The approximability and integrality gap of interval stabbing and independence problems

Abstract

Motivated by problems such as rectangle stabbing in the plane, we study the minimum hitting set and maximum independent set problems for families of $d$-intervals and $d$-union-intervals. We obtain the following: (1) constructions yielding asymptotically tight lower bounds on the integrality gaps of the associated natural linear programming relaxations; (2) an LP-relative $d$-approximation for the hitting set problem on $d$-intervals; (3) a proof that the approximation ratios for independent set on families of 2-intervals and 2-union-intervals can be improved to match tight duality gap lower bounds obtained via topological arguments, if one has access to an oracle for a PPAD-complete problem related to finding Borsuk-Ulam fixed-points.

1 Introduction

In this work, we examine a family of NP-hard packing and covering problems. Our study is motivated by the minimum rectangle stabbing problem, in which we are given a family $\mathcal{H}$ of axis-aligned rectangles in the plane, and the goal is to find a minimum-cardinality family of horizontal and vertical lines that intersect (or ‘stab’) each rectangle in $\mathcal{H}$ at least once. Viewing this as a geometric covering problem, we also consider the related ‘dual’ geometric packing problem of finding a maximum conflict-free subset, where the goal is to find a maximum subset of $\mathcal{H}$ containing no pair of rectangles that can be stabbed by a single horizontal or vertical line.

The rectangle stabbing and conflict-free subset problems have many applications. The rectangles themselves can be the bounding boxes of arbitrary connected objects in the plane, so applications need not be limited to problems involving rectangles. The rectangle stabbing problem can directly encode the problem of optimally subdividing the plane into a grid of axis-aligned cells so as to separate a given family of points, with applications to fault-tolerant sensor networks [3] and resource allocation in parallel processing systems [7]. The maximum conflict-free subset problem, and its higher dimensional analogues, are relevant to areas such as resource allocation, scheduling, and computational biology [2]. The properties of certain rectangle stabbing instances are also of theoretical interest in combinatorics [19].

Given a family $\mathcal{H}$ of axis-aligned rectangles, we write $\rho(\mathcal{H})$ for the minimum cardinality of a family of lines stabbing it, and $\alpha(\mathcal{H})$ for the maximum size of a conflict-free subset. It is clear that $\alpha(\mathcal{H}) \leq \rho(\mathcal{H})$. As in many geometric packing-covering dual problems, there is a bound in the other direction. In 1994, Tardos proved that $\rho(\mathcal{H}) \leq 2\alpha(\mathcal{H})$, which is easily seen to be tight [18]. However, all known proofs of Tardos’s result rely on topological fixed-point theorems, and consequently do not seem to lead to polynomial-time approximations. In fact, only a 4-approximation is known for the maximum conflict-free subset problem [2], despite the fact that we can establish the optimal objective value to within a factor of 2 by solving a linear program. Improving upon this remains an important open problem.

In this paper, we obtain results for generalized versions of the stabbing and conflict-free subset problems. We examine the standard linear programming relaxations for hitting set and independent set problems involving $d$-intervals, and establish asymptotically tight upper and lower bounds on their integrality gaps. These bounds imply that no LP-relative approximation algorithm can obtain a factor below 2 for either the rectangle stabbing or the maximum conflict-free subset problems. Additionally, we establish some interesting theoretical consequences of topological methods such as Tardos’s. For example, we show that the maximum conflict-free subset problem admits a 2-approximation if one has access to an oracle for a PPAD-complete problem.

This article proceeds as follows: in the current section, we define the generalized problems that we study, explain the current state of the art, and describe our contribution. Section 2 contains our integrality gap upper and lower bounds, and Section 3 contains algorithmic results that depend on PPAD oracles.

1.1 Preliminaries

We begin by defining generalized versions of the rectangle stabbing and conflict-free subset problems. For $d \in \mathbb{N}$, a $d$-interval $I$ is a union of $d$ non-empty com-
pact intervals $I^1, \ldots, I^d \subset \mathbb{R}$. The input to all problems we consider will be a finite collection $H$ of $d$-intervals, represented explicitly. We say that a subset of $H$ is independent if its members are pairwise disjoint, and a set $X \subseteq \mathbb{R}$ is a hitting set for $H$ if it intersects every member of $H$. We define the hypergraph $G_H = (V, E)$ where $V = H$ and $E$ consists of all subsets $I \subseteq H$ such that there is a point $p \in \mathbb{R}$ that hits exactly the intervals in $I$. Such a point $p$ shall be called a representative of the hyperedge $I \in E$, and we let $P(H)$ denote a set containing an arbitrary representative for each distinct edge in $G_H$. Note that $|P(H)| \leq 2d|H|$ as there are at most $2d|H|$ interval endpoints. We call $G_H$ a $d$-interval hypergraph, and observe that $d$-interval hypergraphs generalize $d$-regular hypergraphs (which are obtained when each $d$-interval in $H$ is simply $d$ points).

We denote by $\alpha(H)$ the maximum size of an independent set in $H$, and denote by $\rho(H)$ the minimum size of a hitting set for $H$, in analogy with the usual notation of $\alpha(G)$ and $\rho(G)$ for the maximum independent set size and minimum edge cover size of a hypergraph $G$.

Special cases such as the rectangle stabbing problem arise when we impose structural restrictions on $H$. If $\{J_i\}_{i=1}^d$ is a family of disjoint intervals and each $d$-interval $I = \cup_{i=1}^d J_i$ in $H$ satisfies $J_i \subseteq J_i$ for all $i$, then $H$ is known as a collection of $d$-union-intervals, and $G_H$ is known as a $d$-union hypergraph. The term $d$-track-interval is sometimes used for the same concept, with the idea that each $d$-interval contains a piece from one of $d$ different ‘tracks’, each of which is a disjoint copy of $\mathbb{R}$. The rectangle stabbing and minimum conflict-free subset problems correspond precisely to the minimum hitting set and maximum independent set problems on 2-union-intervals, but with each ‘track’ mapped onto a separate Euclidean dimension. In general, one can think of the hitting set problem for $d$-union-intervals as the problem of hitting a family of $d$-dimensional ‘boxes’ using a minimum number of ‘walls’, each of which is orthogonal to one of the coordinate axes.

For 1-interval hypergraphs (which are the same as 1-union hypergraphs), the independent set and edge cover problems can both be solved in polynomial time via simple greedy algorithms that perform a left-to-right sweep across the intervals. However, for 2-union hypergraphs, the independent set and edge cover problems are both APX-hard. Nagashima and Yamazaki, and independently Bar-Yehuda et al., have shown the conflict-free subset problem to be APX-hard [2, 14], even when the rectangles are all unit squares with integer vertices. Kovaleva and Spieksma show that the rectangle stabbing problem is APX-hard even when each rectangle is of the form $[x, x+1] \times [y, y]$ for integers $x$ and $y$ [11].

For a hypergraph $G$, the relations $\alpha(G) \leq \rho(G)$ and $\rho(G) \leq O(\log |V|) \cdot \alpha(G)$ are well known, with the latter being tight for general hypergraphs. However, using methods of topological combinatorics, Kaiser proves that $\frac{\rho(G)}{\alpha(G)}$ is upper bounded by $d^2 - d + 1$ for $d$-interval hypergraphs and $d^2 - d$ for $d$-union hypergraphs (for $d \geq 2$), a bound independent of $|V|$ [10]. His result improves upon that of Tardos, who originally established a tight upper bound for the $d = 2$ case [18]. In a one-page paper, Alon shows that an upper bound of $2d^2$ can be established without topological methods by applying Turán’s theorem [1]. The best known lower bounds for large $d$ are $\Omega(\frac{d^2}{\log d})$ and $\Omega(\frac{d^2}{\log^2 d})$ for $d$-interval and $d$-union hypergraphs respectively [13].

### 1.2 Overview of Results

We use the term duality gap to denote the quantity $\rho(H)/\alpha(H)$, where $H$ ranges over a collection of $d$-intervals. In an effort to study various duality gaps, we examine standard linear programming relaxations for the hitting set and independent set problems. The standard LP relaxation for the maximum independent set problem corresponds to the maximum fractional independent set problem, and can be written as follows:

\[
\begin{align*}
\max & \sum_{I \in \mathcal{P}} x_I \\
\text{s.t.} & \sum_{I \ni p} x_I \leq 1 \quad \forall p \in P(H) \\
& x_I \geq 0 \quad \forall I \in H
\end{align*}
\]

A corresponding dual linear program for the minimum fractional hitting set problem is as follows:

\[
\begin{align*}
\min & \sum_{p \in P(H)} y_p \\
\text{s.t.} & \sum_{I \ni p} y_p \geq 1 \quad \forall I \in H \\
& y_p \geq 0 \quad \forall p \in P(H)
\end{align*}
\]

If $\alpha^*(H)$ is the optimal objective value for (1) and $\rho^*(H)$ is the optimal objective value for (2), then we have $\alpha(H) \leq \alpha^*(H) = \rho^*(H) \leq \rho(H)$ and can write

\[
\sup_{H} \frac{\rho(H)}{\alpha(H)} \leq \sup_{H} \frac{\rho(H)}{\rho^*(H)} \cdot \sup_{H} \frac{\alpha^*(H)}{\alpha(H)}.
\]

The quantity $\sup_H \frac{\rho(H)}{\alpha(H)}$ is called the integrality gap of the minimum hitting set problem (for $d$-intervals or $d$-union-intervals). Similarly, $\sup_H \frac{\alpha^*(H)}{\rho^*(H)}$ is the integrality gap of the maximum independent set problem. Since $\rho^*(H)$ and $\alpha^*(H)$ are always at least 1, both integrality gaps are a lower bound on the duality gap. For the case of 1-intervals, we actually have $\alpha(H) = \rho(H)$; both linear programs have an integrality gap of 1 because the incidence matrix of $G_H$ exhibits the consecutive ones property and is thus totally unimodular.
Often, upper bounds on integrality gaps for packing and covering problems come alongside LP-relative approximation algorithms. Bar-Yehuda et al. employ the local ratio technique to obtain a polynomial-time LP-relative 2d-approximation algorithm for the d-interval maximum independent set problem, proving that the integrality gap of maximum independent set for d-intervals is at most 2d. Their result carries over to the version in which each element in $H$ has a positive weight and a maximum weight independent set is desired. In Section 2, we show that their bound is tight up to an additive constant by establishing the following:

**Theorem 1** For any $\varepsilon > 0$, there exists a collection $H$ of d-intervals (respectively, d-union-intervals) for which $\frac{\alpha(H)}{\rho(H)} \geq 2d - 1 - \varepsilon$ (respectively, $2d - 2 - \varepsilon$).

For both the d-interval and d-union-interval hitting set problems, we are able to prove that the integrality gap is exactly $d$. We show the following:

**Theorem 2** There exists a polynomial-time LP-relative d-approximation for the d-interval hitting set problem. Accordingly, for any collection $H$ of d-intervals, $\frac{\rho(H)}{\rho(H)} \leq d$.

**Theorem 3** For any $\varepsilon > 0$, there exists a collection $H$ of d-union-intervals for which $\frac{\rho(H)}{\rho(H)} \geq d - \varepsilon$.

Theorem 2 uses standard techniques to generalize a 2-approximation algorithm for rectangle stabbing due to [7], but Theorem 3 employs a novel construction.

The table below summarizes the known integrality and duality gap bounds for large $d$:

<table>
<thead>
<tr>
<th>d-Interval</th>
<th>Lower Bound</th>
<th>Upper Bound</th>
</tr>
</thead>
<tbody>
<tr>

We note that for $d = 2$, Kaiser’s topology-based duality gap upper bounds of $d^2 - d + 1$ and $d^2 - d$ match our independent set integrality gap lower bounds of $2d - 1$ and $2d - 2$, but are tighter than the constructive integrality gap upper bounds of $2d$ due to Bar-Yehuda et al. Hence, despite knowing that $\frac{\rho(H)}{\alpha(H)}$ is bounded above by 3 and 2 for families of 2-intervals and 2-union-intervals respectively, no polynomial-time approximation factor below 4 is known for the maximum independent set problem on 2-union-intervals. We observe, however, that Kaiser’s proof can be turned into a 2-approximation if one has access to an oracle to solve the topological subproblems that arise. The particular topological problems in question are closely related to finding Borsuk-Ulam fixed-points. Unfortunately, the problem of finding Borsuk-Ulam fixed-points is PPAD-complete [15] and thus unlikely to admit polynomial algorithms unless a major breakthrough occurs. Nevertheless, we establish the following in Section 3:

**Theorem 4** There exists an algorithm for the maximum independent set problem on 2-intervals (respectively, 2-union-intervals) returning a solution of size at least $\frac{\alpha(H)}{3}$ (respectively $\frac{\alpha(H)}{2}$), requiring $O(\log(\alpha(H)))$ calls to an oracle for a PPAD-complete fixed-point problem, and polynomial time for all other computations.

Despite the fact that Theorem 4 is likely not of practical value, we find it interesting because it implies that the 2-dimensional maximum conflict-free subset problem is a natural APX-hard geometric optimization problem whose best known approximability appears to improve in the presence of a PPAD oracle. It remains an open problem to find an alternative method of achieving the approximation ratios of Theorem 4 while bypassing the need for a PPAD oracle (of course, this may very well be impossible, but proving so would separate P from PPAD, resolving a longstanding open problem).

### 1.3 Related Work

Many variations and special cases of d-interval stabbing and independence problems have been studied in a variety of contexts. Kovalena and Spieksma have examined the special case of the rectangle stabbing problem in which each rectangle is a horizontal line segment [11, 12]. They obtain an LP-relative $\frac{\alpha(H)}{\rho(H)}$-approximation for this case, alongside an example showing that the integrality gap is precisely $\frac{\alpha(H)}{\rho(H)}$.

Even et al. explore weighted and capacitated variations of d-union-interval hitting set [6]. Their results include a 3d-approximation for a variant in which each point may only be used to hit a specified number of d-intervals, but may be purchased multiple times.

Spieksma considers the version of maximum d-interval independent set where the goal is to select a single interval from each d-interval such that none intersect [17]. It is shown that a straightforward greedy procedure yields a 2-approximation.

Some additional hardness results are also known. Even et al. show that there is a constant $c > 0$ such that it is NP-hard to approximate the d-interval hitting set problem to within $c \log d$ [6]. Dom et al. show that rectangle stabbing is $W[1]$-hard, even when the input consists of squares of the same size, implying that the problem is unlikely to be fixed-parameter tractable in the optimal objective value $\rho(H)$ [4].
2 Integrality Gap Bounds

To prove Theorem 1 and establish tight lower bounds on the integrality gap of the independent set problem, we rely on an amplification lemma. We shall refer to the $d$ individual intervals composing a $d$-interval as its pieces, and call a piece inert if it is a point. We shall call $H$ a clique if $a(H) = 1$, and write $r(H)$ for the rank of $G_H$—the maximum number of $d$-intervals intersected by any point in $\mathbb{R}$. We observe that if $H$ is a clique and $r(H) = p$, then a fractional independent set of value $\frac{|H|}{2^p}$ can be obtained by simply putting weight $\frac{1}{p}$ on each $d$-interval in $H$. In some situations, we can do better:

**Lemma 5** Suppose that $H$ is a clique, and that $H$ contains no two inert pieces that intersect and no $d$-intervals consisting entirely of inert pieces. Furthermore, suppose that $r(H^*) = q$, where $H^*$ is a modified version of $H$ obtained by deleting all inert pieces. Then for any $N \in \mathbb{N}$, there is a clique $H'$ of $d$-intervals admitting a fractional independent set of value $\frac{N|H|}{N^q+1}$.

**Proof.** We construct $H'$ by making $N$ copies of each $d$-interval in $H$, and then perturbing all inert pieces in the resulting family of $d$-intervals such that no two inert pieces intersect, while preserving intersections of inert pieces with non-inert pieces. It is immediate that $H'$ is still a clique; note that copies of the same $d$-interval in $H$ must intersect in $H'$ because no $d$-interval consists entirely of inert pieces. Moreover, $r(H') \leq Nq + 1$, so we can place a weight of $\frac{1}{N^q+1}$ on each $d$-interval in $H'$, yielding a fractional independent set of value $\frac{N|H|}{N^q+1}$. □

By taking the limit as $N \to \infty$, Lemma 5 yields an integrality gap lower bound of $\frac{|H|}{q}$ given a $d$-interval graph satisfying the necessary requirements. We note that the amplification in Lemma 5 also works for $d$-union-intervals. We proceed with the proof of Theorem 1:

**Proof of Theorem 1.** For the case of $d$-interval graphs, we exhibit a clique $H$ satisfying the conditions of Lemma 5 with $|H| = 2d - 1$ and $q = 1$. We label the $d$-intervals $\{a_0, a_1, \ldots, a_{2d-3}\}$. Each $d$-interval will have exactly one non-inert piece (a closed interval in $\mathbb{R}$) and $d-1$ inert pieces. We position the non-inert pieces such that no two intersect, ensuring that $q = 1$. Then for all $0 \leq i \leq 2d - 2$, we position the remaining $d-1$ inert pieces of $a_i$ (each of which is a point) on the non-inert pieces of $d$-intervals $\{a_{i+1}, \ldots, a_{i+(d-1)}\}$, where the addition is modulo $2d - 1$. This ensures that an inert piece of $a_i$ intersects non-inert pieces in $\{a_{i+1}, \ldots, a_{i+(d-1)}\}$, hence ensuring that inert pieces of $\{a_{i-1}, \ldots, a_{i-(d-1)}\}$ all intersect the non-inert piece of interval $a_i$. This proves that the construction yields a clique, from which it follows that the independent set problem in $d$-interval graphs has an integrality gap of $\frac{|H|}{q} = 2d - 1$. An example of the construction for $d = 3$ is shown (intervals are vertically separated for clarity):

\[
\begin{array}{cccccc}
\cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\
\cdot & a_0 & a_1 & a_2 & a_3 & a_4 \\
\cdot & a_0 & a_1 & a_2 & a_3 & a_4 \\
\cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\
\end{array}
\]

For the case of $d$-union-intervals, we exhibit a clique $H$ of size $4d - 4$ satisfying the conditions of Lemma 5 with $q = 2$. This yields an integrality gap $\frac{|H|}{q} = 2d - 2$.

We label the $4d - 4$ $d$-union-intervals by $\{a_1, a_2, a_3, a_4\}^{d-1}$. We shall say that each interval has its $k$th piece in the $k$th track, where each track is a copy of $\mathbb{R}$. We first explain what happens in tracks 1 through $d - 1$, and then explain what happens in the final track, which is treated differently. For $1 \leq i \leq d - 1$, all of the pieces in track $i$ are inert (single points) except for the $i$th pieces of $a_1, a_2, a_3,$ and $a_4$, which are arranged as follows:

\[
\begin{array}{cccc}
\cdot & \cdot & \cdot & \cdot \\
a_1 & a_2 & a_3 & a_4 \\
\cdot & \cdot & \cdot & \cdot \\
\end{array}
\]

Now, for all $j \neq i$, the $i$th pieces of $\{a_1, a_2, a_3, a_4\}$ are positioned according to the following rules:

- If $j < i$, put $a_1, a_2$ in $a_1 \cap a_2$; put $a_3, a_4$ in $a_3 \cap a_4$
- If $j > i$, put $a_3, a_4$ in $a_1 \cap a_2$; put $a_1, a_2$ in $a_3 \cap a_4$

In the last track $d$, none of the intervals need to be inert. For all $1 \leq i \leq d - 1$, the $d$th pieces of $\{a_1, a_2, a_3, a_4\}$ are positioned similarly to the diagram above, but are permuted to induce the remaining three dependencies among the $d$-intervals. Figure 1 illustrates this and provides an example of the entire construction for $d = 4$.

Observe that any two $d$-union-intervals with the same superscript $i$ must be adjacent in either track $i$ or track $d$. For $1 \leq i < j \leq d - 1$, we check that all 16 dependencies between $a_1, a_2, a_3, a_4$ and $a_1, a_2, a_3, a_4$ are accounted for: In track $i$, $a_3$ and $a_4$ intersect $a_1 \cap a_2$; $a_1$ and $a_2$ intersect $a_3 \cap a_4$. In track $j$, $a_1$ and $a_2$ intersect $a_1 \cap a_2$; $a_3$ and $a_4$ intersect $a_3 \cap a_4$. Thus $H$ is a clique. It is easy to verify that the other conditions of Lemma 5 are satisfied with $q = 2$, so the proof is complete. □

Next, we provide a polynomial algorithm yielding an upper bound of $d$ for the integrality gap of the general $d$-interval hitting set problem:

**Proof of Theorem 2.** Let $H$ be a collection of $d$-intervals, and let $\{y_p^*: p \in P(H)\}$ be an optimal fractional hitting set of weight $\rho^*(H)$ obtained by solving linear program (2). We demonstrate how to round $\{y_p^*\}$ to an integral solution of weight at most $d \cdot \rho^*(H)$. For a $d$-interval $I$ in $H$, let $I^* \subseteq I$ be any piece of $I$ that is hit by weight at least $\frac{1}{2}$ under $\{y_p^*\}$ (one must exist by the
pigeonhole principle). Then the set $C = \{ I^* : I \in \mathcal{H} \}$ is a set of intervals in $\mathbb{R}$ that are each hit by weight at least $\frac{1}{2}$ under $\{y_p^*\}$.

By multiplying solution $\{y_p^*\}$ by $d$, we obtain a new fractional hitting set $\{dy_p^*\}$ of weight $\rho^*(\mathcal{H})$ that hits, with weight at least 1, all elements of $C$. However, the incidence matrix for the hitting set problem on 1-intervals is totally unimodular, so there must exist an integral hitting set $Q$ of weight at most $d \rho^*(\mathcal{H})$ that hits all of $C$—one can be found by simply solving linear program (2) again for $C$ instead of $\mathcal{H}$. Of course, $Q$ is also a hitting set for $\mathcal{H}$, from which it follows that $\rho(\mathcal{H}) \leq d \cdot \rho^*(\mathcal{H})$. By simply returning $Q$, we obtain a polynomial-time LP-relative $d$-approximation for the $d$-interval hitting set problem, completing the proof. $\Box$

We note that the above algorithm also works for the weighted variant of the minimum hitting set problem, in which each point $p \in P(\mathcal{H})$ is given a positive cost, and the goal is to compute a minimum cost hitting set.

Finally, we establish Theorem 3 by giving a set of $d$-union-intervals with a hitting set integrality gap of $d-\epsilon$:

**Proof of Theorem 3.** Fix $\epsilon > 0$. Choose any integer $t \geq \frac{2d^2}{\epsilon}$ and any integer $n \geq 2t$. Fix some small $\delta$, say $\delta = 0.1$. Here, we regard the $d$ tracks $\{J^1, \ldots, J^d\}$ as disjoint copies of $A$. A $d$-union-interval $I$ is called aligned if, for all $1 \leq k \leq d$, the piece of $I$ in $J^k$ has the form $[i_k + \delta, j_k - \delta]$ for some integers $0 \leq i_k < j_k \leq n$. In other words, a $d$-union-interval is aligned if the endpoints of all of its pieces each barely miss an integer point between 0 and $n$. Let $\mathcal{H}$ be the collection of all aligned $d$-union-intervals $I$ such that the total length of all pieces in $I$ is exactly $t - 2d\delta$. Note that $|\mathcal{H}|$ is finite.

Let $P$ contain all points of the form $i + 0.5$ for $i \in \{0, 1, \ldots, n-1\}$ in each of the $d$ tracks, for a total of $dn$ points. Each $d$-union-interval in $\mathcal{H}$ must contain at least $t$ points in $P$, so we can obtain a fractional hitting set of total weight $\frac{dn}{t}$ by placing a value of $\frac{1}{t}$ at each point in $P$. This shows that $\rho^*(\mathcal{H}) \leq \frac{dn}{t}$.

Let $Q$ be any feasible integral hitting set for $\mathcal{H}$. We wish to show that $\frac{|Q|}{\rho^*(\mathcal{H})} \geq d - \epsilon$, so we may assume that $|Q| < n$. Let $b_i$ be the number of points of $Q$ in $J^i$. By the pigeonhole principle, there must exist an open interval $K^i \subseteq [0, n]$ in track $J^i$ that has integer endpoints, has length at least $\frac{n-b_i}{n+t}$, and contains no points in $Q$. Consequently, there is a $d$-union-interval $K = \cup_{i=1}^d K^i$ having total length $\sum_{i=1}^d \frac{n-b_i}{n+t}$ that has integer endpoints and is missed by $Q$ in all tracks. However, $Q$ hits all aligned $d$-union-intervals having total length $t - 2d\delta$, and $K$ is missed by $Q$, so we must have

$$\sum_{i=1}^d \frac{n-b_i}{b_i+1} < t.$$ 

By rearranging this, we obtain

$$d\left(\frac{\sum_{i=1}^d \frac{1}{b_i+1}}{t}\right)^{-1} > \frac{dn}{t+d}.$$

The left side of the above equation is a harmonic mean. Since an arithmetic mean is always greater than or equal to the corresponding harmonic mean, we get

$$\frac{1}{d} \sum_{i=1}^d (b_i + 1) > \frac{dn}{t+d},$$

and hence $\rho(\mathcal{H}) > \frac{t(n+1)}{n(t+d)} - \frac{t}{n} > \left(1 - \frac{d}{t+d}\right)d - \frac{t}{n}$, where the last inequality is due to $\frac{n+1}{n} > 1$. Since we chose $t$ and $n$ such that $t \geq \frac{2d^2}{\epsilon}$ and $n \geq \frac{2t}{\epsilon}$, we get

$$\rho(\mathcal{H}) > \left(1 - \frac{d}{t+\frac{d}{\epsilon}} + \frac{d}{\epsilon}\right)d - \frac{t}{\epsilon} = d - \epsilon > d - \epsilon,$$

completing the proof of Theorem 2. $\Box$

## 3 Topology-based algorithms

In this section, we sketch a proof of Theorem 4, illustrating how to obtain a 3-approximation (respectively, a 2-approximation) for the independent set problem on 2-intervals (respectively, 2-union-intervals), supposing one has access to oracles for PPAD-complete topological subproblems. We assume familiarity with the complexity class PPAD and its connection to topological fixed-point theorems; see [15] for background information.

Our approach follows Kaiser's duality gap upper bound proof [10], which we outline here. We first consider the case of 2-union-intervals. For concreteness, we consider a family $\mathcal{H}$ of axis-aligned rectangles in the plane. Let $n$ be an arbitrary positive integer. Kaiser considers the space $S^n \times S^n$ (where $S^n$ is the boundary of an $(n+1)$-dimensional unit ball), and associates each
point \( x \in S^n \times S^n \) to a set of \( n \) horizontal lines and \( n \) vertical lines in the plane. Kaiser then constructs a family of \( 2n + 2 \) real-valued functions \( h_1^\mathcal{H}, \ldots, h_{2n+2}^\mathcal{H} \) on \( S^n \times S^n \) having the following properties:

1. If \( h_i^\mathcal{H}(x) = 0 \) for all \( i \), then \( x \) corresponds to a set of lines that intersect all rectangles in \( \mathcal{H} \).

2. If \( h_1^\mathcal{H}(x) = h_2^\mathcal{H}(x) = \ldots = h_{2n+2}^\mathcal{H}(x) \neq 0 \) for all \( i \), then \( x \) corresponds to a set of \( n \) horizontal lines and \( n \) vertical lines defining a grid from which we can easily find a conflict-free set of rectangles of size \( n + 1 \) in polynomial time.

Kaiser then establishes that, for topological reasons, there must exist a point \( x \in S^n \times S^n \) such that \( h_1^\mathcal{H}(x) = h_2^\mathcal{H}(x) = \ldots = h_{2n+2}^\mathcal{H}(x) \neq 0 \) and thus \( x \) must exist satisfying item 1 or item 2 above. Tar- dos’s result that \( \rho(\mathcal{H}) \leq 2n(\mathcal{H}) \) follows immediately by setting \( n = \alpha(\mathcal{H}) \), since then a point where \( h_i^\mathcal{H}(x) \neq 0 \) for all \( i \) cannot exist, and thus a stabbing consisting of \( \alpha(\mathcal{H}) \) horizontal lines and \( \alpha(\mathcal{H}) \) vertical lines must exist.

Kaiser’s proof can easily be adapted to yield a procedure \( \mathcal{P} \) that, given an integer \( n \), finds either a stabbing of size \( 2n \) or a conflict-free subset of size \( n + 1 \), using polynomial time plus a single call to an oracle for a topological fixed-point problem. To obtain a 2-approximation for the maximum conflict-free subset problem, it then suffices to find a cutoff point \( t \in \mathbb{N} \) such that \( \mathcal{P} \) returns a conflict-free subset \( S \) of size \( t \) when run with \( n = t - 1 \), but returns a stabbing of size \( 2t \) when run with \( n = t \) (if this happens, we have \( |S| \geq \frac{\rho(\mathcal{H})}{2} \geq \frac{\alpha(\mathcal{H})}{2} \)). Although there may be many cutoff points \( t \), one must exist in the interval \([\frac{\alpha(\mathcal{H})}{2}, \alpha(\mathcal{H})]\). One can be found using only \( O(\log(\alpha(\mathcal{H}))) \) calls to \( \mathcal{P} \) by running a galloping binary search that first tries \( t = 1, t = 2, t = 4, \ldots \) until a stabbing of size \( 2t \) is returned, and then binary searches between \( \frac{t}{2} \) and \( t \) to find a cutoff point.

Kaiser’s topological argument employs a result of Ramos that generalizes the Borsuk-Ulam theorem to cross products of spheres [16], so procedure \( \mathcal{P} \) must invoke calls to an oracle for Ramos-style fixed-points. Ramos invokes a parity argument that can be adapted, in a straightforward manner, to show that an appropriate computational version of the Ramos fixed-point problem lies in the complexity class PPAD. Indeed, Ramos provides a searching algorithm to locate such fixed-points, although it may be exponential in the worst case. We also note that, by the discreteness of our problem, the particular instances that we must solve can be efficiently represented and have rational solutions. This establishes Theorem 4 for 2-union-intervals.

For the case of general 2-intervals, Kaiser provides a related argument that can be adapted in the same manner to yield a binary search algorithm. In this case, only an oracle for standard Borsuk-Ulam fixed-points is required. However, due to changes in how the functions \( h_i^\mathcal{H} \) must be formulated, only a 3-approximation can be obtained. Still, the integrality gap bounds imply that this is optimal among all LP-relative approximations.
