## WTP to Avoid A Catastrophe that Can Occur Only Once

If nothing is done to avert a catastrophic event that can occur only once, and reduces consumption by a random fraction  $\phi$  if it occurs, welfare is

$$V_0 = \mathbb{E} \int_0^\infty \frac{1}{1-\eta} C_t^{1-\eta} e^{-\delta t} dt = \frac{1}{1-\eta} \mathbb{E} \left[ \int_0^\tau e^{-\rho t} dt + \int_\tau^\infty e^{-\phi(1-\eta)-\rho t} dt \right] ,$$

where  $\mathbb{E}$  denotes the expectation over  $\tau$  and  $\phi$ . As before, WTP is defined as the maximum percentage of consumption, now and throughout the future, that society would give up to eliminate the possibility of the catastrophe. Define  $\rho \equiv \delta + g(\eta - 1)$ . If society gives up a fraction w of consumption to avert this catastrophe, net welfare is

$$V_1 = (1-w)^{1-\eta} \int_0^\infty \frac{1}{1-\eta} e^{-\rho t} dt.$$

WTP is then the value  $w^*$  that equates  $V_0$  and  $V_1$ .

To obtain the WTP for eliminating the event, note that welfare if no action is taken is:

$$V_{0} = \frac{1}{1-\eta} \mathbb{E} \left[ \int_{0}^{T} e^{-\rho t} dt + e^{-\phi(1-\eta)} \int_{T}^{\infty} e^{-\rho t} dt \right]$$
  
$$= \frac{1}{\rho(1-\eta)} \mathbb{E} \left[ 1 + e^{-\rho T} (e^{-\phi(1-\eta)} - 1) \right]$$
  
$$= \frac{1}{\rho(1-\eta)} \left[ 1 + \frac{\lambda}{\lambda+\rho} \left( \mathbb{E} e^{-\phi(1-\eta)} - 1 \right) \right]$$
  
$$= \frac{1}{\rho(1-\eta)} \left[ 1 + \frac{\lambda}{\lambda+\rho} \frac{\eta-1}{\beta-\eta+1} \right]$$
(1)

Here we have used the assumption that  $z = e^{-\phi}$  follows a power distribution. If the event is eliminated, welfare net of the fraction w of consumption sacrificed is

$$V_1 = \frac{(1-w)^{1-\eta}}{\rho(1-\eta)}$$
(2)

Comparing (1) and (2), the WTP to eliminate the event is:

$$w^* = 1 - \left[1 + \frac{\lambda}{\lambda + \rho} \frac{\eta - 1}{\beta - \eta + 1}\right]^{\frac{1}{1 - \eta}}$$

From this equation, we see that (i)  $w^*$  is an increasing function of the mean arrival rate  $\lambda$ ; (ii)  $w^*$  is an increasing function of the expected impact  $\mathbb{E}(\phi)$ , and thus a decreasing function of the distribution parameter  $\beta$ ; and (iii)  $w^*$  is a decreasing function of both the rate of time preference  $\delta$  and the growth rate g. We would expect  $w^*$  to be higher for an event that is expected to occur sooner and have a larger expected impact, and lower if either the rate of time preference or the consumption growth rate is higher. The dependence on  $\eta$  is ambiguous. Given the growth rate g, a higher value of  $\eta$  implies a lower marginal utility of future consumption, and thus a lower WTP to avoid a drop in consumption. On the other hand it also implies a greater sensitivity to uncertainty over future consumption.

As mentioned above, for expected utility to be finite, we need  $\beta > \eta - 1$ . It is easy to see that as  $\eta$  is increased,  $w^*$  approaches 1 as  $\eta$  approaches  $\beta + 1$ . The reason is that the risk-adjusted remaining fraction of consumption is  $\mathbb{E}((1-\phi)^{1-\eta}) = \beta/(\beta - \eta + 1)$ . In risk-adjusted terms, the possibility of a high- $\phi$  outcome weighs heavily on expected future welfare, and thus on the WTP.

A few numbers: Suppose  $\beta = 2$  so the expected loss is  $\mathbb{E} \phi = .33$ ,  $\lambda = .05$  so the expected arrival time is  $\mathbb{E} T = 1/\lambda = 20$  years,  $\delta = g = .02$ , and  $\eta = 2$ . Then  $w^* = 0.22$ . If instead  $\delta = 0$ , then  $w^* = 0.26$ . If  $\delta = .02$  but we increase  $\eta$  to 2.5,  $w^*$  increases sharply, to 0.60.

It is useful to compare the WTP to avoid this "once-only" event with the WTP when the event can occur multiple times. As shown in Martin and Pindyck (2015), in the latter case the WTP is

$$w_m^* = 1 - \left[1 - \frac{\lambda(\eta - 1)}{\rho(\beta - \eta + 1)}\right]^{\frac{1}{\eta - 1}}.$$

(The subscript *m* is added to emphasize that the event can occur multiple times.) Whether the event can occur only once or repeatedly: (i)  $w^*$  is increasing in the mean arrival rate  $\lambda$ ; (ii)  $w^*$  is increasing in the expected impact  $\mathbb{E}(1 - \phi)$ , and thus a decreasing function of the distribution parameter  $\beta$ ; and (iii)  $w^*$  is a decreasing function of both the rate of time preference  $\delta$  and the growth rate g. And as expected,  $w_m^* > w^*$  for all  $\eta > 1, \beta > \eta - 1, \lambda > 0$ . Some comparisons: (1) If  $\eta = 2, g = \delta = .02$  so  $\rho = .04, \lambda = .02$  and  $\beta = 3$  (so  $\mathbb{E}(1-\phi) = .75$ ), then  $w^* = .143$  and  $w_m^* = .250$ . (2) If instead  $\lambda = .04$ , then  $w^* = .200$  and  $w_m^* = .500$ . (3) If  $\lambda = .04$  but  $\beta = 2.1$ , then  $w^* = .313$  and  $w_m^* = .910$ . In the last example,  $\beta$  is just above the limit (2.0) at which expected utility becomes unbounded.
