i^Tu_i = 0, \quad i = 1:k-1, \\
v_i^Tv_i = 0, \quad i = 1:k-1.
\]

Note that the principal angles satisfy \( 0 \leq \theta_1 \leq \cdots \leq \theta_q \leq \pi/2. \) The vectors \( \{u_1, \ldots, u_q\} \) and \( \{v_1, \ldots, v_q\} \) are called the **principal vectors** between the subspaces \( F \) and \( G. \)

Principal angles and vectors arise in many important statistical applications. The largest principal angle is related to the notion of distance between equidimensional subspaces that we discussed in §2.6.3 If \( p = q \) then \( \text{dist}(F, G) = \sqrt{1 - \cos^2(\theta_p)} = \sin(\theta_p). \)

If the columns of \( Q_F \in \mathbb{R}^{m \times p} \) and \( Q_G \in \mathbb{R}^{m \times q} \) define orthonormal bases for \( F \) and \( G \) respectively, then

\[
\max_{\| u \|_2 = 1} \max_{\| v \|_2 = 1} u^Tv = \max_{\| y \|_2 = 1} \max_{x \in \mathbb{R}^p} y^T(Q_F^TQ_G)x
\]
From the minimax characterization of singular values given in Theorem 8.6.1 it follows that if $Y^T(Q_F^T Q_G) Z = \text{diag}(\sigma_1, \ldots, \sigma_q)$ is the SVD of $Q_F^T Q_G$, then we may define the $u_k$, $v_k$, and $\theta_k$ by

$$
\begin{align*}
[u_1, \ldots, u_p] &= Q_F Y \\
[v_1, \ldots, v_q] &= Q_G Z \\
\cos(\theta_k) &= \sigma_k \quad k = 1:q
\end{align*}
$$

Typically, the spaces $F$ and $G$ are defined as the ranges of given matrices $A \in \mathbb{R}^{m \times p}$ and $B \in \mathbb{R}^{m \times q}$. In this case the desired orthonormal bases can be obtained by computing the QR factorizations of these two matrices.

**Algorithm 12.4.3** Given $A \in \mathbb{R}^{m \times p}$ and $B \in \mathbb{R}^{m \times q}$ ($p \geq q$) each with linearly independent columns, the following algorithm computes the orthogonal matrices $U = [u_1, \ldots, u_q]$ and $V = [v_1, \ldots, v_q]$ and $\cos(\theta_1), \ldots, \cos(\theta_q)$ such that the $\theta_k$ are the principal angles between $\text{ran}(A)$ and $\text{ran}(B)$ and $u_k$ and $v_k$ are the associated principal vectors.

Use Algorithm 5.2.1 to compute the QR factorizations

$$
\begin{align*}
A &= Q_A R_A & Q_A^T Q_A &= I_p, & R_A &\in \mathbb{R}^{p \times p} \\
B &= Q_B R_B & Q_B^T Q_B &= I_q, & R_B &\in \mathbb{R}^{q \times q}
\end{align*}
$$

$$
C = Q_A^T Q_B \\
\text{Compute the SVD } Y^T C Z = \text{diag}(\cos(\theta_k)). \\
Q_A Y(:,1:q) = [u_1, \ldots, u_q] \\
Q_B Z = [v_1, \ldots, v_q]
$$

This algorithm requires about $4m(q^2 + 2p^2) + 2pq(m + q) + 12q^3$ flops.

The idea of using the SVD to compute the principal angles and vectors is due to Björck and Golub (1973). The problem of rank deficiency in $A$ and $B$ is also treated in this paper.

### 12.4.4 Intersection of Subspaces

Algorithm 12.4.3 can also be used to compute an orthonormal basis for $\text{ran}(A) \cap \text{ran}(B)$ where $A \in \mathbb{R}^{m \times p}$ and $B \in \mathbb{R}^{m \times q}$.

**Theorem 12.4.2** Let $\{\cos(\theta_k), u_k, v_k\}_{k=1}^q$ be defined by Algorithm 12.4.3. If the index $s$ is defined by $1 = \cos(\theta_1) = \cdots = \cos(\theta_s) > \cos(\theta_{s+1})$, then we have

$$
\text{ran}(A) \cap \text{ran}(B) = \text{span}\{u_1, \ldots, u_s\} = \text{span}\{v_1, \ldots, v_s\}.
$$
12.4. **Computing Subspaces with the SVD**

**Proof.** The proof follows from the observation that if \( \cos(\theta_k) = 1 \), then \( u_k = v_k \).

With inexact arithmetic, it is necessary to compute the approximate multiplicity of the unit cosines in Algorithm 12.4.3.

**Example 12.4.3** If

\[
A = \begin{bmatrix} 1 & 2 \\ 3 & 4 \\ 5 & 6 \end{bmatrix} \quad \text{and} \quad B = \begin{bmatrix} 1 & 5 \\ 3 & 7 \\ 5 & -1 \end{bmatrix}
\]

then the cosines of the principal angles between \( \text{ran}(A) \) and \( \text{ran}(B) \) are 1.000 and .856.

**Problems**

P12.4.1 Show that if \( A \) and \( B \) are \( m \)-by-\( p \) matrices, with \( p \leq m \), then

\[
\min_{Q^TQ = I_p} \| A - BQ \|^2_F = \sum_{i=1}^{p} (\sigma_i(A))^2 - 2\sigma_i(B^T A) + \sigma_i(B)^2.
\]

P12.4.2 Extend Algorithm 12.4.2 so that it can compute an orthonormal basis for \( \text{null}(A_1) \cap \cdots \cap \text{null}(A_n) \).

P12.4.3 Extend Algorithm 12.4.3 to handle the case when \( A \) and \( B \) are rank deficient.

P12.4.4 Relate the principal angles and vectors between \( \text{ran}(A) \) and \( \text{ran}(B) \) to the eigenvalues and eigenvectors of the generalized eigenvalue problem

\[
\begin{bmatrix} 0 & A^TB \\ B^TA & 0 \end{bmatrix} \begin{bmatrix} y \\ z \end{bmatrix} = \sigma \begin{bmatrix} A^TA & 0 \\ 0 & B^TB \end{bmatrix} \begin{bmatrix} y \\ z \end{bmatrix}.
\]

P12.4.5 Suppose \( A, B \in \mathbb{R}^{m \times n} \) and that \( A \) has full column rank. Show how to compute a symmetric matrix \( X \in \mathbb{R}^{m \times n} \) that minimizes \( \| AX - B \|_F \). Hint: Compute the SVD of \( A \).

**Notes and References for Sec. 12.4**

The problem of minimizing \( \| A - BQ \|_F \) over all orthogonal matrices arises in psychometrics. See

When \( B = I \), this problem amounts to finding the closest orthogonal matrix to \( A \). This is equivalent to the polar decomposition problem of \$4.2.10\$. See

If \( A \) is reasonably close to being orthogonal itself, then Björck and Bowie’s technique is more efficient than the SVD algorithm.

The problem of minimizing \( \| AX - B \|_F \) subject to the constraint that \( X \) is symmetric is studied in

Using the SVD to solve the canonical correlation problem is discussed in

The SVD has other roles to play in statistical computation.

### 12.5 Upgrading Matrix Factorizations

In many applications it is necessary to re-factor a given matrix \( A \in \mathbb{R}^{m \times n} \) after it has been altered in some minimal sense. For example, given that we have the QR factorization of \( A \), we may need to calculate the QR factorization of a matrix \( A \) that is obtained by (a) adding a general rank-one matrix to \( A \), (b) appending a row (or column) to \( A \), or (c) deleting a row (or column) from \( A \). In this section we show that in situations like these, it is much more efficient to “upgrade” \( A \)'s QR factorization than to generate it from scratch. We also show how to upgrade the null space of a matrix after it has been augmented with an additional row.

Before beginning, we mention that there are also techniques for updating the factorizations \( PA = LU \), \( A = GG^T \), and \( A = LDL^T \). Updating these factorizations, however, can be quite delicate because of pivoting requirements and because when we tamper with a positive definite matrix the result may not be positive definite. See Gill, Golub, Murray, and Saunders (1974) and Stewart (1979). Along these lines we briefly discuss hyperbolic transformations and their use in the Cholesky downdating problem.

Familiarity with \$3.5\$, \$4.1\$, \$5.1\$, \$5.2\$, \$5.4\$, and \$5.5\$ is required. Complementary reading includes Gill, Murray, and Wright (1991).
12.5. Updating Matrix Factorizations

12.5.1 Rank-One Changes

Suppose we have the QR factorization $QR = B \in \mathbb{R}^{m \times n}$ and that we need to compute the QR factorization $B + uv^T = Q_1 R_1$ where $u, v \in \mathbb{R}^n$ are given. Observe that

$$B + uv^T = Q(R + uv^T)$$

(12.5.1)

where $w = Q^T u$. Suppose that we compute rotations $J_{n-1}, \ldots, J_2, J_1$ such that

$$J_{n-1}^T \cdots J_2^T w = \pm \| w \|_2 e_1 .$$

Here, each $J_k$ is a rotation in planes $k$ and $k+1$. (For details, see Algorithm 5.1.3.) If these same Givens rotations are applied to $R$, it can be shown that

$$H = J_{n-1}^T \cdots J_2^T R$$

(12.5.2)

is upper Hessenberg. For example, in the $n = 4$ case we start with

$$R = \begin{bmatrix}
\times & \times & \times & \times \\
0 & \times & \times & \\
0 & 0 & \times & \\
0 & 0 & 0 & \times
\end{bmatrix} \quad w = \begin{bmatrix}
\times \\
\times \\
\times \\
\times
\end{bmatrix}$$

and then update as follows:

$$R = J_3^T R = \begin{bmatrix}
\times & \times & \times & \times \\
0 & \times & \times & \\
0 & 0 & \times & \\
0 & 0 & 0 & \times
\end{bmatrix} \quad w = J_3^T w = \begin{bmatrix}
\times \\
\times \\
0 \\
0
\end{bmatrix}$$

$$R = J_2^T R = \begin{bmatrix}
\times & \times & \times & \times \\
0 & \times & \times & \\
0 & 0 & \times & \\
0 & 0 & 0 & \times
\end{bmatrix} \quad w = J_2^T w = \begin{bmatrix}
\times \\
0 \\
0 \\
0
\end{bmatrix}$$

$$H = J_1^T R = \begin{bmatrix}
\times & \times & \times & \times \\
\times & \times & \times & \\
0 & x & \times & \\
0 & 0 & \times & \times
\end{bmatrix} \quad w = J_1^T w = \begin{bmatrix}
\times \\
0 \\
0 \\
0
\end{bmatrix}$$

Consequently,

$$(J_{n-1}^T \cdots J_2^T R + uv^T) = H \pm \| w \|_2 e_1 v^T = H_1$$

(12.5.3)

is also upper Hessenberg.

In Algorithm 5.2.3, we show how to compute the QR factorization of an upper Hessenberg matrix in $O(n^2)$ flops. In particular, we can find Givens rotations $G_k$, $k = 1:n - 1$ such that

$$G_{n-1}^T \cdots G_1^T H_1 = R_1$$

(12.5.4)
is upper triangular. Combining (12.5.1) through (12.5.4) we obtain the QR factorization \( B + uu^T = Q_1 R_1 \) where

\[
Q_1 = Q J_{n-1} \cdots J_1 G_1 \cdots G_{n-1}.
\]

A careful assessment of the work reveals that about \( 26n^2 \) flops are required. The vector \( w = Q^T u \) requires \( 2n^2 \) flops. Computing \( H \) and accumulating the \( J_k \) into \( Q \) involves \( 12n^2 \) flops. Finally, computing \( R_1 \) and multiplying the \( G_k \) into \( Q \) involves \( 12n^2 \) flops.

The technique readily extends to the case when \( B \) is rectangular. It can also be generalized to compute the QR factorization of \( B + UV^T \) where \( \text{rank}(UV^T) = p > 1 \).

### 12.5.2 Appending or Deleting a Column

Assume that we have the QR factorization

\[
QR = A = [a_1, \ldots, a_n] \quad a_i \in \mathbb{R}^m
\]

and partition the upper triangular matrix \( R \in \mathbb{R}^{m \times n} \) as follows:

\[
R = \begin{bmatrix}
R_{11} & v & R_{13} \\
0 & r_{kk} & w^T \\
k - 1 & 1 & n - k
\end{bmatrix}
\]

Now suppose that we want to compute the QR factorization of

\[
\tilde{A} = [a_1, \ldots, a_{k-1}, a_{k+1}, \ldots, a_n] \in \mathbb{R}^{m \times (n-1)}.
\]

Note that \( \tilde{A} \) is just \( A \) with its \( k \)th column deleted and that

\[
Q^T \tilde{A} = \begin{bmatrix}
R_{11} & R_{13} \\
0 & w^T \\
0 & R_{33}
\end{bmatrix} = H
\]

is upper Hessenberg, e.g.,

\[
H = \begin{bmatrix}
* & * & * & * & * \\
0 & * & * & * & * \\
0 & 0 & * & * & * \\
0 & 0 & 0 & * & * \\
0 & 0 & 0 & 0 & 0
\end{bmatrix}
\]

Clearly, the unwanted subdiagonal elements \( h_{k+1,k}, \ldots, h_{n,n-1} \) can be zeroed by a sequence of Givens rotations: \( G_{n-1}^T \cdots G_k^T H = R_1 \). Here, \( G_i \) is
a rotation in planes \( i \) and \( i + 1 \) for \( i = k:n - 1 \). Thus, if \( Q_1 = QG_k \cdots G_{n-1} \) then \( \tilde{A} = Q_1 R_1 \) is the QR factorization of \( \tilde{A} \).

The above update procedure can be executed in \( O(n^2) \) flops and is very useful in certain least squares problems. For example, one may wish to examine the significance of the \( k \)th factor in the underlying model by deleting the \( k \)th column of the corresponding data matrix and solving the resulting LS problem.

In a similar vein, it is useful to be able to compute efficiently the solution to the LS problem after a column has been appended to \( \tilde{A} \). Suppose we have the QR factorization (12.5.5) and now wish to compute the QR factorization of

\[
\tilde{A} = [a_1, \ldots, a_k, z, a_{k+1}, \ldots, a_n]
\]

where \( z \in \mathbb{R}^m \) is given. Note that if \( w = Q^T z \) then

\[
Q^T \tilde{A} = [Q^T a_1, \ldots, Q^T a_k, w, Q^T a_{k+1}, \ldots, Q^T a_n] = \tilde{A}
\]

is upper triangular except for the presence of a "spike" in its \( k+1 \)-st column, e.g.,

\[
\tilde{A} = \begin{bmatrix}
\times & \times & \times & \times & \times & \times \\
0 & \times & \times & \times & \times & \times \\
0 & 0 & \times & \times & \times & \times \\
0 & 0 & 0 & \times & \times & \times \\
0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0
\end{bmatrix}
\]

where \( m = 7, n = 5, k = 3 \)

It is possible to determine Givens rotations \( J_{m-1}, \ldots, J_{k+1} \) so that

\[
J_{k+1}^T \cdots J_{m-1}^T w = \begin{bmatrix}
w_1 \\
\vdots \\
w_{k+1} \\
0 \\
\vdots \\
0
\end{bmatrix}
\]

with \( J_{k+1}^T \cdots J_{m-1}^T \tilde{A} = \tilde{R} \) upper triangular. We illustrate this by continuing with the above example:

\[
H = J_6^T \tilde{A} = \begin{bmatrix}
\times & \times & \times & \times & \times & \times \\
0 & \times & \times & \times & \times & \times \\
0 & 0 & \times & \times & \times & \times \\
0 & 0 & 0 & \times & \times & \times \\
0 & 0 & 0 & x & 0 & x \\
0 & 0 & 0 & x & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0
\end{bmatrix}
\]
\[ H = J_5^T H = \begin{bmatrix} \times & \times & \times & \times & \times & \times \\ 0 & \times & \times & \times & \times & \times \\ 0 & 0 & \times & \times & \times & \times \\ 0 & 0 & 0 & \times & \times & \times \\ 0 & 0 & 0 & 0 & \times & \times \\ 0 & 0 & 0 & 0 & 0 & \times \end{bmatrix} \]

\[ H = J_4^T H = \begin{bmatrix} \times & \times & \times & \times & \times & \times \\ 0 & \times & \times & \times & \times & \times \\ 0 & 0 & \times & \times & \times & \times \\ 0 & 0 & 0 & \times & \times & \times \\ 0 & 0 & 0 & 0 & \times & \times \\ 0 & 0 & 0 & 0 & 0 & \times \end{bmatrix} \]

This update requires \( O(mn) \) flops.

### 12.5.3 Appending or Deleting a Row

Suppose we have the QR factorization \( QR = A \in \mathbb{R}^{m \times n} \) and now wish to obtain the QR factorization of

\[ \tilde{A} = \begin{bmatrix} w^T \\ A \end{bmatrix} \]

where \( w \in \mathbb{R}^n \). Note that

\[ \text{diag}(1, Q^T) \tilde{A} = \begin{bmatrix} w^T \\ R \end{bmatrix} = H \]

is upper Hessenberg. Thus, Givens rotations \( J_1, \ldots, J_n \) could be determined so \( J_n^T \cdots J_1^T H = R_1 \) is upper triangular. It follows that

\[ \tilde{A} = Q_1 R_1 \]

is the desired QR factorization, where \( Q_1 = \text{diag}(1, Q)J_1 \cdots J_n \).

No essential complications result if the new row is added between rows \( k \) and \( k + 1 \) of \( A \). We merely apply the above with \( A \) replaced by \( PA \) and \( Q \) replaced by \( PQ \) where

\[ P = \begin{bmatrix} 0 & I_{m-k} \\ I_k & 0 \end{bmatrix}. \]

Upon completion \( \text{diag}(1, P^T)Q_1 \) is the desired orthogonal factor.
Lastly, we consider how to update the QR factorization \( QR = A \in \mathbb{R}^{m \times n} \) when the first row of \( A \) is deleted. In particular, we wish to compute the QR factorization of the submatrix \( A_1 \) in

\[
A = \begin{bmatrix} z^T \\ A_1 \end{bmatrix}
\]

\[
1 \\ m - 1
\]

(The procedure is similar when an arbitrary row is deleted.) Let \( q^T \) be the first row of \( Q \) and compute Givens rotations \( G_1, \ldots, G_{m-1} \) such that

\[
G_1^T \cdots G_{m-1}^T q = \alpha e_1,
\]

where \( \alpha = \pm 1 \). Note that

\[
H = G_1^T \cdots G_{m-1}^T R = \begin{bmatrix} v^T \\ R_1 \end{bmatrix}
\]

\[
1 \\ m - 1
\]

is upper Hessenberg and that

\[
QG_{m-1} \cdots G_1 = \begin{bmatrix} \alpha & 0 \\ 0 & Q_1 \end{bmatrix}
\]

where \( Q_1 \in \mathbb{R}^{(m-1) \times (m-1)} \) is orthogonal. Thus,

\[
A = \begin{bmatrix} z^T \\ A_1 \end{bmatrix} = (QG_{m-1} \cdots G_1)(G_1^T \cdots G_{m-1}^T R) = \begin{bmatrix} \alpha & 0 \\ 0 & Q_1 \end{bmatrix} \begin{bmatrix} v^T \\ R_1 \end{bmatrix}
\]

from which we conclude that \( A_1 = Q_1 R_1 \) is the desired QR factorization.

### 12.5.4 Hyperbolic Transformation Methods

Recall that the "\( R \)" in \( A = QR \) is the transposed Cholesky factor in \( A^T A = GG^T \). Thus, there is a close connection between the QR modifications just discussed and analogous modifications of the Cholesky factorization. We illustrate this with the Cholesky downdating problem which corresponds to the removal of an \( A \)-row in QR. In the Cholesky downdating problem we have the Cholesky factorization

\[
GG^T = A^T A = \begin{bmatrix} z^T \\ A_1 \end{bmatrix}^T \begin{bmatrix} z^T \\ A_1 \end{bmatrix}
\]

(12.5.6)

where \( A \in \mathbb{R}^{m \times n} \) with \( m > n \) and \( z \in \mathbb{R}^n \). Our task is to find a lower triangular \( G_1 \) such that \( G_1 G_1^T = A_1^T A_1 \). There are several approaches to this interesting and important problem. Simply because it is an opportunity to introduce some new ideas, we present a downdating procedure that relies on hyperbolic transformations.
We start with a definition. $H \in \mathbb{R}^{m \times m}$ is pseudo-orthogonal with respect to the signature matrix $S = \text{diag}(\pm 1) \in \mathbb{R}^{m \times m}$ if $H^T SH = S$. Now from (12.5.6) we have $A^T A = A_1^T A_1 + zz^T = GG^T$ and so

$$A_1^T A_1 = A^T A - zz^T = GG^T - zz^T = \begin{bmatrix} G & z \\ \end{bmatrix} \begin{bmatrix} I_n & 0 \\ 0 & -1 \end{bmatrix} \begin{bmatrix} G^T \\ z^T \end{bmatrix}.$$ 

Define the signature matrix

$$S = \begin{bmatrix} I_n & 0 \\ 0 & -1 \end{bmatrix} \quad (12.5.7)$$

and suppose that we can find $H \in \mathbb{R}^{(n+1) \times (n+1)}$ such that $H^T SH = S$ with the property that

$$H \begin{bmatrix} G^T \\ z^T \end{bmatrix} = \begin{bmatrix} G_1^T \\ 0 \end{bmatrix} \quad (12.5.8)$$

is upper triangular. It follows that

$$A_1^T A_1 = \begin{bmatrix} G & z \end{bmatrix} H^T SH \begin{bmatrix} G^T \\ z^T \end{bmatrix} = \begin{bmatrix} G_1 & 0 \end{bmatrix} S \begin{bmatrix} G_1^T \\ 0 \end{bmatrix} = G_1 G_1^T$$

is the sought after Cholesky factorization.

We now show how to construct the hyperbolic transformation $H$ in (12.5.8) using hyperbolic rotations. A 2-by-2 hyperbolic rotation has the form

$$H = \begin{bmatrix} \cosh(\theta) & -\sinh(\theta) \\ -\sinh(\theta) & \cosh(\theta) \end{bmatrix} = \begin{bmatrix} c & -s \\ -s & c \end{bmatrix}.$$ 

Note that if $H \in \mathbb{R}^{2 \times 2}$ is a hyperbolic rotation then $H^T SH = S$ where $S = \text{diag}(-1,1)$. Paralleling our Givens rotations developments, let us see how hyperbolic rotations can be used for zeroing. From

$$\begin{bmatrix} c & -s \\ -s & c \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = \begin{bmatrix} \tau \\ 0 \end{bmatrix} \quad c^2 - s^2 = 1$$

we obtain the equation $cx_2 = sx_1$. Note that there is no solution to this equation if $x_1 = x_2 \neq 0$, a clue that hyperbolic rotations are not as numerically solid as their Givens rotation counterparts. If $x_1 \neq x_2$ then it is possible to compute the cosh-sinh pair:

if $x_2 = 0$

$s = 0; c = 1$

else

if $|x_2| < |x_1|$

$\tau = x_2/x_1; \quad c = 1/\sqrt{1-\tau^2}; \quad s = c\tau$

elseif $|x_1| < |x_2|$

$\tau = x_1/x_2; \quad s = 1/\sqrt{1-\tau^2}; \quad c = s\tau$

end

end
Observe that the norm of the hyperbolic rotation produced by this algorithm gets large as \( x_1 \) gets close to \( x_2 \).

Now any matrix \( H = H(p, n + 1, \theta) \in \mathbb{R}^{(n+1) \times (n+1)} \) that is the identity everywhere except \( h_{p,p} = h_{n+1,n+1} = \cosh(\theta) \) and \( h_{p,n+1} = h_{n+1,p} = -\sinh(\theta) \) satisfies \( H^T S H = S \) where \( S \) is prescribed in (12.5.7). Using (12.5.9), we attempt to generate hyperbolic rotations \( H_k = H(1, k, \theta_k) \) for \( k = 2:n + 1 \) so that

\[
H_n \cdots H_1 \begin{bmatrix} G^T \\ z^T \end{bmatrix} = \begin{bmatrix} \tilde{G}^T \\ 0 \end{bmatrix}.
\]

This turns out to be possible if \( A \) has full column rank. Hyperbolic rotation \( H_k \) zeros entry \((k + 1, k)\). In other words, if \( A \) has full column rank, then it can be shown that each call to (12.5.9) results in a cosh-sinh pair. See Alexander, Pan, and Plemmons (1988).

### 12.5.5 Updating the ULV Decomposition

Suppose \( A \in \mathbb{R}^{m \times n} \) is rank deficient and that we have a basis for its null space. If we add a row to \( A \),

\[
\tilde{A} = \begin{bmatrix} A \\ z^T \end{bmatrix},
\]

then how easy is it to compute a null basis for \( \tilde{A} \)? When a sequence of such update problems are involved the issue is one of tracking the null space. Subspace tracking arises in a number of real-time signal processing applications.

Working with the SVD is awkward in this context because \( O(n^3) \) flops are required to recompute the SVD of a matrix that has undergone a unit rank perturbation. On the other hand, Stewart (1993) has shown that the null space updating problem becomes \( O(n^2) \) per step if we properly couple the ideas of condition estimation of §3.5.4 and complete orthogonal decomposition. Recall from §5.4.2 that a complete orthogonal decomposition is two-sided and reveals the rank of the underlying matrix,

\[
U^T A V = \begin{bmatrix} T_{11} & 0 \\ 0 & 0 \end{bmatrix}, \quad T_{11} \in \mathbb{R}^{r \times r}, \quad r = \text{rank}(A).
\]

A pair of QR factorizations (one with column pivoting) can be used to compute this. In this case \( T_{11} = L \) is lower triangular in exact arithmetic. But with noise and roundoff we instead compute
\[ U^T A V = \begin{bmatrix} L & 0 \\ H & E \\ 0 & 0 \end{bmatrix} \] (12.5.10)

where \( L \in \mathbb{R}^{r \times r} \) and \( E \in \mathbb{R}^{(n-r) \times (n-r)} \) are lower triangular and \( H \) and \( E \) are "small" compared to \( \sigma_{\text{min}}(L) \). In this case we refer to (12.5.10) as a rank-revealing ULV decomposition.\(^1\) Note that if

\[
V = \begin{bmatrix} V_1 & V_2 \\ r & n-r \end{bmatrix}, \quad U = \begin{bmatrix} U_1 & U_2 \\ r & m-r \end{bmatrix}
\]

then the columns of \( V_2 \) define an approximate null space:

\[
\| AV_2 \|_2 = \| U_2 E \|_2 \leq \| E \|_2.
\]

Our goal is to produce a rank-revealing ULV decomposition for the row-appended matrix \( \tilde{A} \). To be more specific, our aim is to show how to produce updates of \( L, E, H, V, \) and (possibly) the rank in \( O(n^2) \) flops.

Note that

\[
\begin{bmatrix} U & 0 \\ 0 & 1 \end{bmatrix}^T \begin{bmatrix} A \\ z^T \end{bmatrix} V = \begin{bmatrix} L & 0 \\ H & E \\ 0 & 0 \end{bmatrix}.
\]

By permuting the bottom row up "underneath" \( H \) and \( E \) we see that the challenge is to compute a rank-revealing ULV decomposition of

\[
\begin{bmatrix} L & 0 \\ H & E \\ w^T & y^T \end{bmatrix} = \begin{bmatrix} \ell & 0 & 0 & 0 & 0 & 0 & 0 \\ \ell & \ell & 0 & 0 & 0 & 0 & 0 \\ \ell & \ell & \ell & 0 & 0 & 0 & 0 \\ \ell & \ell & \ell & \ell & 0 & 0 & 0 \\ h & h & h & h & e & 0 & 0 \\ h & h & h & h & e & e & 0 \\ h & h & h & h & e & e & e \\ w & w & w & w & y & y & y \end{bmatrix}
\] (12.5.11)

in \( O(n^2) \) flops. Here and in the sequel, we set \( r = 4 \) and \( n = 7 \) to illustrate the main ideas. Bear in mind that the \( h \) and \( e \) entries are small and that\(^1\)

\(1\) Dual to this is the URV decomposition in which the rank-revealing form is upper triangular. There are updating situations that sometimes favor the manipulation of this form instead of ULV.
we have deduced that the numerical rank is four. In practice, this involves comparisons with a small tolerance as discussed in §5.5.7.

Using zeroing techniques similar to those presented in §12.5.3, the bottom row can be zeroed with a sequence of row rotations giving

\[
\begin{bmatrix}
\tilde{L} \\
0 
\end{bmatrix} = \begin{bmatrix}
\times & 0 & 0 & 0 & 0 & 0 & 0 \\
\times & \times & 0 & 0 & 0 & 0 & 0 \\
\times & \times & \times & 0 & 0 & 0 & 0 \\
\times & \times & \times & \times & 0 & 0 & 0 \\
\times & \times & \times & \times & \times & 0 & 0 \\
\times & \times & \times & \times & \times & \times & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 \\
\end{bmatrix}.
\]

Because this zeroing process intermingles the (presumably large) entries of the bottom row with the entries from each of the other rows, the triangular form typically is not rank revealing. However, we can restore the rank-revealing structure with a combination of condition estimation and zero-chasing with rotations. Let us assume that with the added row, the new null space has dimension two.

With a reliable condition estimator we produce a unit 2-norm vector \( p \) such that

\[\| p^T \tilde{L} \|_2 \approx \sigma_{\min}(\tilde{L}).\]

See §3.5.4. Rotations \( \{U_{i,i+1}\}_{i=1}^6 \) can be found such that

\[U_{67}^T U_{56}^T U_{45}^T U_{34}^T U_{23}^T U_{12}^T p = e_8 = I_8(:,8).\]

The matrix

\[H = U_{67}^T U_{56}^T U_{45}^T U_{34}^T U_{23}^T U_{12}^T \tilde{L}\]

is lower Hessenberg and can be restored to a lower triangular form \( L_+ \) by a sequence of column rotations:

\[L_+ = HV_{12} V_{23} V_{34} V_{45} V_{56} V_{67}.\]

It follows that

\[e_8^T L_+ = (e_8^T H) V_{12} V_{23} V_{34} V_{45} V_{56} V_{67} = (p^T \tilde{L}) V_{12} V_{23} V_{34} V_{45} V_{56} V_{67}\]

has approximate norm \( \sigma_{\min}(\tilde{L}) \). Thus, we obtain a lower triangular matrix of the form
with small $h$'s and $e$. We can repeat the condition estimation and zero chasing on the leading 6-by-6 portion thereby producing (perhaps) another row of small numbers:

$$
\begin{bmatrix}
  \times & 0 & 0 & 0 & 0 & 0 & 0 \\
  \times & \times & 0 & 0 & 0 & 0 & 0 \\
  \times & \times & \times & 0 & 0 & 0 & 0 \\
  \times & \times & \times & \times & 0 & 0 & 0 \\
  \times & \times & \times & \times & \times & 0 & 0 \\
  h & h & h & h & h & h & e \\
\end{bmatrix}
$$

(If not, then the revealed rank is 6.) Continuing in this way, we can restore any lower triangular matrix to rank-revealing form.

In the event that the $y$ vector in (12.5.11) is small, we can reach rank-revealing form by a different, more efficient route. We start with a sequence of left and right Givens rotations to zero all but the first component of $y$:
Here, "$U_{ij}$" means a rotation of rows $i$ and $j$ and "$V_{ij}$" means a rotation of columns $i$ and $j$. It is important to observe that there is no intermingling of small and large numbers during this process. The $h$'s and $e$'s are still small.

Following this, we produce a sequence of rotations that transform the matrix to

\[
\begin{bmatrix}
\ell & 0 & 0 & 0 & 0 & 0 & 0 \\
\ell & \ell & 0 & 0 & 0 & 0 & 0 \\
\ell & \ell & \ell & 0 & 0 & 0 & 0 \\
\ell & \ell & \ell & \ell & 0 & 0 & 0 \\
h & h & h & h & e & 0 & 0 \\
h & h & h & h & e & e & 0 \\
h & h & h & h & e & e & e \\
y & y & y & y & y & 0 & 0 \\
\end{bmatrix}
\]

(12.5.12)

where all the $y$'s are small:

\[
U_{48} \rightarrow \begin{bmatrix}
\ell & 0 & 0 & 0 & 0 & 0 & 0 \\
\ell & \ell & 0 & 0 & 0 & 0 & 0 \\
\ell & \ell & \ell & 0 & 0 & 0 & 0 \\
\ell & \ell & \ell & \ell & \mu & 0 & 0 \\
h & h & h & h & e & 0 & 0 \\
h & h & h & h & e & e & e \\
h & h & h & h & e & e & e \\
x & x & x & x & y & 0 & 0 \\
\end{bmatrix}
\]

\[
U_{38} \rightarrow \begin{bmatrix}
\ell & 0 & 0 & 0 & 0 & 0 & 0 \\
\ell & \ell & 0 & 0 & 0 & 0 & 0 \\
\ell & \ell & \ell & 0 & 0 & \mu & 0 \\
\ell & \ell & \ell & \ell & \mu & 0 & 0 \\
h & h & h & h & e & 0 & 0 \\
h & h & h & h & e & e & 0 \\
h & h & h & h & e & e & e \\
x & x & 0 & 0 & y & 0 & 0 \\
\end{bmatrix}
\]

\[
U_{28} \rightarrow \begin{bmatrix}
\ell & 0 & 0 & 0 & 0 & 0 & 0 \\
\ell & \ell & 0 & 0 & \mu & 0 & 0 \\
\ell & \ell & \ell & 0 & \mu & 0 & 0 \\
\ell & \ell & \ell & \ell & \mu & 0 & 0 \\
h & h & h & h & e & e & 0 \\
h & h & h & h & e & e & 0 \\
h & h & h & h & e & e & e \\
x & 0 & 0 & 0 & y & 0 & 0 \\
\end{bmatrix}
\]

\[
U_{18} \rightarrow \begin{bmatrix}
\ell & 0 & 0 & 0 & \mu & 0 & 0 \\
\ell & \ell & 0 & 0 & \mu & 0 & 0 \\
\ell & \ell & \ell & 0 & \mu & 0 & 0 \\
\ell & \ell & \ell & \ell & \mu & 0 & 0 \\
h & h & h & h & e & 0 & 0 \\
h & h & h & h & e & e & 0 \\
h & h & h & h & e & e & e \\
0 & 0 & 0 & 0 & y_{**} & 0 & 0 \\
\end{bmatrix}
\]

Note that $y_{**}$ is small because of 2-norm preservation. Column rotations
in planes \((1,5), (2,5), (3,5),\) and \((4,5)\) can remove the \(\mu\)’s:

\[
\begin{bmatrix}
\ell & 0 & 0 & 0 & 0 & 0 \\
\ell & \ell & 0 & 0 & \mu & 0 \\
\ell & \ell & \ell & 0 & \mu & 0 \\
\ell & \ell & \ell & \ell & \mu & 0 \\
h & h & h & h & e & 0 \\
h & h & h & h & e & e \\
h & h & h & h & e & e \\
y & 0 & 0 & 0 & y & 0
\end{bmatrix}
\begin{bmatrix}
\ell & 0 & 0 & 0 & 0 & 0 \\
\ell & \ell & 0 & 0 & \mu & 0 \\
\ell & \ell & \ell & 0 & \mu & 0 \\
\ell & \ell & \ell & \ell & \mu & 0 \\
h & h & h & h & e & 0 \\
h & h & h & h & e & e \\
h & h & h & h & e & e \\
y & 0 & 0 & 0 & y & 0
\end{bmatrix}
\]

thus producing the structure displayed in (12.5.12). All the \(y\)’s are small and thus a sequence of row rotations \(U_{57}, U_{47}, \ldots, U_{17}\), can be constructed to clean out the bottom row giving the rank-revealed form

\[
\begin{bmatrix}
\ell & 0 & 0 & 0 & 0 & 0 \\
\ell & \ell & 0 & 0 & 0 & 0 \\
\ell & \ell & \ell & 0 & 0 & 0 \\
\ell & \ell & \ell & \ell & 0 & 0 \\
h & h & h & h & e & 0 \\
h & h & h & h & e & e \\
h & h & h & h & e & e \\
y & y & y & y & y & 0
\end{bmatrix}
\begin{bmatrix}
\ell & 0 & 0 & 0 & 0 & 0 \\
\ell & \ell & 0 & 0 & 0 & 0 \\
\ell & \ell & \ell & 0 & 0 & 0 \\
\ell & \ell & \ell & \ell & 0 & 0 \\
h & h & h & h & e & 0 \\
h & h & h & h & e & e \\
h & h & h & h & e & e \\
y & y & y & y & y & 0
\end{bmatrix}
\]

Problems

P12.5.1 Suppose we have the QR factorization for \(A \in \mathbb{R}^{n \times n}\) and now wish to minimize \(\| (A + uv^T)x - b \|_2 \) where \(u, b \in \mathbb{R}^n\) and \(v \in \mathbb{R}^n\) are given. Give an algorithm for solving this problem that requires \(O(mn)\) flops. Assume that \(Q\) must be updated.

P12.5.2 Suppose we have the QR factorization \(QR = A \in \mathbb{R}^{m \times n}\). Give an algorithm for computing the QR factorization of the matrix \(A\) obtained by deleting the \(k\)th row of \(A\). Your algorithm should require \(O(mn)\) flops.

P12.5.3 Suppose \(T \in \mathbb{R}^{n \times n}\) is tridiagonal and symmetric and that \(v \in \mathbb{R}^n\). Show how the Lanczos algorithm can be used (in principle) to compute an orthogonal \(Q \in \mathbb{R}^{n \times n}\) in \(O(n^2)\) flops such that \(Q^T (T + vv^T)Q = \tilde{T}\) is also tridiagonal.

P12.5.4 Suppose

\[
A = \begin{bmatrix}
c^T \\
B
\end{bmatrix}, \quad c \in \mathbb{R}^n, \quad B \in \mathbb{R}^{(m-1) \times n}
\]
has full column rank and \( m > n \). Using the Sherman-Morrison-Woodbury formula show that

\[
\frac{1}{\sigma_{\text{min}}(B)} \leq \frac{1}{\sigma_{\text{min}}(A)} + \frac{\| (A^T A)^{-1} c \|_2^2}{1 - c^T (A^T A)^{-1} c}.
\]

**P12.5.5** As a function of \( x_1 \) and \( x_2 \), what is the 2-norm of the hyperbolic rotation produced by (12.5.9)?

**P12.5.6** Show that the hyperbolic reduction in §12.5.4 does not breakdown if \( A \) has full column rank.

**P12.5.7** Assume

\[
A = \begin{bmatrix} R & H \\ 0 & E \end{bmatrix}
\]

where \( R \) and \( E \) are square with

\[
\rho = \frac{\| E \|_2}{\sigma_{\text{min}}(R)} < 1.
\]

Show that if

\[
Q = \begin{bmatrix} Q_{11} & Q_{12} \\ Q_{21} & Q_{22} \end{bmatrix}
\]

is orthogonal and

\[
\begin{bmatrix} R & H \\ 0 & E \end{bmatrix} \begin{bmatrix} Q_{11} & Q_{12} \\ Q_{21} & Q_{22} \end{bmatrix} = \begin{bmatrix} R_1 & 0 \\ H_1 & E_1 \end{bmatrix},
\]

then \( \| H_1 \|_2 \leq \rho \| H \|_2 \).

**Notes and References for Sec. 12.5**

Numerous aspects of the updating problem are presented in

Applications in the area of optimization are covered in

Updating issues in the least squares setting are discussed in

Another important topic concerns the updating of condition estimates:

Hyperbolic transformations are discussed in

Cholesky update issues have also attracted a lot of attention.

Updating and downdating the ULV and URV decompositions and related topics are covered in

Finally, we mention the following paper concerned with SVD updating:
12.6 Modified/Structured Eigenproblems

In this section we treat an array of constrained, inverse, and structured eigenvalue problems. Although the examples are not related, collectively they show how certain special eigenproblems can be solved using the basic factorization ideas presented in earlier chapters.

The dependence of this section upon earlier portions of the book is as follows:

\[ \S\S 5.1, 5.2, 8.1, 8.3 \quad \rightarrow \quad \S 12.6.1 \]
\[ \S\S 8.1, 8.3, 9.1 \quad \rightarrow \quad \S 12.6.2 \]
\[ \S\S 4.7, 8.1 \quad \rightarrow \quad \S 12.6.3 \]
\[ \S\S 5.1, 5.2, 5.4, 7.4, 8.1, 8.2, 8.3, 8.6 \quad \rightarrow \quad \S 12.6.4 \]

12.6.1 A Constrained Eigenvalue Problem

Let \( A \in \mathbb{R}^{n \times n} \) be symmetric. The gradient of \( r(x) = x^T Ax/x^T x \) is zero if and only if \( x \) is an eigenvector of \( A \). Thus the stationary values of \( r(x) \) are therefore the eigenvalues of \( A \).

In certain applications it is necessary to find the stationary values of \( r(x) \) subject to the constraint \( C^T x = 0 \) where \( C \in \mathbb{R}^{n \times p} \) with \( n \geq p \). Suppose

\[
Q^T C Z = \begin{bmatrix} S & 0 \\ 0 & 0 \end{bmatrix} \begin{bmatrix} r \\ n-r \end{bmatrix} \quad r = \text{rank}(C)
\]

is a complete orthogonal decomposition of \( C \). Define \( B \in \mathbb{R}^{n \times n} \) by

\[
Q^T A Q = B = \begin{bmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{bmatrix} \begin{bmatrix} r \\ n-r \end{bmatrix}
\]

and set

\[
y = Q^T x = \begin{bmatrix} u \\ v \end{bmatrix} \begin{bmatrix} r \\ n-r \end{bmatrix}.
\]

Since \( C^T x = 0 \) transforms to \( S^T u = 0 \), the original problem becomes one of finding the stationary values of \( r(y) = y^T B y/y^T y \) subject to the constraint that \( u = 0 \). But this amounts merely to finding the stationary values (eigenvalues) of the \((n-r)\)-by-\((n-r)\) symmetric matrix \( B_{22} \).
12.6.2 Two Inverse Eigenvalue Problems

Consider the \( r = 1 \) case in the previous subsection. Let \( \tilde{\lambda}_1 \leq \ldots \leq \tilde{\lambda}_{n-1} \) be the stationary values of \( x^T A x / x^T x \) subject to the constraint \( c^T x = 0 \). From Theorem 8.1.7, it is easy to show that these stationary values interlace the eigenvalues \( \lambda_i \) of \( A \):

\[
\lambda_n \leq \tilde{\lambda}_{n-1} \leq \lambda_{n-1} \leq \cdots \leq \lambda_2 \leq \tilde{\lambda}_1 \leq \lambda_1.
\]

Now suppose that \( A \) has distinct eigenvalues and that we are given the values \( \tilde{\lambda}_1, \ldots, \tilde{\lambda}_{n-1} \) that satisfy

\[
\lambda_n < \tilde{\lambda}_{n-1} < \lambda_{n-1} < \cdots < \lambda_2 < \tilde{\lambda}_1 < \lambda_1.
\]

We seek to determine a unit vector \( c \in \mathbb{R}^n \) such that the \( \tilde{\lambda}_i \) are the stationary values of \( x^T A x \) subject to \( x^T x = 1 \) and \( c^T x = 0 \).

In order to determine the properties that \( c \) must have, we use the method of Lagrange multipliers. Equating the gradient of

\[
\phi(x, \lambda, \mu) = x^T A x - \lambda(x^T x - 1) + 2\mu x^T c
\]

to zero we obtain the important equation \((A - \lambda I)x = -\mu c\). Thus, \( A - \lambda I \) is nonsingular and so \( x = -\mu(A - \lambda I)^{-1} c \). Applying \( c^T \) to both sides of this equation and substituting the eigenvalue decomposition \( Q^T AQ = \text{diag}(\lambda_i) \) we obtain

\[
0 = \sum_{i=1}^{n} \frac{d_i^2}{\lambda_i - \lambda}
\]

where \( d = Q^T c \), i.e.,

\[
p(\lambda) \equiv \sum_{i=1}^{n} d_i^2 \prod_{\substack{j=1 \atop j \neq i}}^{n} (\lambda_j - \lambda) = 0.
\]

Notice that \( 1 = \| c \|_2^2 = \| d \|_2 = d_1^2 + \cdots + d_n^2 \) is the coefficient of \((-\lambda)^{n-1}\).

Since \( p(\lambda) \) is a polynomial having zeroes \( \tilde{\lambda}_1, \ldots, \tilde{\lambda}_{n-1} \) we must have

\[
p(\lambda) = \prod_{j=1}^{n-1} (\tilde{\lambda}_j - \lambda).
\]

It follows from these two formulas for \( p(\lambda) \) that

\[
d_k^2 = \prod_{j=1}^{n-1} (\tilde{\lambda}_j - \lambda_k) \left/ \prod_{\substack{j=1 \atop j \neq k}}^{n-1} (\lambda_j - \lambda_k) \right. \quad k = 1:n.
\]

(12.6.1)
This determines each $d_k$ up to its sign. Thus there are $2^n$ different solutions $c = Qd$ to the original problem.

A related inverse eigenvalue problem involves finding a tridiagonal matrix

$$T = \begin{bmatrix}
\alpha_1 & \beta_1 & \cdots & 0 \\
\beta_1 & \alpha_2 & \cdots & \\
& \ddots & \ddots & \\
0 & \cdots & \beta_{n-1} & \alpha_n
\end{bmatrix}$$

such that $T$ has prescribed eigenvalues $\{\lambda_1, \ldots, \lambda_n\}$ and $T(2:n, 2:n)$ has prescribed eigenvalues $\{\tilde{\lambda}_1, \ldots, \tilde{\lambda}_{n-1}\}$ with

$$\lambda_1 > \tilde{\lambda}_1 > \lambda_2 > \cdots > \lambda_{n-1} > \tilde{\lambda}_{n-1} > \lambda_n.$$

We show how to compute the tridiagonal $T$ via the Lanczos process. Note that the $\tilde{\lambda}_i$ are the stationary values of

$$\phi(y) = \frac{y^T b y}{y^T y}$$

subject to $d^T y = 0$ where $b = \text{diag}(\lambda_1, \ldots, \lambda_n)$ and $d$ is specified by (12.6.1). If we apply the Lanczos iteration (9.1.3) with $A = \Lambda$ and $q_1 = d$, then it produces an orthogonal matrix $Q$ and a tridiagonal matrix $T$ such that $Q^T \Lambda Q = T$. With the definition $x = Q^T y$, it follows that the $\tilde{\lambda}_i$ are the stationary values of

$$\psi(x) = \frac{x^T T x}{x^T x}$$

subject to $e_1^T x = 0$. But these are precisely the eigenvalues of $T(2:n, 2:n)!

12.6.3 A Toeplitz Eigenproblem

Assume that

$$T = \begin{bmatrix}
1 & r^T \\
r & G
\end{bmatrix}$$

is symmetric, positive definite, and Toeplitz with $r \in \mathbb{R}^{n-1}$. Our goal is to compute the smallest eigenvalue $\lambda_{\text{min}}(T)$ of $T$ given that

$$\lambda_{\text{min}}(T) < \lambda_{\text{min}}(G).$$

This problem is considered in Cybenko and Van Loan (1986) and has applications in signal processing.

Suppose

$$\begin{bmatrix}
1 & r^T \\
r & G
\end{bmatrix} \begin{bmatrix}
\alpha \\
y
\end{bmatrix} = \lambda \begin{bmatrix}
\alpha \\
y
\end{bmatrix},$$

subject to $e_1^T x = 0$. But these are precisely the eigenvalues of $T(2:n, 2:n)!
i.e.,
\[
\begin{align*}
\alpha + r^T y &= \lambda \alpha \\
\alpha r + Gy &= \lambda y.
\end{align*}
\]

If \( \lambda \notin \lambda(G) \), then \( y = -\alpha(G - \lambda I)^{-1}r \), \( \alpha \neq 0 \), and
\[
\alpha + r^T [-\alpha(G - \lambda I)^{-1}r] = \lambda \alpha.
\]

Thus, \( \lambda \) is a zero of the rational function
\[
f(\lambda) = 1 - \lambda - r^T (G - \lambda I)^{-1}r.
\]

We have dealt with similar functions in §8.5 and §12.1. In this case, \( f \) always has a negative slope
\[
f'(\lambda) = -1 - \| (G - \lambda I)^{-1}r \|^2_2 \leq -1.
\]

If \( \lambda < \lambda_{\text{min}}(G) \), then it also has a negative second derivative:
\[
f''(\lambda) = -2r^T (G - \lambda I)^{-3}r \leq 0.
\]

Using these facts it can be shown that if
\[
\lambda_{\text{min}}(T) \leq \lambda^{(0)} < \lambda_{\text{min}}(G),
\] (12.6.2)
then the Newton iteration
\[
\lambda^{(k+1)} = \lambda^{(k)} - \frac{f(\lambda^{(k)})}{f'(\lambda^{(k)})}
\] (12.6.3)
converges to \( \lambda_{\text{min}}(T) \) monotonically from the right. Note that
\[
\lambda^{(k+1)} = \lambda^{(k)} + \frac{1 + r^T w - \lambda^{(k)}}{1 + w^T w}
\]
where \( w \) solves the "shifted" Yule-Walker system
\[
(G - \lambda^{(k)} I)w = -r.
\]

Since, \( \lambda^{(k)} < \lambda_{\text{min}}(G) \), this system is positive definite and Algorithm 4.7.1 is applicable if we simply apply it to the normalized Toeplitz matrix \((G - \lambda^{(k)} I)/(1 - \lambda^{(k)})\).

A starting value that satisfies (12.6.2) can be obtained by examining the Durbin algorithm when it is applied to \( T_\lambda = (T - \lambda I)/(1 - \lambda) \). For this matrix the "r" vector is \( r/(1 - \lambda) \) and so the Durbin algorithm (4.7.1) transforms to
\[ r = r/(1 - \lambda) \]
\[ y^{(1)} = -r_1 \]

\textbf{for} \; k = 1:n - 1
\[ \beta_k = 1 + [r^{(k)}]^T y^{(k)} \]
\[ \alpha_k = -(r_{k+1} + r^{(k)} E_k y^{(k)})/\beta_k \]
\[ z^{(k)} = y^{(k)} + \alpha_k E_k y^{(k)} \]
\[ y^{(k+1)} = \begin{bmatrix} z^{(k)} \\ \alpha_k \end{bmatrix} \]
\textbf{end}

From the discussion in §4.7.2 we know that \( \beta_1, \ldots, \beta_k > 0 \) implies that \( T_\lambda(1:k + 1, 1:k + 1) \) is positive definite. Hence, a suitably modified (12.6.4) can be used to compute \( m(\lambda) \), the largest index \( m \) such that \( \beta_1, \ldots, \beta_m \) are all positive but that \( \beta_{m+1} \leq 0 \). Note that if \( m(\lambda) = n - 2 \), then (12.6.2) holds. This suggests the following bisection scheme:

Choose \( L \) and \( R \) so \( L \leq \lambda_{\text{min}}(T) < \lambda_{\text{min}}(G) \leq R. \)

Until \( m = n - 2 \)
\[ \lambda = (L + R)/2 \]
\[ m = m(\lambda) \]
\textbf{if} \; m < n - 2
\[ R = \lambda \]
\textbf{end}
\textbf{if} \; m = n - 1
\[ L = \lambda \]
\textbf{end}

The bracketing interval \([L, R]\) always contains a \( \lambda \) such that \( m(\lambda) = n - 2 \) and so the current \( \lambda \) has this property upon termination.

There are several possible choices for a starting interval. One idea is to set \( L = 0 \) and \( R = 1 - |r_1| \) since

\[ 0 < \lambda_{\text{min}}(T) < \lambda_{\text{min}}(G) \leq \lambda_{\text{min}} \left( \begin{bmatrix} 1 & r_1 \\ r_1 & 1 \end{bmatrix} \right) = 1 - |r_1| \]

where the upper bound follows from Theorem 8.1.7.

Note that the iterations in (12.6.4) and (12.6.5) involve at most \( O(n^2) \) flops. A heuristic argument that \( O(\log n) \) iterations are required is given in Cybenko and Van Loan (1986).

### 12.6.4 An Orthogonal Matrix Eigenproblem

Computing the eigenvalues and eigenvectors of a real orthogonal matrix \( A \in \mathbb{R}^{n \times n} \) is a problem that arises in signal processing, see Cybenko (1985).
The eigenvalues of $A$ are on the unit circle and moreover,
\[
\cos(\theta) \pm i \sin(\theta) \in \lambda(A) \iff \cos(\theta) \in \lambda \left( \frac{A + A^{-1}}{2} \right) = \lambda \left( \frac{A + A^T}{2} \right).
\]

This suggests computing $\text{Re}(\lambda(A))$ via the Schur decomposition
\[
Q^T \left( \frac{A + A^T}{2} \right) Q = \text{diag}(\cos(\theta_1), \ldots, \cos(\theta_n))
\]
and then computing $\text{Im}(\lambda(A))$ with the formula $s = \sqrt{1 - c^2}$. Unfortunately, if $|c| \approx 1$, then this formula does not produce an accurate sine because of floating point cancellation. We could work with the skew-symmetric matrix $(A - A^T)/2$ to get the "small sine" eigenvalues, but then we are talking about a method that requires a pair of full Schur decomposition problems and the approach begins to lose its appeal.

A way around these difficulties that involves an interesting SVD application is proposed by Ammar, Gragg, and Reichel (1986). We present just the eigenvalue portion of their algorithm. The derivation is instructive because it involves practically every decomposition that we have studied.

The first step is to orthogonally reduce $A$ to upper Hessenberg form, $Q^T A Q = H$. (Frequently, $A$ is already in Hessenberg form.) Without loss of generality, we may assume that $H$ is unreduced with positive subdiagonal elements.

If $n$ is odd, then it must have a real eigenvalue because the eigenvalues of a real matrix come in complex conjugate pairs. In this case it is possible to deflate the problem with $O(n)$ work to size $n - 1$ by carefully working with the eigenvector equation $Hx = x$ (or $Hx = -x$). See Gragg (1986). Thus, we may assume that $n$ is even.

For $1 \leq k \leq n - 1$, define the reflection $G_k \in \mathbb{R}^{n \times n}$ by
\[
G_k = G_k(\phi_k) = \begin{bmatrix}
I_{k-1} & 0 & 0 & 0 \\
0 & -c_k & s_k & 0 \\
0 & s_k & c_k & 0 \\
0 & 0 & 0 & I_{n-k-1}
\end{bmatrix}
\]
where $c_k = \cos(\phi_k)$, $s_k = \sin(\phi_k)$, and $0 < \phi_k < \pi$. It is possible to determine $G_1, \ldots, G_{n-1}$ such that
\[
H = (G_1 \cdots G_{n-1}) \text{diag}(1, \ldots, 1, -c_n)
\]
where $c_n = \pm 1$. This is just the QR decomposition of $H$. The sines $s_1, \ldots, s_{n-1}$ are the subdiagonal entries of $H$. The "$R$" matrix is diagonal because it is orthogonal and triangular. Since the determinant of a reflection is $-1$, $\det(H) = c_n$. This quantity is the product of $H$'s eigenvalues and so if $c_n = -1$, then $\{-1, 1\} \subseteq \lambda(H)$. In this situation it is also possible to deflate.
So altogether we may assume that \( n \) is even and

\[
H = G_1(\phi_1) \cdots G_{n-1}(\phi_{n-1})G_n(\phi_n)
\]

where \( G_n = G_n(\phi_n) = \text{diag}(1, \ldots, 1, -c_n) \) and \( c_n = 1 \). Designate the sought after eigenvalues by

\[
\lambda(H) = \{ \cos(\theta_k) \pm i \cdot \sin(\theta_k) \}_{k=1}^m
\]

(12.6.4)

where \( m = n/2 \).

The cosines \( c_1, \ldots, c_n \) are called the Schur parameters and as we mentioned, the corresponding sines are the subdiagonal entries of \( H \). Using these numbers it is possible to construct explicitly a pair of bidiagonal matrices \( B_C, B_S \in \mathbb{R}^{n \times n} \) with the property that

\[
\sigma(B_C(1:m, 1:m)) = \{ \cos(\theta_1/2), \ldots, \cos(\theta_m/2) \} \quad (12.6.5)
\]

\[
\sigma(B_S(1:m, 1:m)) = \{ \sin(\theta_1/2), \ldots, \sin(\theta_m/2) \} \quad (12.6.6)
\]

The singular values of \( B_C(1:m, 1:m) \) and \( B_S(1:m, 1:m) \) can be computed using the bidiagonal SVD algorithm. The angle \( \theta_k \) can be accurately computed from \( \sin(\theta_k/2) \) if \( 0 < \theta_k \leq \pi/2 \) and accurately computed from \( \cos(\theta_k/2) \) if \( \pi/2 \leq \theta_k < \pi \). The construction of \( B_C \) and \( B_S \) is based on three facts:

1. \( H \) is similar to

\[
\tilde{H} = H_o H_e
\]

where \( H_o \) and \( H_e \) are the odd and even reflection products

\[
H_o = G_1 G_3 \cdots G_{n-1}
\]

\[
H_e = G_2 G_4 \cdots G_n.
\]

These matrices are block diagonal with 2-by-2 and 1-by-1 blocks, i.e.,

\[
H_o = \text{diag}(R(\phi_1), R(\phi_3), \ldots, R(\phi_{n-1})) \quad (12.6.7)
\]

\[
H_e = \text{diag}(1, R(\phi_2), R(\phi_4), \ldots, R(\phi_{n-2}), -1) \quad (12.6.8)
\]

where

\[
R(\phi) = \begin{bmatrix} -\cos(\phi) & \sin(\phi) \\ \sin(\phi) & \cos(\phi) \end{bmatrix}.
\]

(12.6.9)

2. The eigenvalues of the symmetric tridiagonal matrices

\[
C = \frac{H_o + H_e}{2} \quad \text{and} \quad S = \frac{H_o - H_e}{2}
\]

are given by

\[
\lambda(C) = \{ \pm \cos(\theta_1/2), \ldots, \pm \cos(\theta_m/2) \} \quad (12.6.11)
\]

\[
\lambda(S) = \{ \pm \sin(\theta_1/2), \ldots, \pm \sin(\theta_m/2) \}.
\]

(12.6.12)
3. It is possible to construct bidiagonalizations
\[ U_C^T C V_C = B_C \quad \text{and} \quad U_S^T S V_S = B_S \]
that satisfy (12.6.5) and (12.6.6). The transformations \( U_C, V_C, U_S, \) and \( V_S \) are products of known reflections \( G_k \) and simple permutations.

We begin the verification of these three facts by showing that \( H \) is similar to \( H_0 H_e \). The \( n = 8 \) case is sufficient for this purpose. Define the orthogonal matrix \( P \) by
\[ P = F_7 F_5 F_3 \quad \text{where} \quad \begin{cases} 
F_3 = G_3 G_4 G_5 G_6 G_7 G_8 \\
F_5 = G_5 G_6 G_7 G_8 \\
F_7 = G_7 G_8.
\end{cases} \]
Since reflections are symmetric and \( G_i G_j = G_j G_i \) if \( |i - j| \geq 2 \), we see that
\[ F_3 H F_3^T = (G_3 G_4 G_5 G_6 G_7 G_8)(G_1 G_2 G_3 G_4 G_5 G_6 G_7 G_8)(G_3 G_4 G_5 G_6 G_7 G_8)^T \\
= (G_3 G_4 G_5 G_6 G_7 G_8) G_1 G_2 \\
= G_1 G_3 G_2 G_4 G_5 G_6 G_7 G_8, \]
\[ F_5 (F_3 H F_3^T) F_5^T = (G_5 G_6 G_7 G_8)(G_1 G_3 G_2 G_4 G_5 G_6 G_7 G_8)(G_5 G_6 G_7 G_8)^T, \]
\[ = (G_5 G_6 G_7 G_8) G_1 G_3 G_2 G_4 \\
= G_1 G_3 G_5 G_2 G_4 G_6 G_7 G_8, \]
\[ P H P^T = F_7 (F_5 F_3 H F_3^T F_5^T) F_7^T \\
= (G_7 G_8)(G_1 G_3 G_5 G_2 G_4 G_6 G_7 G_8)(G_7 G_8)^T \\
= (G_1 G_3 G_5 G_7)(G_2 G_4 G_6 G_8) \equiv H_0 H_e. \]

The second of the three facts that we need to establish relates the eigenvalues of \( \tilde{H} = H_0 H_e \) to the eigenvalues of the \( C \) and \( S \) matrices defined in (12.6.10). It follows from (12.6.7) and (12.6.8) that these matrices are symmetric, tridiagonal, and unreduced, e.g.,
\[ C = \frac{1}{2} \begin{bmatrix}
-c_1 & s_1 & 0 & 0 \\
 s_1 & c_1 - c_2 & s_2 & 0 \\
 0 & s_2 & c_2 - c_3 & s_3 \\
 0 & 0 & s_3 & c_3 - c_4
\end{bmatrix} \]
\[ S = \frac{1}{2} \begin{bmatrix}
-c_1 & s_1 & 0 & 0 \\
 s_1 & c_1 + c_2 & -s_2 & 0 \\
 0 & -s_2 & -c_2 - c_3 & s_3 \\
 0 & 0 & s_3 & c_3 + c_4
\end{bmatrix}. \]

By working with the definitions it is easy to verify that
\[ \frac{\tilde{H} + \tilde{H}^T}{2} = \frac{H_0 H_e + (H_0 H_e)^{-1}}{2} = \frac{H_0 H_e + H_e H_0}{2} = 2C^2 - I \]
and

\[
\frac{\tilde{H} + \tilde{H}^T}{2i} = \frac{H_oH_e - (H_oH_e)^{-1}}{2i} = \frac{H_oH_e - H_eH_o}{2i} = -2iSC.
\]

This shows that \(\text{Re}(\lambda(\tilde{H})) = \lambda(2C^2 - I)\) and \(\text{Im}(\lambda(\tilde{H})) = \lambda(-2iCS)\) thereby establishing (12.6.11) and (12.6.12).

Instead of thinking of these half-angle cosines and sines as eigenvalues of \(n\)-by-\(n\) matrices, it is more efficient to think of them as singular values of \(m\)-by-\(m\) matrices. This brings us to the bidiagonalization of \(C\) and \(S\). The orthogonal equivalence transformations that carry out this task are based upon the Schur decompositions of \(H_o\) and \(H_e\). A 2-by-2 reflection \(R(\phi)\) defined by (12.6.9) has eigenvalues 1 and -1 and the following Schur decomposition:

\[
R(\phi/2)R(\phi)R(\phi/2) = \begin{bmatrix}
1 & 0 \\
0 & -1
\end{bmatrix}.
\]

Thus, if

\[
Q_o = \text{diag}(R(\phi_1/2), R(\phi_2/2), \ldots, R(\phi_{n-1}/2))
\]

\[
Q_e = \text{diag}(1, R(\phi_2/2), R(\phi_4/2), \ldots, R(\phi_{n-2}/2), -1)
\]

then from (12.6.7) and (12.6.8) \(H_o\) and \(H_e\) have the following Schur decompositions:

\[
Q_oH_oQ_o = D_o = \text{diag}(1, -1, 1, -1, \ldots, 1, -1)
\]

\[
Q_eH_eQ_e = D_e = \text{diag}(1, 1, -1, 1, -1, \ldots, 1, -1, -1, -1)
\]

The matrices

\[
C^{(1)} = Q_oCQ_e = \frac{1}{2}Q_o(H_o + H_e)Q_e = \frac{1}{2}(D_o(Q_oQ_e) + (Q_oQ_e)D_e)
\]

\[
S^{(1)} = Q_oSQ_e = \frac{1}{2}Q_o(H_o - H_e)Q_e = \frac{1}{2}(D_o(Q_oQ_e) - (Q_oQ_e)D_e)
\]

have the same singular values as \(C\) and \(S\) respectively. To analyze their structure we first note that \(Q_oQ_e\) is banded:

\[
Q_oQ_e = \begin{bmatrix}
\times & \times & \times & 0 & 0 & 0 & 0 \\
\times & \times & \times & 0 & 0 & 0 & 0 \\
0 & \times & \times & \times & 0 & 0 & 0 \\
0 & \times & \times & \times & 0 & 0 & 0 \\
0 & 0 & 0 & \times & \times & \times & 0 \\
0 & 0 & 0 & \times & \times & \times & 0 \\
0 & 0 & 0 & 0 & \times & \times & \times \\
0 & 0 & 0 & 0 & \times & \times & \times
\end{bmatrix}.
\]
(The main ideas from this point on are amply communicated with \( n = 8 \) examples.) If \( D_o(i,i) \) and \( D_e(j,j) \) have the opposite sign, then \( C_{ij}^{(1)} = 0 \) from which we conclude that \( C^{(1)} \) has the form

\[
C^{(1)} = Q_o C Q_e =
\begin{bmatrix}
  a_0 & b_1 & 0 & 0 & 0 & 0 & 0 & 0 \\
  0 & 0 & b_2 & 0 & 0 & 0 & 0 & 0 \\
  0 & a_2 & 0 & b_3 & 0 & 0 & 0 & 0 \\
  0 & 0 & a_3 & 0 & b_4 & 0 & 0 & 0 \\
  0 & 0 & 0 & a_4 & 0 & b_5 & 0 & 0 \\
  0 & 0 & 0 & 0 & a_5 & 0 & b_6 & 0 \\
  0 & 0 & 0 & 0 & 0 & a_6 & 0 & 0 \\
  0 & 0 & 0 & 0 & 0 & 0 & a_7 & b_8
\end{bmatrix}.
\]

Analogously, if \( D_o(i,i) \) and \( D_e(j,j) \) have the same sign, then \( S_{ij}^{(1)} = 0 \) from which we conclude that \( S^{(1)} \) has the form

\[
S^{(1)} = Q_o S Q_e =
\begin{bmatrix}
  0 & 0 & f_1 & 0 & 0 & 0 & 0 & 0 \\
  e_2 & d_2 & 0 & 0 & 0 & 0 & 0 & 0 \\
  0 & 0 & d_3 & 0 & f_3 & 0 & 0 & 0 \\
  0 & e_4 & 0 & d_4 & 0 & 0 & 0 & 0 \\
  0 & 0 & 0 & 0 & d_5 & 0 & f_5 & 0 \\
  0 & 0 & 0 & e_6 & 0 & d_6 & 0 & 0 \\
  0 & 0 & 0 & 0 & 0 & d_7 & f_7 & 0 \\
  0 & 0 & 0 & 0 & 0 & 0 & e_8 & 0
\end{bmatrix}.
\]

Row/column permutations of these matrices result in bidiagonal forms:

\[
B_C = C^{(1)}([1 \ 3 \ 5 \ 7 \ 2 \ 4 \ 6 \ 8], [1 \ 2 \ 4 \ 6 \ 3 \ 5 \ 7 \ 8])
\]

\[
= \begin{bmatrix}
  a_0 & b_1 & 0 & 0 & 0 & 0 & 0 & 0 \\
  0 & a_2 & b_3 & 0 & 0 & 0 & 0 & 0 \\
  0 & 0 & a_4 & b_5 & 0 & 0 & 0 & 0 \\
  0 & 0 & 0 & a_6 & 0 & 0 & 0 & 0 \\
  0 & 0 & 0 & 0 & b_2 & 0 & 0 & 0 \\
  0 & 0 & 0 & 0 & a_3 & b_4 & 0 & 0 \\
  0 & 0 & 0 & 0 & 0 & a_5 & b_6 & 0 \\
  0 & 0 & 0 & 0 & 0 & 0 & a_7 & b_8
\end{bmatrix}.
\]
\[ B_S = S^{(1)}([2\ 4\ 6\ 8\ 1\ 3\ 5\ 7\ 4\ 6\ 3\ 5\ 7\ 8]) \]

\[
\begin{bmatrix}
e_2 & d_2 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & e_4 & d_4 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & e_6 & d_6 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & e_8 & f_1 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & d_3 & f_3 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & d_5 & f_5 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & d_7 & f_7 & 0 & 0 & 0 \\
\end{bmatrix}
\]

It is not hard to verify that a's, b's, d's, e's, and f's are all nonzero and this implies that the singular values of \( B_C(1:m, 1:m) \) and \( B_S(1:m, 1:m) \) are distinct. Since

\[
\sigma(C) = \sigma(B_C) = \{ \cos(\theta_1/2), \cos(\theta_2/2), \ldots, \cos(\theta_m/2), \cos(\theta_m/2) \}
\]

\[
\sigma(S) = \sigma(B_S) = \{ \sin(\theta_1/2), \sin(\theta_2/2), \ldots, \sin(\theta_m/2), \sin(\theta_m/2) \}
\]

we have verified (12.6.5) and (12.6.6).

Problems

P12.6.1 Let \( A \in \mathbb{R}^{n \times n} \) and consider the problem of finding the stationary values of

\[
R(x, y) = \frac{y^T A x}{\|y\|_2 \|x\|_2} \quad y \in \mathbb{R}^m, x \in \mathbb{R}^n
\]

subject to the constraints

\[
C^T x = 0 \quad C \in \mathbb{R}^{n \times p} \quad n \geq p
\]

\[
D^T y = 0 \quad D \in \mathbb{R}^{m \times q} \quad m \geq q
\]

Show how to solve this problem by first computing complete orthogonal decompositions of \( C \) and \( D \) and then computing the SVD of a certain submatrix of a transformed \( A \).

P12.6.2 Suppose \( A \in \mathbb{R}^{m \times n} \) and \( B \in \mathbb{R}^{p \times n} \). Assume that rank(A) = \( n \) and rank(B) = \( p \). Using the methods of this section, show how to solve

\[
\min_{Bx = 0} \frac{\|b - Ax\|_2^2}{\|x\|_2^2 + 1} = \min_{Bx = 0} \left\| \begin{bmatrix} A \ b \\ -1 \end{bmatrix} \begin{bmatrix} x \\ -1 \end{bmatrix} \right\|_2^2
\]

Show that this is a constrained TLS problem. Is there always a solution?

P12.6.3 Suppose \( A \in \mathbb{R}^{m \times n} \) is symmetric and that \( B \in \mathbb{R}^{p \times n} \) has rank \( p \). Let \( d \in \mathbb{R}^p \). Show how to solve the problem of minimizing \( x^T A x \) subject to the constraints \( \|x\|_2 = 1 \) and \( Bx = d \). Indicate when a solution fails to exist.

P12.6.4 Assume that \( A \in \mathbb{R}^{m \times n} \) is symmetric, large, and sparse and that \( C \in \mathbb{R}^{n \times p} \) is also large and sparse. How can the Lanczos process be used to find the stationary values of

\[
r(x) = \frac{x^T A x}{x^T x}
\]
subject to the constraint \( C^T x = 0 \). Assume that a sparse QR factorization \( C = QR \) is available.

**P12.6.5** Relate the eigenvalues and eigenvectors of

\[
A = \begin{bmatrix}
0 & A_1 & 0 & 0 \\
0 & 0 & A_2 & 0 \\
0 & 0 & 0 & A_3 \\
A_4 & 0 & 0 & 0 \\
\end{bmatrix}
\]

to the eigenvalues and eigenvectors of \( \tilde{A} = A_1 A_2 A_3 A_4 \). Assume that the diagonal blocks in \( A \) are square.

**P12.6.6** Prove that if (12.6.2) holds, then (12.6.3) converges to \( \lambda_{\min}(T) \) montonically from the right.

**P12.6.7** Recall from §4.7 that it is possible to compute the inverse of a symmetric positive definite Toeplitz matrix in \( O(n^2) \) flops. Use this fact to obtain an initial bracketing interval for (12.6.5) that is based on \( \| T^{-1} \|_\infty \) and \( \| G^{-1} \|_\infty \).

**P12.6.8** A matrix \( A \in \mathbb{R}^{n \times n} \) is centro symmetric if it is symmetric and persymmetric, i.e., \( A = E_n A E_n \) where \( E_n = I_n(:, n-1:1) \). Show that if \( n = 2m \) and \( Q \) is the orthogonal matrix

\[
Q = \frac{1}{\sqrt{2}} \begin{bmatrix}
I_m \\ E_m \\ -E_m \\
\end{bmatrix},
\]

then

\[
Q^T A Q = \begin{bmatrix}
A_{11} + A_{12} E_m & 0 \\
0 & A_{11} - A_{12} E_m \\
\end{bmatrix}
\]

where \( A_{11} = A(1:m, 1:m) \) and \( A_{12} = A(1:m, m+1:n) \). Show that if \( n = 2m \), then the Schur decomposition of a centro symmetric matrix can be computed with one-fourth the flops that it takes to compute the Schur decomposition of a symmetric matrix, assuming that the QR algorithm is used in both cases. Repeat the problem if \( n = 2m + 1 \).

**P12.6.9** Suppose \( F, G \in \mathbb{R}^{n \times n} \) are symmetric and that

\[
Q = \begin{bmatrix}
Q_1 & Q_2 \\
0 & n - p \\
\end{bmatrix}
\]

is an \( n \)-by-\( n \) orthogonal matrix. Show how to compute \( Q \) and \( p \) so that

\[
f(Q, p) = \text{tr}(Q_1^TFQ_1) + \text{tr}(Q_2^TGQ_2)
\]

is maximized. Hint: \( \text{tr}(Q_1^TFQ_1) + \text{tr}(Q_2^TGQ_2) = \text{tr}(Q_1^T(F - G)Q_1) + \text{tr}(G) \).

**P12.6.10** Suppose \( A \in \mathbb{R}^{n \times n} \) is given and consider the problem of minimizing \( \| A - S \|_F \) over all symmetric positive semidefinite matrices \( S \) that have rank \( r \) or less. Show that

\[
\min_{k \leq r} S = \sum_{i=1}^{\min(k, r)} \lambda_i q_i q_i^T
\]

solves this problem where

\[
\frac{A + A^T}{2} = Q\text{diag}(\lambda_1, \ldots, \lambda_n)Q^T
\]

is the Schur decomposition of \( A \)'s symmetric part, \( Q = [q_1, \ldots, q_n] \), and

\[
\lambda_1 \geq \cdots \geq \lambda_k > 0 \geq \lambda_{k+1} \geq \cdots \geq \lambda_n.
\]

**P12.6.11** Verify for general \( n \) (even) that \( H \) is similar to \( H_a H_c \) where these matrices are defined in §12.6.4.

**P12.6.12** Verify that the bidiagonal matrices \( B_G(1:m, 1:m) \) and \( B_S(1:m, 1:m) \) in §12.6.4
have nonzero entries on their diagonal and superdiagonal and specify their value.

P12.6.13 A real $2n$-by-$2n$ matrix of the form

$$
M = \begin{bmatrix} A & G \\ F & -A^T \end{bmatrix}
$$

is Hamiltonian if $A \in \mathbb{R}^{n \times n}$ and $F, G \in \mathbb{R}^{n \times n}$ are symmetric. Equivalently, if the orthogonal matrix $J$ is defined by

$$
J = \begin{bmatrix} 0 & I_n \\ -I_n & 0 \end{bmatrix},
$$

then $M \in \mathbb{R}^{2n \times 2n}$ is Hamiltonian if and only if $J^T M J = -M^T$. (a) Show that the eigenvalues of a Hamiltonian matrix come in plus-minus pairs. (b) A matrix $S \in \mathbb{R}^{2n \times 2n}$ is symplectic if $J^T S J = -S^T$. Show that if $S$ is symplectic and $M$ is Hamiltonian, then $S^{-1} M S$ is also Hamiltonian. (c) Show that if $Q \in \mathbb{R}^{2n \times 2n}$ is orthogonal and symplectic, then

$$
Q = \begin{bmatrix} Q_1 & Q_2 \\ -Q_2 & Q_1 \end{bmatrix}
$$

where $Q_1^T Q_1 + Q_2^T Q_2 = I_n$ and $Q_2^T Q_1$ is symmetric. Thus, a Givens rotation of the form $G(i, i+n, \theta)$ is orthogonal symplectic as is the direct sum of $n$-by-$n$ Householders. (d) Show how to compute a symplectic orthogonal $U$ such that

$$
U^T M U = \begin{bmatrix} H & R \\ D & -H^T \end{bmatrix}
$$

where $H$ is upper Hessenberg and $D$ is diagonal.

Notes and References for Sec. 12.6

The inverse eigenvalue problems discussed in this §12.6.1 and §12.6.2 appear in the following survey articles:

References for the stationary value problem include

An algorithm for minimizing $x^T A x$ where $x$ satisfies $B x = d$ and $\| x \|_2 = 1$ is presented in

Selected papers that discuss a range of inverse eigenvalue problems include

Various Toeplitz eigenvalue computations are presented in

Unitary/orthogonal eigenvalue problems are treated in

Hamiltonian eigenproblems (see P12.6.13) occur throughout optimal control theory and are very important.

Other papers on modified/structured eigenvalue problems include

D. Lay (1994). Linear Algebra and Its Applications, Addison-Wesley, Reading, MA.
