Running title: GPR56 regulates angiogenesis in melanoma.

Keywords: GPR56, adhesion GPCR, VEGF, angiogenesis, melanoma
Abstract

Angiogenesis is a critical step during cancer progression. The vascular endothelial growth factor (VEGF) is a major stimulator for angiogenesis and is predominantly contributed by cancer cells in tumors. Inhibition of the VEGF signaling pathway has shown promising therapeutic benefits for cancer patients, but adaptive tumor responses are often observed, indicating the need for further understanding of VEGF regulation. We report that a novel G protein-coupled receptor, GPR56, inhibits VEGF production from the melanoma cell lines and impedes melanoma angiogenesis and growth, through the serine threonine proline-rich (STP) segment in its N-terminus and a signaling pathway involving protein kinase Cα. We also present evidence that the two fragments of GPR56, which are generated by autocatalyzed cleavage, played distinct roles in regulating VEGF production and melanoma progression. Finally, consistent with its suppressive roles in melanoma progression, the expression levels of GPR56 are inversely correlated with the malignancy of melanomas in human subjects. We propose that components of the GPR56-mediated signal pathway may serve as new targets for anti-angiogenic treatment of melanoma.
Introduction

Angiogenesis is a process of nascent blood vessel formation (1) and is critical for tumor growth and metastasis (2). When tumors reach ~1 mm in diameter, hypoxia develops and induces the secretion of vascular growth factor A (VEGFA, or VEGF) from cancer cells (3). VEGF recruits endothelial cells and stimulates new blood vessel formation (4) to ensure sufficient oxygen and nutrient supply for the proliferation of cancer cells. Inhibiting this process reduces tumor sizes and has been proposed as a non-conventional therapy for cancer treatment (5, 6). Various angiogenesis inhibitors have been developed and many of them show promising tumor inhibitory effects (7). However, adaptive responses to single anti-angiogenic therapy, manifested as increased invasion and metastasis of cancer cells, have been observed both experimentally and clinically (8-10). The mechanisms for this adaptive response are not clear, but its occurrence strongly argues for combinations of anti-angiogenic regimens to effectively treat cancer.

VEGF is a potent growth factor for angiogenesis and is a common target for anti-angiogenesis inhibition (11). It binds to the VEGF receptors (VEGFRs) on endothelial cells and promotes their proliferation and migration during angiogenesis. The main source of VEGF in tumors is cancer cells and its expression is tightly regulated at both transcriptional and post-transcriptional levels (12). Under hypoxic conditions, VEGF mRNA is induced by the hypoxia-inducible factor alpha (HIF-1alpha) and subsequently regulated by alternative splicing. Four main isoforms of VEGF have been identified: VEGF_{121}, VEGF_{165}, VEGF_{189}, and VEGF_{206}, with VEGF_{165} being the most abundantly expressed. All VEGF isoforms except VEGF_{121} could
associate with extracellular matrix (ECM). The ECM-bound VEGF can be released and activated by heparinases or matrix metalloproteinases, providing an additional layer of regulation for VEGF activity in vivo (13). A less well-characterized mechanism of VEGF regulation is secretion. VEGF contains a signal peptide (14) and presumably is secreted through conventional vesicle trafficking process, from ER to Golgi, and to plasma membrane. In mast cells (15) and neutrophils (16), for example, VEGF is stored in secretory granules, and its release is stimulated by the activation of protein kinase C (PKC).

We report here that VEGF production from melanoma cells is regulated by an atypical G protein-coupled receptor (GPCR), GPR56. GPR56 belongs to the family of adhesion GPCRs, a newly identified family of class B GPCRs implicated in both cell adhesion and G protein-coupled signaling (17). The adhesion GPCRs are highly conserved and their importance in development and diseases has been increasingly recognized (17-22), but their regulatory mechanisms remain poorly understood. Adhesion GPCRs share a GPCR proteolytic site (GPS), through which the extracellular stalks are separated from the transmembrane domains by autocatalytic cleavage. The cleaved fragments could still associate with each other non-covalently and form a heterodimeric complex. This cleavage in adhesion GPCRs is required for their proper functions, since mutations in GPS motifs resulted in failure of the receptors to localize on cell surface (23, 24).

Our previous work showed that GPR56 inhibited melanoma growth and metastasis from MC-1 cells in a xenograft model (25). We present evidence here that, depending on the presence or absence of a serine threonine proline-rich (STP) segment in its N-terminus, GPR56
differentially regulates VEGF production, angiogenesis, and melanoma growth, via a signaling pathway involving PKCα. We propose that GPR56 exists in different activation states in melanoma cells, which are modulated by its STP segment and induce opposing outcomes on angiogenesis and melanoma progression. Specific targeting of tumor-promoting activity of GPR56 may thus serve as a new strategy for angiogenesis inhibition and melanoma treatment.

Materials and Methods

Cell lines

The MC-1, SM, and MA-1 cells were derived from the human melanoma cell line, A375 (ATCC #CRL-1619) (25, 26), and maintained in Dulbecco’s Modified Eagle Medium (DMEM) with 10% FBS and 4 mM glutamine. WM266-4 cells were obtained from ATCC (CRL-1676) and maintained in Minimal Essential Medium with Earle’s salt, 10% FBS, 0.1 mM non-essential amino acids, 1 mM sodium pyruvate, 1.5 g/L sodium bicarbonate, and 2 mM glutamine. YURIF cells were purchased from the Yale University Cell Core Facility (27) and maintained in Opi-MEM (Invitrogen) with 5% FBS. HEK293 cells were maintained in DMEM with 10% FBS and 2 mM glutamine. All the cell lines were passaged in our laboratory for less than six months after receipt.

Mice

NOD-SCID mice (NOD.CB17-Prkdcscid/J) and NSG mice (NOD.Cg-Prkdcscid Il2rgtm1WjlszJ) were purchased from the Jackson Laboratory (Bar Harbor, Maine). Gpr56-/- mice (Genentech Inc., CA) were maintained through crossbreedings between Gpr56-/- mice. All the mice were housed in the animal facility at the University of Rochester Medical
Center or Massachusetts Institute of Technology, in accordance to the animal care guidelines from the Division of Laboratory Animal Medicine at University of Rochester Medical Center or MIT.

**ELISA for VEGF Quantification**

Cells were seeded at a density of $1.0 \times 10^5$ cells per well in 24-well plates and cultured in serum-free medium for three days. Media were collected every 24 hours for VEGF-specific ELISA analyses, following the instructions from the manufacturer (R&D Systems).

To test the effects of PKC on VEGF production, MC-1 cells were incubated with the PKC inhibitors, chelerythrine chloride and Ro-31-8425 (EMD4Biosciences, NJ), or the PKC activator, phorbol myristate acetate (PMA; Sigma, MO), for 48 hours in serum-free medium. The media of the treated cells were subjected to ELISA. To examine the effects of PKCα on VEGF production, MC-1(ΔSTP-GPR56) and MC-1(GPRC) cells were transiently transfected with the construct expressing a dominant negative (DN) mutant of PKCα, or vector control (Addgene). Media were collected 48 hours after transfection for ELISA analyses. To assess whether the DN-PKCα sequesters PMA-induced VEGF production, MC-1(GPR56) cells transiently expressing DN-PKCα or vector control were subjected to PMA (10 μg/ml) stimulation. Media were collected 48 hours after stimulation for ELISA analyses.

**Analyses of Activation of PKC Isoforms**

Cell fractionation to assess activated PKC isoforms was performed as previously reported (28). Briefly, cells were lysed in isotonic buffer (20 mM Tris–HCl (pH 7.5, 150 mM NaCl, 10 mM...
EDTA, 5 mM EGTA, 20 mM sodium fluoride, 5 mM sodium pyrophosphate, 1 mM sodium vanadate, 1 μM okadaic acid and a cocktail of protease inhibitor). Membrane fractions were collected after two rounds of centrifugations and were subjected to western blot analyses, using antibodies against PKCα, PKCβ1, PKCβ2, PKCγ, PKCδ, or PKCε (1: 1000, Santa Cruz Biotechnology). The rabbit anti-LRP6 antibody (1: 500, Cell Signaling) was used as a loading control. The intensity of each PKC band was measured by Alphalnager software and normalized to the intensity of LRP6 band from the same sample. The ratio of the PKC level in MC-1(GPR56), MC-1(ΔSTP-GPR56), or MC-1(GPRC) cells, over that in MC-1(EV) cells (which was arbitrarily set to 1) was defined as the “Relative Intensity” score.

**Western Blots**

Cells were lysed in RIPA buffer and separated on a 12% SDS-polyacrylamide gel for western blot analyses using the goat anti-VEGF antibody (0.2 mg/ml, R&D systems, MN), sheep anti-GPRN (0.4 mg/ml, R&D systems), rabbit anti-GPRC (1- 300), FcGPRN (1 mg/ml), mouse anti-TG2 (1: 100, Abcam, MA), or mouse anti-GAPDH (1: 1000) antibodies, followed by detection by HRP-conjugated secondary antibodies and enhanced chemiluminescence detection system (Pelkin Elmer, MA).

**Tumor Studies**

5 x 10⁵ of melanoma cells were injected subcutaneously into NOD-SCID, or NSG mice. Tumor were harvested and weighted five weeks after injections. To study tumor angiogenesis, frozen sections of tumors were stained with rat anti-PECAM antibody (1:5, BD
Pharmingen, CA), or mouse anti-human vimentin antibody (1:50, Leica Microsystems, IL), and rabbit anti-GPRC antibody (1:300), followed by detection with Alexa 488 or Alexa 594 donkey anti-rabbit, anti-mouse, or anti-rat secondary antibodies (1:400, Invitrogen). Images were captured by the SPOT software and processed with Adobe Photoshop. The numbers of blood vessels in two to five randomly chosen fields on each tumor section, or GPR56-positive and GPR56-negative areas on each GPR56-expressing tumor section, were counted.

Results

GPR56 inhibits angiogenesis in melanoma

We previously reported that GPR56 inhibited melanoma growth and metastasis in xenograft models (25). Angiogenesis is a critical process during tumor progression (2). To determine whether GPR56 inhibits melanoma progression by regulating angiogenesis, tumor sections from MC-1 cells expressing GPR56 or vector control were sectioned and stained with an antibody against the platelet and endothelial cell adhesion molecule-1 (PECAM-1). Significantly fewer blood vessels were observed on sections from MC-1(GPR) cells than the controls (Figure 1A and B), suggesting that GPR56 inhibits angiogenesis in melanomas.

We frequently observed loss of GPR56 expression in some areas of tumors from MC-1(GPR) cells, probably due to the growth advantage of cells that express low levels of ectopic GPR56. We postulated that these areas would contain more blood vessels than the adjacent areas that retain GPR56 expression. To test this, MC-1(GPR56) tumor sections were co-stained with the anti-GPR56 antibody (anti-GPRC) and the anti-PECAM antibody, or an antibody...
against the human-specific vimentin (Figure 1A and Supplementary Figure S1). GPR56-low and –high areas that contain tumor cells but not mouse stroma were selected. Quantification of blood vessels in these areas revealed an inverse relationship between expression levels of GPR56 and blood vessel density (Figure 1A and C), arguing strongly that ectopic expression of GPR56 in MC-1 cells inhibits melanoma angiogenesis.

**Expression of the C-terminal fragment of GPR56 induces angiogenesis and melanoma growth.**

Like many members of the adhesion GPCR family, mature GPR56 receptor is cleaved into two fragments at the junction between its N-terminus (GPRN) and C-terminal transmembrane domains (GPRC) (25). The GPRN and GPRC fragments still associate with each other after cleavage, but significant portions of them remain unbound. We hypothesized that the GPRN signals through GPRC to inhibit melanoma growth and angiogenesis and deletion of GPRN in GPR56 should abolish this inhibition. To test this, the GPRC fragment was over-expressed in MC-1 cells. This expression did not alter cell proliferation significantly *in vitro* (Supplementary Figure S2), but, *in vivo*, it not only failed to inhibit melanoma growth, but dramatically induced melanoma growth and angiogenesis (Figure 2A-C), in direct contrast with the inhibition observed from full-length GPR56. These results indicated a potential antagonistic relationship between the GPRN and GPRC fragments in MC-1 cells.

**The STP segment in GPR56 binds to TG2 and its deletion in GPR56 led to enhanced angiogenesis and tumor growth.**
The antagonistic relationship of GPRN and GPRC fragments implicated from the above finding led us to speculate that a factor might bind to GPRN and modulate the stimulatory or inhibitory effects of GPRC. We previously reported that tissue transglutaminase, TG2, binds to GPRN (25). To test whether TG2 might mediate the inhibitory function of GPRC, we mapped the region in GPR56 that binds to TG2. GPRN fragments of various lengths were expressed and purified as human Fc fusion proteins (Supplementary Figure S3A and B) and their binding to TG2 was tested on overlay assays (25). A serine, threonine, proline-rich (STP) segment of around 70 aa was shown to be both necessary and sufficient for binding with TG2 (Supplementary Figure S3C and D).

We reasoned that, if TG2 mediates the suppressive roles of GPR56 in melanoma progression, deletion of the STP motif in GPR56 would reverse the inhibition by GPR56. To test this hypothesis, ΔSTP-GPR56 was expressed in MC-1 cells (MC-1(ΔSTP-GPR56)), processed into a C-terminal fragment of ~25 kDa and an N-terminal fragment of ~45 kDa (Figure 3A), and localized on cell surface as the full-length GPR56 (Supplementary Figure S4). The expression of ΔSTP-GPR56 did not perturb MC-1 cell proliferation significantly in vitro (Supplementary Figure S2), but led to increased tumor growth and blood vessel densities in vivo (Figure 3B, C and D), similar to GPRC but in contrast to the full-length receptor, indicating that the STP segment is required for the inhibitory effect of GPR56 on melanoma angiogenesis and growth.

ΔSTP-GPR56 induces VEGF production in melanoma cell lines.
To examine whether GPR56 affects tumor angiogenesis by modulating VEGF production, the concentrations of VEGF in the media from the MC-1(EV), MC-1(GPR), and MC-1(ΔSTP-GPR56) cells were determined by ELISA. VEGF was lower in the media of MC-1(GPR) cells than that of MC-1(EV) cells (Figure 4A), but dramatically elevated in the media from MC-1 (ΔSTP-GPR56) and MC-1(GPRC) cells (Figure 4A and B), suggesting that GPR56 inhibits, but ΔSTP-GPR56 or GPRC promotes, the production of VEGF by MC-1 cells. Consistent with these *in vitro* observations, the level of VEGF in the circulation of mice bearing MC-1(ΔSTP-GPR56) cells or MC-1(GPRC) tumors was higher than controls, and the reverse was observed for MC-1(GPR56) tumors (Supplementary Figure S5). To examine whether GPR56 regulates VEGF production in melanoma cells other than MC-1 cells, ΔSTP-GPR56 was expressed in four additional human melanoma cell lines, SM, WM266-4, MA-1, and YURIF. Its expression induced VEGF production in all of them (Figure 4C), suggesting that regulation of VEGF production by GPR56 might be a shared mechanism in malignant melanoma.

The above opposing roles of GPRC and full-length GPR56 on VEGF production predicted an antagonistic relationship between GPRN and GPRC in melanoma cells. To directly test this, purified FcGPRN fusion protein (shown as FcGPRN-1 in Figure S3) was added onto MC-1(GPRC) cells and resulted in a significant reduction of VEGF production relative to controls (Figure 4D), suggesting strongly that GPRN inhibits the activity of GPRC during VEGF production of melanoma cells. Since GPRC could be detected in both “GPRN-bound” and “GPRN-free” states in melanoma cell lysates (25), depleting the whole GPR56 molecule would abolish both and, depending on the ratio of the two states, may result in no net change or cell-specific changes of VEGF production in melanoma cells. Consistent with this, we did not
observe significant changes of VEGF production from MA-1 cells expressing GPR56 shRNAs (Supplementary Figure S6).

The level of VEGF produced from MC-1(ΔSTP-GPR56) cells was increased relative to controls, demonstrating that the STP segment in GPR56 is essential for its inhibitory role on VEGF production. The STP segment binds to TG2, therefore TG2 might participate in the inhibition of VEGF production by GPR56. To test this, TG2 mRNA was knocked down in MC-1 cells by shRNAs (Supplementary Figure S7A). Although a minimal increase of VEGF was observed in the MC-1(TG2-shRNA) cells relative to the controls (Supplementary Figure S7B), this increase was much smaller than the massive induction of VEGF observed in MC-1(ΔSTP-GPR56) cells, indicating that TG2 might not mediate the inhibitory effects of GPR56 on VEGF production.

We next explored the molecular mechanism by which GPR56 might regulate VEGF production in MC-1 cells. We did not observe significant difference in VEGF mRNA levels among the MC-1(EV), MC-1(GPR), and MC-1(GPRC) cells; the level of VEGF mRNA in MC-1(ΔSTP-GPR56) cells was slightly higher than those in the other two cell lines, but the magnitude of increase (~2 fold) could not account for the large increase of VEGF levels in the conditioned medium (> 20 fold) (Supplementary Figure S8A). Similarly, no significant difference in intracellular VEGF levels was observed between the MC-1(EV) and MC-1(GPR) cells, and in MC-1(ΔSTP-GPR56) cells, the amount of intracellular VEGF was reduced relative to the other two cell lines (Supplementary Figure S8B). We also did not observe alterations in alternative splicing or ECM retention of VEGF in MC-1 cells expressing GPR56 or ΔSTP-
GPR56 (data not shown). These data collectively imply that GPR56 might not regulate VEGF production at the levels of mRNA or protein synthesis, but instead might inhibit its secretion/release from melanoma cells.

VEGF Secreted from MC-1(EV), MC-1(GPR56), and MC-1(ΔSTP-GPR56) cells contribute to angiogenesis and tumor growth.

VEGF is a major stimulator of angiogenesis during development and diseases. In tumors, it is mainly secreted by cancer cells (30) and its level correlates with poor prognosis of cancer (31). To test whether VEGF secreted from MC-1 cells contribute to the angiogenesis and tumor progression regulated by GPR56, VEGF mRNA was knocked down in MC-1(ΔSTP-GPR56) cells by shRNAs (Figure 4E). These MC-1(ΔSTP-GPR56+VEGF-shRNA) cells were injected subcutaneously into mice. Tumor growth from these cells was significantly impaired compared with controls (Figure 4F), demonstrating that VEGF produced from MC-1(ΔSTP-GPR56) cells directly contributes to their tumor progression. Consistent with this, conditioned media from MC-1(ΔSTP-GPR56) cells accelerated the wound closure of endothelial monolayer in a VEGF-dependent manner in scratch assays (Supplementary Figure S9A and B).

GPR56 regulates VEGF production through protein kinase Cα (PKCα).

PKC activation has been shown to induce VEGF release from specific granules in multiple cell types (16, 32, 33). To test whether GPR56 also regulates VEGF secretion in melanoma cells through PKC, phorbol myristate acetate (PMA), a potent PKC activator, was added to MC-1(GPR) cells and shown to abrogate the inhibition of VEGF secretion by GPR56
Conversely, administration of PKC inhibitors, chelerythrine chloride and Ro-31-8425, resulted in significant reduction of VEGF secretion in MC-1 and MC-1(ΔSTP-GPR56) cells (Figure 5B and C), suggesting that GPR56 regulates VEGF production from MC-1 cells via PKC.

PKCs are represented by as many as ten different isoforms (34). Except for the two atypical PKCs, all other eight isoforms (PKCα, PKCβ1, PKCβ2, PKCγ, PKCδ, PKCε, PKCη, PKCθ) are sensitive to PMA activation and could be involved in stimulating VEGF secretion. To examine which isoform might be regulated by GPR56, we investigated their activities in MC-1 cells expressing full-length GPR56, ΔSTP-GPR56, GPRC, and vector control. Because activated PKC typically translocates from cytosol to membranes (35), its level in the particular fraction of cell lysates directly correlates with its activation state. Consequently, the particular fractions of MC-1(EV), MC-1(GPR), MC-1(ΔSTP-GPR), and MC-1(GPRC) cells were collected and the levels of PKCα, PKCβ1, PKCβ2, PKCγ, PKCδ, and PKCε in each fraction were determined by western blotting analyses using isoform-specific antibodies. We found that the level of PKCα was reduced in the particular fractions of MC-1(GPR) cells and increased in those of MC-1(ΔSTP-GPR) and MC-1(GPRC) cells (Figure 5D and Supplementary Figure S10), suggesting that PKCα is inhibited by full-length GPR56 and activated by ΔSTP-GPR56 and GPRC, and thus may mediate the regulation of VEGF production by these receptors. Consistent with this, expression of a dominant negative mutant of PKCα led to a significant reduction of VEGF secretion in MC-1(ΔSTP-GPR) and MC-1(GPRC) cells as well as the PMA-induced VEGF secretion from MC-1(GPR56) cells (Figure 5E and F). The level of PKCβ2 was decreased in the particular fractions of MC-1(GPR) cells, but did not show any increase in those
of MC-1(ΔSTP-GPR) and MC-1(GPRC) cells, thus unlikely contribute directly to the VEGF production regulated by GPR56 and its derivatives. None of the remaining PKC isoforms tested showed significant differential regulation by GPR56 (Figure 5D and Supplementary Figure S10).

Expression levels of GPR56 are inversely correlated with the progression of human melanomas

To investigate expression of GPR56 in melanocytic lesions, we analyzed the expression pattern of GPR56 on human tissue microarrays (TMAs) of nevi, primary melanomas, and metastatic melanomas by immunohistochemistry using an antibody raised against the STP segment of GPR56. The antibody specifically recognized GPR56 on formalin-fixed sections from mouse tissues and human melanoma xenografts (Figure 6A and B). Expression intensities of GPR56 on the TMAs were determined by one of us (G.S.) and decreased significantly as melanoma progresses from nevi to primary melanomas, and appeared to follow this trend of decline (although not with statistical significance) in metastatic melanomas (Figure 6C and D).

Discussion

Malignant melanoma is a devastating disease with significant resistance to current therapies (36). Recently, anti-angiogenic inhibitors have shown promising therapeutic potentials in melanoma (7, 37). A common target for anti-angiogenic therapy is VEGF. Several VEGF inhibitors have been pursued clinically and some of them have been approved by FDA (38). However, relapse was frequently observed in VEGF inhibitor-treated patients (6, 7), partly
attributable to incomplete inhibition of VEGF activity. Most of the VEGF inhibitors block the downstream effects of VEGF, after its secretion and release from cells, either by neutralizing diffusible VEGF or inhibiting the signaling pathway it stimulates. Since the supply of VEGF is not affected, continuous administration of inhibitors is required to sequester its activity and frequently some VEGF escapes the inhibition, by its retention in extracellular matrix (ECM), for example (39). This problem may be alleviated by reducing production and/or secretion of bioactive VEGF at source, thus increasing the efficacy of anti-angiogenic effects of VEGF inhibitors.

G protein-coupled receptors constitute over 40% of drug targets for treatment of human diseases, but they have not been the main targets for cancer control, mostly due to a lack of understanding of their roles in cancer progression. The involvement of GPCRs on VEGF production in cancer cells has been reported and shown to involve the p38/MAPK pathway (40). We report here that an adhesion GPCR, GPR56, regulates VEGF production and melanoma angiogenesis through a signaling pathway mediated by protein kinase Cα (Figure 7). We also present evidence that the two fragments of GPR56, generated by cleavage upon receptor maturation, could play distinct roles in their regulation of melanoma angiogenesis and progression. While expression of its C-terminal fragment (GPRC) induced VEGF secretion in MC-1 cells, expression of the full-length receptor inhibited it. Most signaling receptors exhibit a certain degree of basal/constitutive activities (41). We postulate that the “free” GPRC might be in such a state and its over-expression led to stimulated VEGF production and melanoma progression (Figure 7). GPRN and ΔSTP-GPRN might inhibit and activate this basal activity of GPRC, respectively, resulting in opposing effects on melanoma progression. Consistent with
this notion, our data showed that purified FcGPRN protein was sufficient to inhibit VEGF production from MC-1(GPRC) cells (Figure 4D).

ΔSTP-GPR56 promoted VEGF production in multiple melanoma cell lines (Figure 4C), suggesting that the activation mechanisms and resulted functions of GPR56 may be shared among malignant melanomas. Interestingly, alternatively spliced isoforms of GPR56 were reported recently and two of them encode proteins similar to ΔSTP-GPR56 (42). Although the ΔSTP isoforms may function differently in different cell types - they were shown to inhibit the VEGF promoter in HEK293 cells rather than enhancing VEGF production (42), their very existence suggests that perturbing GPR56, by inhibiting its endogenous ΔSTP or activated isoforms, could be used as a strategy to effectively curb angiogenesis and melanoma progression, especially when combined with other VEGF inhibitors. Normal adult tissues tend to express low levels of GPR56 relative to cancerous tissues (43), and Gpr56−/− mice or human patients carrying mutations in the GPR56 gene are viable and grossly healthy, despite defects in brain development (18, 44). Therefore, perturbing GPR56 and its mediated signaling pathway may have few detrimental side effects on cancer patients as long as they do not penetrate the blood-brain barrier.

Whether GPR56 functions similarly in endogenous melanoma progression as in xenografts is yet to be determined. We reported previously that melanoma development in the Ink4a/Arf−/− tyr-HRAS mice did not alter significantly in the absence of GPR56 (43). Perhaps GPR56 plays dual roles in endogenous melanoma progression, as in xenografts, and its complete absence abolishes both and leads to an outcome similar to that in wild-type mice. Alternatively,
GPR56 expressed on stromal cells also affect tumor development in endogenous melanomas, which was not assessed in the xenograft model.

The signaling pathways mediated by GPR56, or adhesion GPCRs in general, are poorly understood, despite their increasingly recognized importance in development and diseases (17-22). The results from our study serve as a platform for further investigations in this area. For example, it is not clear whether the inhibition or activation of GPRC imposed by GPRN or ΔSTP-GPRN might involve other interacting proteins. We previously reported that TG2 binds to GPRN (25). However, knockdown of TG2 in MC-1(GPR56) cells by RNAi did not lead to an increase of VEGF production as observed in MC-1(ΔSTP-GPR56) cells, suggesting that the roles of TG2 in GPR56-mediated signaling are not straightforward. It is possible that other factor(s) binds to the STP segment in GPRN and mediates the inactivation of GPRC. The expression or stability of this factor(s) may thus determine the activity of GPR56 in cancer cells. Finally, GPR56 was reported to associate with Gαq (45), consistent with its regulation of PKC activation. Whether this is the case also needs to be investigated.

The apparent separate functions of GPRN and GPRC indicated by our results support the recent proposal that the two subunits of adhesion GPCRs might function as distinct entities (46). It was reported that the two fragments of latrophilin, another adhesion GPCR, could associate with and potentially signal through fragments from other adhesion GPCRs. The GPCR proteolytic site (GPS) is conserved in all adhesion GPCRs and those tested were shown to be cleaved into two fragments (17). Their potential to play distinct functions promises a great
complexity of regulation by the adhesion GPCRs in a range of biological processes, including cancer.

D. PKCα was reduced in the particular fractions from MC-1(GPR) cells, but increased in those of MC-1(ΔSTP-GPR) and MC-1(GPRC) cells, relative to MC-1(EV) cells. LRP6 was used as a loading control.

E. Expression of dominant negative (DN) PKCα in MC-1(ΔSTP-GPR) or MC-1(GPRC) cells led to reduced VEGF production in the medium.

F. Expression of DN-PKCα inhibited PMA-induced production of VEGF in MC-1(GPR56) cells.

Figure 6. The expression levels of GPR56 are inversely correlated with melanoma progression.

A, B. Immunohistochemical analyses on sections from wild-type or Gpr56−/− testes (A), or tumors from MC-1 cells that express human GPR56 (B). The anti-GPRN antibody specifically recognized GPR56 on these sections.

C. Immunohistochemical analyses on melanoma tissue microarrays using the anti-GPRN antibody.

D. Expression intensity scores of GPR56 on melanoma tissue microarrays. **: p < 0.001; ***: p < 0.0001.

Figure 7. Model of GPR56 function in VEGF production by melanoma cells.

We hypothesize that the free GPRC fragment of GPR56 represents a basal/constitutive “on” state to induce the activation of PKCα, VEGF production, angiogenesis, and melanoma progression. The binding of full-length GPRN switches GPRC to an “off” state and inhibits those processes. The binding of ΔSTP-GPRN, however, activates it and promotes melanoma progression.
