

## 4g. Thermal Conductivity

ROBERT L. POWELL AND GREGG E. CHILDS

*Cryogenics Division, NBS Institute for Basic Standards*

---

### Symbols and Units

- $A$  cross-sectional area, meters<sup>2</sup>
- $c_p$  specific heat at constant pressure, joules/kilogram · kelvin
- $c_v$  specific heat at constant volume, joules/kilogram · kelvin
- $J$  heat current density, watts/meter<sup>2</sup>
- $L$  Lorenz ratio  $\equiv \lambda/\sigma T$ , volts<sup>2</sup>/kelvin<sup>2</sup>
- $l$  mean free path, meters

|           |  |
|-----------|--|
| $\bar{M}$ | molecular weight, kilograms/mole                                     |
| $\dot{Q}$ | heat current, watts  |
| $R$       | gas constant per mole, 8.3143 joule/kelvin · mole                    |
| $T$       | temperature, kelvins   |
| $t$       | time, seconds  |
| $v$       | velocity, meters/second  |
| $x$       | space coordinate, meters   |
| $\alpha$  | thermal diffusivity, meters <sup>2</sup> /second                     |
| $\lambda$ | thermal conductivity, watts/meter · kelvin                           |
| $\mu$     | dynamic viscosity, Newton · second/meter <sup>2</sup> , (= 10 poise) |
| $\rho$    | density, kilograms/meter <sup>3</sup>                                |
| $\sigma$  | electrical conductivity, 1/ohm · meter                               |

**4g-1. General Definitions and Units.** The thermal conductivity is a nonequilibrium property usually determined in a steady-state experiment utilizing the Fourier law for linear heat flow in a homogeneous, isotropic substance:

$$\dot{Q} = -\lambda A \frac{dT}{dx}$$

where  $\dot{Q}$  is the thermal energy current,  $A$  is the cross-sectional area,  $dT/dx$  is the temperature gradient, and  $\lambda$  is the thermal conductivity coefficient. Commonly used units and their conversion factors are given in Table 4g-1. For nonisotropic bodies such as some dielectric crystals the basic differential equation is modified to

$$J = -\lambda \text{grad } T$$

where  $J$  is the vector thermal current density, and  $\lambda$  is a symmetric tensor of second order. Heat-conduction equations and their solutions for nonhomogeneous and nonlinear systems are discussed at length by McAdams [38], Schneider [62], and Carslaw and Jaeger [10].

In general, the total heat *transport* is affected by radiation, convection, and conduction mechanisms and may depend on temperature, pressure, density, material, and temperature gradient, etc. However, the coefficient  $\lambda$ , as defined by the above equations, refers only to heat transport by conduction mechanisms. It is usually assumed that the thermal conductivity is not a function of the temperature gradient, but is a function of the temperature, composition, purity, perfection, and other similar intensive parameters of the system. It is also assumed that the conductivity is not size- or shape-dependent, though this is not always true. Size and shape effects become significant whenever the size of the conductor is comparable to the mean free path for motion of the particles (or quasi-particles) that transport the thermal energy. These effects have been observed for conduction by molecules in rarefied gases and for conduction by phonons (quantized normal modes of lattice vibration) in small, high-purity dielectric crystals at low temperatures.

Representative values for the temperature dependence of several substances are given in Fig. 4g-1. They are typical curves for a high-purity metal (copper), high-purity crystalline dielectric (sapphire), nonferrous alloy (aluminum alloy), ferrous alloy (stainless steel), disordered dielectric (glass), fluid (helium), and water.

The Thermophysical Properties Research Center at Purdue University has published a large compilation of thermal conductivity data and graphs over large temperature ranges for many solids and fluids [72]. A general survey of the experimental and theoretical aspects of thermal conductivity is given in the book edited by Tye [73]. Proceedings of the annual conferences on thermal conductivity [71] are usually available from the sponsoring agency; sometimes they are formally published.

FIG. 4g-1. Typical curves showing temperature dependence of thermal conductivity.

A similar coefficient useful in *transient* heat-flow problems is the thermal diffusivity  $\alpha$  defined by

$$\alpha \equiv \frac{\lambda}{\rho c_p}$$

where  $\rho$  is the density, and  $c_p$  is the specific heat at constant pressure. For an isotropic, homogeneous body without local heat sources or sinks, the basic partial differential equation for transient heat conduction is

$$\frac{\partial T}{\partial t} = \alpha \nabla^2 T$$

The more complicated equations and their solutions are discussed by Jakob [29], Schneider [62], and Carslaw and Jaeger [10]. Values of the diffusivity  $\alpha$  are not tabulated, but may be calculated, using conductivity values from this section, densities from Sec. 2b, and specific heats from Sec. 4e.

**4g-2. Heat Transport in Fluids.** In fluids three types of heat transport can occur: radiation, convection, and conduction. Thermal radiation becomes more important as the temperature of a system is increased. For most systems above about 1000 K it becomes a significant contribution to the total heat transfer. Radiative heat

transfer is also significant, however, in low-temperature apparatus if any of the critical components are exposed to room-temperature radiation. Radiative constants are given in Sec. 6g of this Handbook. Convection is particularly important in systems with fluid density inversions, heated vertical surfaces, or forced fluid flow. Convection is not actually a separate mode of heat transfer, but rather a complex combination of fluid conduction, solid-to-fluid boundary conduction, and fluid flow. Therefore it is not surprising that solutions for realistic convective heat-transfer problems are complicated but inexact. The physical parameters entering the equations are complex, for they depend not only on the temperature and pressure but also on the shape, position, material, and roughness of the surfaces; the composition and density of the fluids; and the velocity and the type of fluid flow, whether laminar or turbulent, forced, or free. Convective heat transfer is discussed in detail by McAdams [38]; Bird, Stewart, and Lightfoot [6]; and Rohsenow and Choi [58].

For a dilute gas, the thermal conductivity increases slowly with temperature ( $\sim T^{0.6}$ ), and is in principle independent of density or pressure. A definition of "diluteness" is given by Childs and Hanley [12]. A gas is essentially dilute up to about 10 atm at room temperatures and about 40 atm at 1000 K.

A convenient equation for estimating the thermal conductivity of a dilute monatomic gas is

$$\lambda = \frac{15}{4} \frac{R}{M} \mu$$

where  $R$  is the gas constant,  $M$  the molecular weight, and  $\mu$  the viscosity. For dilute polyatomic gases a correction factor is needed. The simplest is the Eucken formula,

$$\lambda = \frac{15}{4} \frac{R}{M} \mu \left( \frac{3}{5} + \frac{4}{15} \frac{c_v}{R} \right)$$

where  $c_v$  is the specific heat at constant volume. A survey of more sophisticated corrections and of the theories and equations for thermal conductivities of gases is given by Hirschfelder, Curtiss, and Bird [25]. More recent work on dense gas theories is discussed by Sengers [64]. The thermal conductivities for dilute inorganic gases are given in Table 4g-2; for dilute organic gases in Table 4g-3.

Near the critical or condensation region, the thermal conductivity of a fluid is very density- and pressure-dependent, as is shown by the typical set of curves in Fig. 4g-2. Most classical fluids show a similar behavior. Water, however, is an exception. Its conductivity along the liquidus curve above the dome has a broad maximum near 140°C. Green and Sengers [19] review recent work on the anomalous behavior of the thermal conductivity of fluids near the critical point.

The conductivity of a gas is also density and pressure-dependent at high pressures. Data on the effect of pressure on the conductivity of four gases are given in Table 4g-4. Rough estimates for the conductivity of other gases at high pressures can be made, using the principle of corresponding states as explained by Hirschfelder, Curtiss, and Bird [25].

At low pressures where the effective mean free path of the molecule is limited by the dimensions of the container (below about  $10^{-4}$  atm for many systems), heat conduction through a gas is directly proportional to the pressure. Conduction is then not a property of the gas alone, but also depends upon the gas-wall interactions as represented by the accommodation coefficients or temperature discontinuities at the walls. The conductivity values listed in Tables 4g-2 to 4g-4 do not apply under the above conditions. This transport phenomenon at low pressures is called *free-molecule* or *Knudsen gas conduction*. Formulas, discussions, and coefficients for this effect have been given by Kennard [32] and, more recently, by Corruccini [14], von Ubisch [74],

and Devienne [15]. Corruccini also discusses the transition region between free-molecule and regular gas conduction.

The thermal conductivity of classical liquids decreases with increasing temperatures, although water is again an exception. Data for the conductivities of normal liquids near room temperature and at atmospheric pressure are given in Table 4g-5; of cryogenic liquids at saturation pressures in Table 4g-6; and of liquid metals in Table 4g-7. Liquid conductivities at very high pressures are given by Bridgman [7]. For most substances, the conductivity is about 10 times larger in the liquid phase than in the gaseous phase. Similarly, solid conductivity near the melting point is considerably larger than liquid conductivity, liquid bismuth and tellurium being exceptions.

FIG. 4g-2. Effect of pressure on the thermal conductivity of argon. [B. J. Bailey and K. Kellner, *Physica* 39, 444 (1968).]

**4g-3. Heat Transport in Solids.** Two principal mechanisms are responsible for the transport of heat energy in a solid. The first is the drift motion of conduction electrons; the second is the directional cooperative vibration of interacting lattice ions, represented by the quasi-particle concept, phonons. Other mechanisms such as internal radiation or excitons may be important in some materials. Electron conduction is predominant in metals and alloys; phonon conduction in dielectrics and some highly disordered alloys. Both electron and phonon conduction are limited at low temperatures by impurity and imperfection scattering. Therefore the thermal conductivity at low temperatures is critically dependent on the exact amount and types of impurities and imperfections. At high temperatures electron conduction is limited by phonon or lattice scattering primarily and therefore is not critically dependent on the impurities. The conductivities of various metals or alloys of approximately the same composition tend to converge at high temperatures. Phonon conduction in crystalline dielectrics is limited at high temperatures by phonon-phonon scattering. Therefore the thermal conductivities of crystalline dielectrics also tend to converge to common values at high temperatures. Phonon conduction in disordered dielectrics is highly limited at most temperatures by imperfection scattering.

THERMAL CONDUCTIVITY

TABLE 4g-1. CONVERSION FACTORS FOR THERMAL CONDUCTIVITY\*

|   | $\frac{\text{Watt cm}}{\text{cm}^2 \text{ } ^\circ\text{K}}$ | $\frac{\text{Watt m}}{\text{m}^2 \text{ } ^\circ\text{K}}$ | $\frac{\text{Watt in.}}{\text{in.}^2 \text{ } ^\circ\text{R}}$ | $\frac{\text{Cal cm}}{\text{cm}^2 \text{ sec } ^\circ\text{K}}$ | $\frac{\text{Kcal m}}{\text{m}^2 \text{ hr } ^\circ\text{K}}$ | $\frac{\text{Cal in.}}{\text{in.}^2 \text{ sec } ^\circ\text{R}}$ | $\frac{\text{Btu in.}}{\text{in.}^2 \text{ sec } ^\circ\text{R}}$ | $\frac{\text{Btu in.}}{\text{in.}^2 \text{ hr } ^\circ\text{R}}$ | $\frac{\text{Btu ft}}{\text{ft}^2 \text{ hr } ^\circ\text{R}}$ | $\frac{\text{Btu in.}}{\text{ft}^2 \text{ hr } ^\circ\text{R}}$ |

| $\frac{\text{Btu in.}}{\text{ft}^2 \text{ hr } ^\circ\text{R}}$   | = 1.441  | 0.1441   | $2.034 \times 10^{-1}$   | $3.445 \times 10^{-4}$  | 0.1240  | $4.861 \times 10^{-4}$  | $1.929 \times 10^{-6}$  | $6.944 \times 10^{-3}$   | $8.333 \times 10^{-2}$   | 1.000   |

\* Units are given in terms of (1) the absolute joule per second or watt, (2) the defined thermochemical calorie = 4.184 joules, or (3) the defined British thermal unit (Btu) where 1.8 Btu/lb = 1 cal/g and therefore 1 Btu = 1,054.35 joules.

Therefore the thermal conductivity of disordered dielectrics is very low compared with that of metals or crystalline dielectrics. A review of the phenomena and various mechanisms for metals at low temperatures was given by Powell [44], and a more detailed study of the theories and concepts for solids by Rosenberg [60]. The book edited by Tye [73] also contains reviews of both the theoretical and experimental aspects for solids.

The thermal conductivity of a metal or alloy can be estimated by using the Wiedemann-Franz-Lorenz law,

$$\lambda = L\sigma T$$

where  $\sigma$  is the electrical conductivity,  $\lambda$  is the thermal conductivity,  $T$  is temperature, and  $L$  is the Lorenz ratio whose Sommerfeld classical value is

$$L \approx 2.45 \times 10^{-8} \text{ (volt/kelvin)}^2$$

For both pure metals and alloys the Lorenz ratio generally approaches the Sommerfeld value at high and very low temperatures. For pure metals  $L$  is lower than the above number at temperatures below the ice point; for alloys it is higher, as much as 10 times greater (near 20 K) for very disordered, multicomponent alloys.

Data for the conductivity of metals are given in Table 4g-8. It should be noted that the values quoted at 4.2 K, and often at 20 K, are for the most pure specimen that has been measured at the present. Future measurements on more pure metals may give substantially higher conductivities. Above 20 K the quoted values should not change substantially (more than 5 per cent) as more pure metals are measured with more refined techniques. Data for the conductivity of some commercial alloys are given in Table 4g-9; of semiconductors in Table 4g-10; of crystalline dielectrics and optical materials in Table 4g-11; and of disordered materials in Table 4g-12.

A few selected values for solids below 1 K are given in Table 4g-13. The conductivity of normal metals varies linearly with temperature at temperatures below their conductivity maximum. In superconductors the electrons do not contribute significantly to the transport of heat. Therefore their conductivity is governed by phonon processes and usually varies as  $T^3$ . The conductivity of crystalline solids is usually size-dependent below 1 K and therefore depends on the exact specimen configuration.

A recent review of the literature by Childs et al. [46] includes data, tables, and graphs on most solids for temperatures at and below 300 K.

\* Indicates a liquid below its critical pressure.

† 1 atm =  $1.01325 \times 10^5$  N/m<sup>2</sup>.

Various authors differ from 2 to 10 % on the experimental results for the conductivities of gases.

\* Heat conduction in liquid helium II is not governed by the usual heat-conduction mechanisms and equations.

Various authors differ from 2 to 8% on the experimental results for the conductivities of liquids at saturation pressure.

TABLE 4g-7. THERMAL CONDUCTIVITY OF LIQUID METALS

\* Solid A, H<sub>2</sub>, and He are in Table 4g-11. Symbols in parentheses indicate heat flow parallel or perpendicular to b or c axes. For other elements the results are for isotropic or polycrystalline elements.

† The low-temperature conductivity depends critically on the exact amount and types of impurities and imperfections. The values quoted are for the most pure specimen that has been measured at the present.

‡ For temperatures greater than 973 K see reviews by refs. 46 and 52.

Values quoted are from the reviews and compilations by R. L. Powell and Blanpied (ref. 46) and R. W. Powell et al. (ref. 52). The values are generally for the highest-purity metals tested. Disagreements among different modern authors are caused primarily by differences in sample purity and preparation.

\* Commercial alloys of the same nominal composition may vary in conductivity from 5 to 25 % because of differences in heat treatment and uncontrolled impurities. Contracid, Inconel, and Monel are registered trade names for nickel alloys. See ref. 46 for additional data.

† When composition is given, it is by weight percent.

TABLE 4g-10 THERMAL CONDUCTIVITY OF SEMICONDUCTORS\*

\* Pure Ge and Si are in Table 4g-8.  
Various authors differ from 5 to 10% on the experimental results for the conductivities of semiconductors.  
See also the review by E. F. Steigmeier in vol. 2, pp. 203-251, of rel. 73.

Various authors differ from 5 to 25 % on the experimental results for the conductivities of crystalline dielectrics and optical materials.  
See ref. 46 for additional data.

TABLE 4g-12. THERMAL CONDUCTIVITY OF DISORDERED DIELECTRICS, CERAMICS, REFRACTORY OXIDES, AND INSULATING MATERIALS (In watts/meter · kelvin)

| Material               | Density g/cc | t, °C | Conductivity | Material                                   | Density g/cc | t, °C | Conductivity |

Values quoted are from W. D. Kingery et al. (ref. 33), R. W. Powell (ref. 48), and "International Critical Tables" (ref. 42).

Various authors differ from 10 to 50 % on the experimental results for the conductivities of disordered dielectrics, ceramics, refractory oxides, and insulating materials.

TABLE 4g-13. THERMAL CONDUCTIVITY OF SOME MATERIALS BELOW 1 K†  
(In watts/meter · kelvin)

| Material                          | Ref.   | Temperature |        |        |         |         |

The conductivities of materials below 1 K are strongly dependent upon their chemical purity and physical perfection and, for small specimens, depend on the actual dimensions and surfaces. The values quoted are typical for these materials. See ref. 46 for additional data.

\* Extrapolated values.

† The thermal conductivity of normal metals in the impurity range varies as  $\lambda = aT$ .

‡ Epibond is a diglycidal ether of bisphenol which is a fluid mixed in a ratio of 4:1 with powdered Bentonite clay. Kel-F is a polychlorotrifluoroethylene. Nylon is a polyamide. Teflon is a polytetrafluoroethylene.
