Cost Approximation Methods/Single Policy

Bellman Equation for Single Policy in Finite-State MDP:

\[ J = g + \alpha PJ, \quad \alpha \in (0, 1] \]

We approximate \( J \) by \( \Phi r \)

\[ J \approx \Phi r \]

Columns of \( \Phi \) are basis functions

Algorithms:
- Direct approach
- Equation error methods
- TD methods

Alternatives: Q-learning, including for multiple policies; approximate LP
Projected Bellman Equation and TD Methods

Bellman Equation:

\[ J = TJ = g + \alpha PJ, \quad \alpha \in (0, 1] \]

TD(\(\lambda\)) with Function Approximation: approximate the solution by solving 
projected Bellman equation

\[ \Phi r = \Pi T^{(\lambda)}(\Phi r), \quad T^{(\lambda)} = (1 - \lambda) \sum_{k=0}^{\infty} \lambda^k T^{k+1}, \quad \lambda \in [0, 1] \]

- Weighted Euclidean projection

\[ \Pi J = \arg \min_{r \in \mathbb{R}^s} \| J - \Phi r \|_{\xi} \]

(\(\xi_1, \ldots, \xi_n\)): invariant distribution of \(P\)

- Contraction and error bounds
Algorithms: Recursive TD vs. LS

Both recursive TD and LS algorithms solve, in the limit,

$$\Phi r = \Pi T^{(\lambda)}(\Phi r)$$

using a single sample trajectory \((i_0, i_1, \ldots)\) (or multiple ones)

Recursive TD(\(\lambda\)) (Sutton '88):

- Use each sample state only once

\[ r_{t+1} = r_t + \gamma_t z_t (g_t + \alpha \phi(i_{t+1})' r_{t} - \phi(i_t)' r_t) \]

- Stochastic approximation, small stepsize for averaging out noise
- Analyzed by Tsitsiklis and Van Roy '97, '99, and by others

Methods with Least Squares Forms:

- Reuse the samples at every iteration
- Implicitly approximate \(\Pi T^{(\lambda)}\), restricted on the approximation subspace, with increasing accuracy
LS Algorithms: Equation/Mapping Approximation

Least Squares Temporal Difference (LSTD)
- Proposed by Bradtke and Barto ’96, Boyan ’99
- Solve approximate projected Bellman equation

\[ \Phi \tilde{r}_{t+1} = \Pi_t \hat{T}_t^{(\lambda)}(\Phi \tilde{r}_{t+1}) \]

Least Squares Policy Evaluation (LSPE)
- Proposed by Bertsekas and Ioffe ’96 and analyzed by several others
- Approximate projected value iteration

\[ \Phi r_{t+1} = \Pi_t \hat{T}_t^{(\lambda)}(\Phi r_t) = \Pi T^{(\lambda)}(\Phi r_t) + \epsilon_t \]
Convergence of LSPE with constant stepsize for $\alpha \in (0, 1]$ (Bertsekas, Borkar, and Nedić ’04, Yu and Bertsekas ’06):

- Iteration can be viewed as “deterministic portion + stochastic noise”
  \[
  \Phi r_{t+1} = F(\Phi r) + \epsilon_t, \quad \text{where } F = (1 - \gamma)I + \gamma \Pi T^{(\lambda)}
  \]
- The constant stepsize $\gamma$ plays a role of “damping” the projected value iteration $\Pi T^{(\lambda)}$
- If the deterministic portion $F$ is a contraction, then noise diminishes asymptotically, and LSPE converges

Proposition

*Convergence stepsize ranges for LSPE:*

(i) discounted case ($\alpha < 1$): $\gamma \in (0, \frac{2}{1+\alpha})$

(ii) average cost case ($\alpha = 1$):

- $\lambda \in (0, 1): \quad \gamma \in (0, 1]$  
- $\lambda = 0, \quad P\text{ aperiodic}: \quad \gamma \in (0, 1]$, \quad $\lambda = 0: \quad \gamma \in (0, 1)$
Convergence Analysis of LSPE

Asymptotically Optimal Rate of Convergence (Yu and Bertsekas ’06) shown by a comparison analysis of LSPE/LSTD:

\[
\begin{align*}
\text{LSPE:} & \quad \Phi_r_{t+1} = (1 - \gamma) \Phi_r_t + \gamma \widehat{r}_t^{(\lambda)}(\Phi_r) \\
\text{LSTD:} & \quad \Phi_{\tilde{r}}_{t+1} = \widehat{r}_t^{(\lambda)}(\Phi_{\tilde{r}}_{t+1})
\end{align*}
\]

Proposition

For all stepsize \( \gamma \) in the convergence range of LSPE,

\[
\| \Phi_r_t - \Phi_{\tilde{r}}_t \| < \infty, \quad \text{w.p.1.}
\]

Implications:

- Empirical phenomenon: \( r_t \) “tracks” \( \tilde{r}_t \)
- More precisely: \( r_t - \tilde{r}_t \to 0 \) at the rate of \( O(t) \), faster than \( r_t, \tilde{r}_t \to r^* \) at the rate of \( O(\sqrt{t}) \)
- LSTD has the optimal convergence rate comparing to recursive TD (Konda ’02), so LSPE shares this property

Stoppers Problems – Overview

Extension to Optimal Stopping Problems – Main Idea:

- Apply the same mapping approximation idea to solve the non-linear projected Bellman equation

Basic Optimal Stopping Problem:

- An irreducible Markov chain with $n$ states and transition matrix $P$
- Action: stop or continue
- Cost at state $i$: $c(i)$ if stop; $g(i)$ if continue
- Minimize the expected discounted total cost till stop

Bellman equations for $\alpha \in (0, 1)$

$$J^* = \min \{ c, g + \alpha PJ^* \}, \quad Q^* = g + \alpha P \min \{ c, Q^* \}$$

$Q$-factor: $Q^*(i, a) =$ optimal cost from state $i$ with first action $a$

Optimal: stop as soon as the state hits the set

$$\mathcal{D} = \{ i \mid c(i) \leq Q^*(i) \}$$
**Q-Learning with Function Approximation**  
(Tsitsiklis and Van Roy '99)

**Subspace Approximation**

\[ \tilde{Q} = \Phi r \quad \text{or,} \quad \tilde{Q}(i, r) = \phi(i)'r \]

**Weighted Euclidean Projection**

\[ \Pi Q = \arg \min_{r \in \mathbb{R}^s} \| Q - \Phi r \|_\xi, \quad (\xi_1, \ldots, \xi_n) : \text{invariant distribution of } P \]

**Key Fact:** DP mapping \( F \) is \( \| \cdot \|_\xi \)-contraction and so is \( \Pi F \)

\[ FQ \overset{\text{def}}{=} g + \alpha P \min\{c, Q\} \]

**Projected Bellman Equation** solvable by using TD:

\[ \Phi r^* = \Pi F(\Phi r^*) \]

**Suboptimality:** stop as soon as the state hits \( \{i \mid c(i) \leq \phi(i)'r^*\} \)

\[ \sum_{i=1}^{n} \xi(i) (J_\mu(i) - J^*(i)) \leq \frac{2}{(1 - \alpha)\sqrt{1 - \alpha^2}} \| \Pi Q^* - Q^* \|_\xi \]
Least Squares Q-Learning

The Algorithm

\((i_0, i_1, \ldots)\) unstopped state process, \(\gamma \in (0, \frac{2}{1+\alpha})\) constant stepsize

\[ r_{t+1} = r_t + \gamma (\hat{r}_{t+1} - r_t) \]

where \(\hat{r}_{t+1}\) is the LS solution:

\[ \hat{r}_{t+1} = \arg\min_{r \in \mathbb{R}^s} \sum_{k=0}^{t} \left( \phi(i_k)'r - g(i_k, i_{k+1}) - \alpha \min \{ c(i_{k+1}), \phi(i_{k+1})'r_t \} \right)^2 \]

Proposition

For all \(\gamma \in \left(0, \frac{2}{1+\alpha}\right)\), \(\lim_{t \to \infty} r_t = r^*, \ w.p.1.\)
The algorithm can be viewed as approximate projected value iteration

$$\hat{r}_{t+1} = \left( \sum_{k=0}^{t} \phi(i_k)\phi(i_k)' \right)^{-1} \sum_{k=0}^{t} \phi(i_k) \left( g(i_k, i_{k+1}) + \alpha \min \{ c(i_{k+1}), \phi(i_{k+1})' r_t \} \right)$$

$$\Phi \hat{r}_{t+1} = \hat{\Pi}_t \hat{F}_t(\Phi r_t) = \hat{\Pi}_t \left( \hat{g}_t + \alpha \hat{P}_t \min \{ c, \Phi r_t \} \right)$$

$$\Phi r_{t+1} = (1 - \gamma) \Phi r_t + \gamma \hat{\Pi}_t \hat{F}_t(\Phi r_t)$$

▶ Convergence follows from mapping approximation and contraction: w.p.1, for all $t$ sufficiently large,
- $\hat{\Pi}_t \hat{F}_t$ is $\| \cdot \|_\xi$-contraction with modulus $\hat{\alpha} \in (\alpha, 1)$
- $(1 - \gamma)I + \gamma \hat{\Pi}_t \hat{F}_t$ is $\| \cdot \|_\xi$-contraction for $\gamma \in (0, \frac{2}{1+\alpha})$

▶ Computation overhead: require repartitioning past states into stopping or continuation sets
Comparison to an LSTD Analogue

LS Q-learning: \[ \Phi r_{t+1} = (1 - \gamma)\Phi r_t + \gamma \hat{\Pi}_t \hat{F}_t(\Phi r_t) \quad (1) \]
LSTD analogue: \[ \Phi \tilde{r}_{t+1} = \hat{\Pi}_t \hat{F}_t(\Phi \tilde{r}_{t+1}) \quad (2) \]

Eq. (1) is one single fixed point iteration for solving Eq. (2). Yet, they have the same convergence rate [two-time scale argument, similar to the comparison analysis of LSPE/LSTD]:

**Proposition**

For all \( \gamma \in \left(0, \frac{2}{1 + \alpha}\right) \), \( t\|\Phi r_t - \Phi \tilde{r}_t\| < \infty \), w.p.1.
Variants

A Variant: repartition each sample state at most $m$ times

$$r_{t+1} = \arg \min_{r \in \mathbb{R}^s} \sum_{k=0}^t \left( \phi(i_k)' r - g(i_k, i_{k+1}) - \alpha \min \{ c(i_{k+1}), \phi(i_{k+1})' r_{k,t} \} \right)^2$$

Intermediate between TD and mapping approximation:

- $m \to \infty$: LS $Q$-learning algorithm
- $m = 1$: the fixed point Kalman filter (Choi and Van Roy ‘06), equivalent to TD with scaling,

$$r_{t+1} = r_t + \frac{1}{t+1} B_t^{-1} \phi(i_t)(g(i_t, i_{t+1}) + \alpha \min \{ c(i_{t+1}), \phi(i_{t+1})' r_t \} - \phi(i_t)' r_t)$$

Convergence for $m \geq 1$ can be shown, using o.d.e. analysis (Borkar ‘06, Borkar and Meyn ‘01), or an alternative “direct” proof.

Extensions to undiscounted optimal stopping problems
Overview of Cost Approximation Methods
- Projected Bellman Equation and TD Methods
- LS Algorithms using Equation/Mapping Approximation

Extension I: LS Q-Learning for Optimal Stopping Problems
- Background
- Least Squares Q-Learning Algorithm
- Variants with Reduced Computation

Extension II: Solving Linear Equations
- Key Ideas
- Single Step and Multistep Algorithms
- Related Ideas: Basis/Feature Generation
Overview and Key Ideas from ADP

Large Systems of Linear Equations

\[ x = T(x) = b + Ax \]

Ideas Inspired by ADP:
- Subspace approximation by solving *projected equation*
  \[ x = \Pi T(x) \quad \text{i.e.,} \quad \Phi r = \Pi T(\Phi r) = \Pi b + \Pi A(\Phi r) \]
- Avoid matrix-vector product by sampling entries of \( A \)
- Weighted sampling with an artificial Markov chain can be used to construct implicitly a projection

Overall Characteristics:
- Need only low-order calculation
- Equation/mapping approximation-based LS algorithms applicable
- Error bounds analogous to those in ADP, if e.g., \( \Pi T \) is a contraction
- Multistep methods, such as analogues of TD(\( \lambda \)), are as easy to implement using simulation as the single step method
Single Step Version

Solve the projected equation $x = \Pi T(x)$, i.e.,

$$r = \left( \sum_{i=1}^{n} \xi_i \phi(i) \phi(i)' \right)^{-1} \sum_{i=1}^{n} \xi_i \phi(i) \left( b_i + \sum_{j=1}^{n} a_{ij} \phi(j)' r \right)$$

Sampling Schemes

- generate row and column-index pairs $\{(i_0, j_0), (i_1, j_1), \ldots\}$ independently such that $i_t \sim \xi$, $j_t \sim i_t$-th row of $P$; or
- generate $(i_0, i_1, \ldots)$ using a Markov chain $P$ ($\xi$ need not be known)

Desirable Properties of $P$: $a_{ij} \neq 0 \Rightarrow p_{ij} \neq 0$, no transient states, fast mixing, easy to simulate

Equation Approximation Method (LSTD analogue): solve

$$r_{t+1} = \left( \sum_{k=0}^{t} \phi(i_k) \phi(i_k)' \right)^{-1} \sum_{k=0}^{t} \phi(i_k) \left( b_{i_k} + \frac{a_{i_k j_k}}{p_{i_k j_k}} \phi(j_k)' r_{t+1} \right)$$

Projected Jacobi Method (LSPE analogue)
Constructing Markov Chain and Projection

Generalization of DP

If $\Pi T$ or its damped version is a contraction, then

- Error bound analogous to that in DP is available
- Projected Jacobi method is also applicable

Generalization of Discounted/Undiscounted Cases in DP:

**Proposition**

Assume $|A| \leq P$ for some irreducible $P$, and $\xi$ is such that $\xi' P = \xi'$.

(i) $\Pi T$ is contraction with respect to some norm if $\sum_{i,j} |a_{ij}| < 1$ for some $i$.

(ii) $\Pi((1 - \gamma)I + \gamma T)$, $\gamma \in (0, 1)$ is $\| \cdot \|_{\xi}$-contraction if $(I - \Pi A)$ is invertible.

- Example of $|A| \leq P$: $Cx = d$, $C$ weakly diagonally dominant, i.e, $\sum_{j \neq i} |c_{ij}| \leq |c_{ii}| \neq 0$

- Extend to solving non-linear fixed point equations with certain separable structure and contraction/non-expansive property (such as in optimal stopping problems)
Multistep Versions

Solve projected multistep versions of the fixed point equation

\begin{align*}
x &= \Pi T^l(x), \quad x = \Pi T^{(\lambda)}(x) \\
T^l &= A^l x + \sum_{m=0}^{l-1} A^m b, \quad T^{(\lambda)} = (1 - \lambda) \sum_{k=0}^{\infty} \lambda^k T^{k+1}
\end{align*}

Sampling using a Markov chain gives recursive update formulas

▶ Intuition: \( i^m_0 = (i_0, i_1, \ldots, i_m) \) with \( i_0 = i \); for any vector \( v \), just as

\[ E\{ v(i_m) | i_0 = i \} = (P^m v)(i), \quad E\{ w_m(i^m_0) v(i_m) | i_0 = i \} = (A^m v)(i) \]

where \( w_m(i^m_0) \) is a properly defined weight

\[ w_m(i^m_0) = \frac{a_{i_0 i_1} a_{i_1 i_2} \ldots a_{i_{m-1} i_m}}{p_{i_0 i_1} p_{i_1 i_2} \ldots p_{i_{m-1} i_m}}. \]

Implementation is as easy as in the single step case, because of the product structure of \( w_m \).
Example: Multistep Algorithm Analogous to TD($\lambda$)

Assume $(I - A)$ invertible and $\sigma(A) \leq 1$; solve

$$x = \Pi T^{(\lambda)}(x), \quad \lambda \in (0, 1)$$

- $\Pi T^{(\lambda)}$ is contraction for $\lambda$ sufficiently close to 1 for all $\Pi$
- Solution of projected equation approaches $\Pi x^*$ as $\lambda \rightarrow 1$; however, $\lambda$ affects the variance as in DP

Update formulas resulting from using temporal difference expressions:

**LSPE:** $r_{t+1} = r_t + \gamma B_t^{-1}(C_t r_t + h_t), \quad \text{LSTD: } \tilde{r}_{t+1} = -C_t^{-1} h_t$

$$B_t = B_{t-1} + \phi(i_t)\phi(i_t)^{\prime}, \quad C_t = C_{t-1} + z_t \left( \frac{a_{i_t i_{t+1}}}{p_{i_t i_{t+1}}} \phi(i_{t+1}) - \phi(i_t) \right)^{\prime}$$

$$h_t = h_{t-1} + z_t b_i, \quad z_t = \lambda \frac{a_{i_{t-1} i_t}}{p_{i_{t-1} i_t}} z_{t-1} + \phi(i_t)$$

- DP is a special case with $a_{i_t i_{t+1}}/p_{i_t i_{t+1}} = \alpha, \alpha \in (0, 1]$
- Analogue of recursive TD is also applicable
Generating Basis/Feature by Sampling

Consider using basis functions of the form

$$B^m g$$

- Reminiscent of Krylov subspace methods
- In the context of DP, $B^m g$ can be the finite-stage costs of some base policy

Implementation:
- For the simulation-based algorithms, one unbiased sample of $\phi(i)$ is sufficient
- So we only need to use an additional sampling procedure, independent of the one that generates $(i_0, i_1, \ldots, i_t, \ldots)$, to generate an unbiased estimate of $(B^m g)(i_t)$
Questions and Discussion

- Non-linear fixed point equations
to what extent the mapping approximation approach can be applied

- Linear equations
in the context of applications, how does the proposed method compare with commonly used numerical methods

- Approximate dynamic programming
methods of basis selection and exploration
