OBJECTIVE: To map the relation between a dynamic saltatory pneumatic stimulus array delivered at 3 different velocities on the glabrous hand and the evoked cerebral BOLD response in human adults.
METHODS: Participants: 20 neurotypical, Rt-handed adults (19-30 years). Saltatory cutaneous stimulation using 60 ms pneumatic pulses in a 5-channel TAC-Cell array (Galileo Somatosensory) was used to deliver traverse velocities (5, 25, and 65 cm/s) on the glabrous hand [D1 (thumb), D2 (index finger), and D3 (middle finger)]. An MPRAGE (1 mm isotropic, TE=3.37 ms, TR=2400 ms) and 3 functional scans (2.5 mm isotropic, TE=30 ms, TR=2500 ms) were acquired using a 3T Siemens Skyra (32-chan head coil). SPM12 was used to realign, normalize, and smooth 960 acquired brain volumes/subject. Results from each subject were inserted to the one-way ANOVA within-subjects and one sample t-test to evaluate the group main effect of various velocity stimuli and individual velocities, respectively.
RESULTS: The group main effect among saltatory velocity stimuli revealed an extensive network of BOLD responses in sensorimotor areas (S1, S2, M1, M2, insula) and the cerebellum (P_{unc} <.0001). When the individual velocities were compared to the No stimulus condition, contralateral BOLD responses were found in insula, BA1, and sensorimotor cortex for '25 cm/s > No stimulus', whereas '5 cm/s > No stim' and '65 cm/s > No stim' evoked BOLD responses were limited to somatosensory cortex. Contralateral BOLD responses in sensorimotor cortex also

were found at two velocity conditions (5 cm/s, and 25 cm/s > All ON), whereas ipsilateral BOLD activations in BA9 were only observed at '25 cm/s > All ON'.
CONCLUSIONS: fMRI BOLD responses revealed an expandable cortical and subcortical network (sensorimotor cortex, insula and cerebellum), which reliably encodes the 3 different velocities tactile stimulus on the glabrous hand in humans, with the largest spatial extent of the evoked BOLD response at the intermediate velocity (25cm/s).

Title: Laminar and cross-columnar refinement of sensory-evoked activity in developing mouse barrel cortex

Authors: *A. VAN DER BOURG[1], J.-W. YANG[2], V. REYES-PUERTA[2], M. C. STÜTTGEN[3], F. HELMCHEN[1], H. LUHMANN[2];
[1]Brain Res. Inst., Zürich, Switzerland; [2]Inst. of Physiol., [3]Inst. of Pathophysiology, Johannes Gutenberg Uiversity, Mainz, Germany

Abstract: Rodent rhythmic whisking behavior develops in a critical period two weeks after birth when animals start to increasingly use tactile sensation to explore the environment. How sensory processing of whisker-induced inputs develops in primary somatosensory cortex S1 ("barrel cortex") in this period remains poorly understood. Here, we characterized neuronal dynamics evoked by single- or multi-whisker stimuli in developing mouse barrel cortex across all cortical layers. We performed multi-electrode recordings in anesthetized mice of three age groups: before (<P13), during (P13-P16) and after (P17-P30) the onset of active whisking behavior. We find layer-specific changes in multi-unit activity (MUA) for principal and neighboring whisker-

related barrel columns: MUA increased with stimulus intensity of single-whisker deflections in mice younger than P13 in L2/3 and L4 which was confined to the principal barrel column. In animals older than P16, MUA significantly decreased in L2/3 and L4 for the principal column but increased for the neighboring column. At the same time, MUA increased in L5 and L6 for the principal column. Paired-pulse stimulation of single whiskers with varying stimulus intervals showed facilitation in L2/3 and L4 before the critical period whereas in animals older than P16, MUA was strongly reduced after the second pulse in all layers. Sequential activation of two neighboring whiskers with varying stimulus intervals evoked distinct response profiles in the stimulated barrel columns, depending on the direction and temporal separation of the stimuli. Isolated single units showed progressively more diverse activation patterns with age, indicating refined processing of these inputs. We conclude that neuronal activity is decreased in L2/3 and L4 but increased in L5 and L6 starting with the critical period. At the same time, cross-columnar activation is increased in L2/3 and L4. In the future, our findings may help to understand how the processing of sensory information relates to emerging whisking behaviors of young mice.

Title: Touch and self-motion coding by Merkel cell-associated primary afferents

Authors: *K. S. SEVERSON[1], D. XU[1], L. BAI[1,2], D. D. GINTY[2], D. H. O'CONNOR[1]; [1]Dept. of Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Dept. of Neurobio., Harvard Med. Sch., Boston, MA

Abstract: Touch perception depends on integrating signals from multiple types of peripheral mechanoreceptors. During haptic exploration, neural activity triggered by contact forces must be combined with proprioceptive information about sensor position. Merkel cell-associated afferents ("Merkel afferents") are thought to play a role in perception of spatial form. However, Merkel afferent activity has been studied almost entirely with passively applied stimuli. Touch is an active sense and typically occurs in the context of self-generated motions, where mechanics that govern interactions with the world can be quite different. The role of Merkel afferents in active touch is unknown.
We obtained electrophysiological recordings from Merkel afferents that innervate the whisker follicle-sinus complex. Optogenetic tagging allowed us to record spikes from single Merkel afferents during behavior (n = 12). We also obtained recordings from unidentified slowly adapting (SA, n = 12; likely including Merkel) and rapidly adapting (RA, n = 7) afferents. Mice whisked freely in air and against a pole presented at multiple locations as they ran on a treadmill, generating mechanical signals at the whisker base. High-speed video allowed us to quantify mechanical variables expected to cause spiking at 2 ms resolution. Using a strategy that combined machine learning with manual curation, we scored individual video frames into one of three categories: (1) not whisking (no contact); (2) whisking in air (no contact); and (3) whisking against the pole (contact).
During non-whisking periods, most Merkel and unidentified afferents spiked at low rates (baseline rate 2.1 ± 6.6 Hz, n = 31). During whisking in free air, a subset of neurons showed increased spike rates (> 1 Hz mean rate; 12 of 31 afferents total, including 4 Merkels and 1 RA). Spike rates increased further during contact. All Merkel and unidentified afferents responsive to free air whisking were also dramatically modulated by position in the whisk cycle (phase), with 100% modulation depths and peak responses occurring across a wide range of phases.
During periods of whisker-pole touch, statistical modeling and analysis of tuning surfaces revealed that bending moment at the base of the whisker and its rate of change were critical drivers of Merkel afferent spiking. A simple mathematical model of viscoelastic coupling between whisker and sites of mechanoreception explained spiking and the sensitivity to both moment and its rate of change. Together, our results show that Merkel afferents send to the brain multiplexed information about sensor motion and surface features.

Title: Characterizing tactile coding in the whisker-barrel system using calcium epifluorescence imaging in rats

Authors: M. M. MANSY[1], I. S. BADRELDIN[2], *K. G. OWEISS[2,1,3];
[1]J Crayton Pruitt Family Dept. of Biomed. Engin., [2]Electrical & Computer Engin., [3]Dept. of Neurosci., Univ. of Florida, Gainesville, FL

Abstract: Genetically encoded calcium indicators (GECIs) that indirectly measure neural discharge patterns with subcellular resolution have witnessed substantial progress over the last few years. While recent experimental paradigms have capitalized on this progress, they have utterly focused on mouse models, owing to the availability of many transgenic mice lines. Here we sought to compare the efficacy of different GECI variants in the representation of sensory stimuli in rats—an important animal model for studying complex behaviors.
We compared the reliability of GCamp6s (G6s) and GCamP6f (G6f) in measuring stimulus-evoked responses to whiskers' mechanical deflection in the vibrissae area of the primary somatosensory cortex (vS1) in anesthetized rats (n=2 G6s; n=2 G6f). Stimuli consisted of high and low whisker deflection velocities that were applied randomly to a single whisker. We used chronically implanted single multimodal fibers (400µm) to measure green fluorescence of Ca^{2+} dynamics over multiple sessions from layer 4 neurons that have been virally transfected with 1uL of G6s or G6f. We found stimulus evoked Ca^{2+} responses to be precisely time locked to the stimulus onset (G6s:mean±sd; $t_{peak/high}$=455ms±19ms and $t_{peak/low}$ = 423±23ms; G6f:mean±sd; $t_{peak/high}$=241ms±10ms and $t_{peak/low}$ = 243±9ms) compared to spontaneous activity (mean±sd; t_{peak}=3.84s±2.43s from trial onset). Stimulus-evoked average response waveforms were significantly different from spontaneous responses (KS, $p<0.001$). Response probabilities (RPs) were similar to previous reports documenting RPs derived from spiking activity in the same area (G6s: RP_{high} =0.65±0.21, RP_{low} =0.36±0.13, $p<0.002$, bootstrapped ; G6f: RP_{high} =0.79±0.08, RP_{low} =0.68±0.22, $p<0.002$, bootstrapped). These results suggest that G6s and G6f imaged through chronically implanted fibers that can access deep brain areas could represent aspects of neural responses that would be critical to improve our understanding of tactile coding in awake freely behaving rats in future studies.

Title: Discrimination of temporally patterned stimuli in a high throughput, automated behavioural training system: AutonoMouse

Authors: ***A. ERSKINE**[1,2], T. ACKELS[1], D. DASGUPTA[1], I. FUKUNAGA[1], A. T. SCHAEFER[1,2];

[1]Neurophysiol. of Behaviour Lab., Francis Crick Inst., London, United Kingdom; [2]Dept. of Neuroscience, Physiol. and Pharmacol., Univ. Col. London, London, United Kingdom

Abstract: Naturally occurring odor plumes contain a rich temporal structure of odor concentration variation. Although the air turbulence that creates these plumes is a random process, statistical regularities exist in the temporal dynamics that are dependent on e.g. the distance the plume has travelled from its source. It has therefore been hypothesized that odor concentration fluctuations can form the basis of a strategy used by animals to localize and navigate to odor sources in natural environments.
Critical to this hypothesis is to determine whether mice are capable of perceiving these fluctuations. To investigate this, we developed a high-speed odor delivery device, capable of reliably modulating odor concentration at >500Hz and replicating many of the temporal features of naturally occurring odor plumes. In order to efficiently assess the psychophysical limits of perception of these features, we constructed an automated behavioral training system ("AutonoMouse") in which groups of socially housed mice tagged with RFID chips can be trained simultaneously for periods of several months with limited human interference.
We trained a cohort of animals (n=9) in AutonoMouse to discriminate between odor stimuli with differing temporal patterns. Stimuli consisted of trains of alternating clean vs. odorized air pulses between 1-20Hz. Total odor released, total air flow and pulse frequency in these stimuli were constant, but individual pulse amplitudes were varied randomly within trials. We observed that mice were able to discriminate between different temporal patterns with accuracy >80% for several hundreds of continuous trials (1st block of 50 trials >80% correct: 1296 ± 320; mean ± std final performance: 91% ± 10%). Removal of the target odor resulted in chance level performance (mean ± std final performance: 52% ± 3%, 1-tailed t-test vs. chance p=0.4), suggesting the accuracy of performance was due primarily to perception of odor fluctuation differences. Furthermore, degradation of the fluctuation information was achieved by replacing clean air pulses with odorized air, again significantly reducing performance accuracy to near chance levels (mean ± std: 56% ± 5%, 1-tailed t-test vs. chance p=0.13).
We conclude that mice are capable of perceiving differences in the rate of odor concentration fluctuations, suggesting a possible parameter from naturally occurring odor plumes that may contain salient, perceptible behavioral information.

Title: From Shape to Smell: Predicting olfactory perception of single molecules

Authors: *R. C. GERKIN[1], A. KELLER[2], J. MAINLAND[3], Y. IHARA[4], L. VOSSHALL[2], P. MEYER[5];
[1]Sch. of Life Sci., Arizona State Univ., Tempe, AZ; [2]The Rockefeller Univ., New York, NY; [3]Monell Chem. Senses Ctr., Philadelphia, PA; [4]Ajinomoto Co, Inc, Tokyo, Japan; [5]IBM, New York, NY

Abstract: Accurately predicting human olfactory perception from the structural features of odorant molecules has remained elusive. The DREAM olfaction prediction challenge was organized to both assess and improve on the state-of-the-art in such predictions. We took advantage of the largest-to-date dataset of olfactory perception obtained from 49 human subjects who sampled 476 structurally and perceptually diverse molecules at two concentrations. 26 research teams from around the world used structural features of these molecules to build predictive algorithms; the prediction target consisted of subject-provided numerical ratings of odor intensity, pleasantness, and 19 other verbal odor descriptors. Importantly, these algorithms were constructed using only a subset of these data, and then tested out-of-sample by the challenge organizers on the remaining data, which was unpublished at the time of the challenge. Using either the best-performing models or taking a “wisdom of the crowds” approach, odor descriptor predictions - as measured by correlation with the test data - were considerably more accurate than those from previously published models, both at the population level and for the prediction of individual subject ratings. The best performing models were in the “decision tree” class of machine learning algorithms, and these both outperformed conventional regression models and did so using fewer molecular features. This suggests the importance of non-linearity and feature interactions in producing olfactory percepts.
The best-performing models also showed an error rate indistinguishable from within-subject test-retest variability, indicating that - despite the unprecedented size and scope of the dataset - predictive accuracy is still fundamentally limited by the volume of the collected data; no further scientifically-meaningful model improvements may be possible in the future using this dataset alone. Lastly, we show that given a perceptual template, the molecule whose odor will best match that template can be selected efficiently from a large library of diverse compounds using a very restricted search. This implies tremendous savings in time and money in industrial olfaction applications.

Title: Development of a new odor battery for testing odor quality discrimination

Authors: *A. J. FISCELLA[1], C. MURPHY[2];
[2]Psychology, [1]San Diego State Univ., San Diego, CA

Abstract: Alzheimer's disease (AD) is a form of dementia marked by the presence of Aβ-plaques, neurofibrillary tangles (NFTs) and cognitive decline. There is increasing evidence that the pathophysiological symptoms of AD may begin decades before cognitive decline appears. One prevalent risk factor for AD is the APOE-ε4 allele, which can increase a person's risk of developing AD by 3-12x. The formation of NFTs in the Alzheimer's brain may begin in the olfactory cortices and studies examining APOE-ε4 carriers have shown deficits in odor processing before the development of AD. Few studies have investigated the links between odor quality discrimination and AD. Previous studies of odor quality discrimination developed odor batteries, but did not account for differences in odor intensity, pleasantness and/or familiarity of odors. The purpose of this study is to develop a new odor battery suitable for use in odor quality discrimination testing accounting for these factors. Participants were 12 undergraduate and graduate students at a large southwestern US university. Odor discrimination was tested with a pairwise task in which participants were presented with pairs of odors and indicated whether the odors in a pair were the "same" or "different". A total of 24 pairs of odors were presented. Twelve pairs were the "same" (an odor presented against itself) and six pairs were "different." The different pairs were presented twice in an A-B/B-A format and were classified as "similar" (shared a common odorant) or "dissimilar" (no common odorant). The odors pairs were also rated for similarity using a modified general labeled magnitude scale (gLMS). Odor intensity and pleasantness were also rated using modified gLMSs and odor familiarity was examined using a free-recall odor identification task. Results of repeated-measures ANOVAs indicated that there were significant differences between odors in ratings of intensity ($F(14,140) = 2.347$, $p = .005$), but not pleasantness ($F(14,140) = 1.691$, $p = .064$). There was a significant difference in similarity ratings for the different odor pairs ($F(5,55) = 11.727$, $p < .001$). There was no

significant correlation between accuracy in odor identification and odor discrimination ($r = -.237$, $p = .484$). These results suggest that this odor battery is a viable option for tests of odor quality discrimination.

Title: Simple and affordable microcontroller based platform for quantifying odor preferences in rodents.

Authors: S. JAGETIA[1], *D. W. WESSON[2];
[1]Hathaway Brown High Sch., Shaker Heights, OH; [2]Neurosciences, Case Western Reserve Univ., Cleveland, OH

Abstract: One of the most widely-displayed behaviors throughout the animal kingdom is the active investigation of odors. A major question of wide importance is what motivates animals to sample odors? Furthermore, why do animals sample some odors more than others? Understanding these questions would provide information regarding brain mechanisms of olfaction and also the brain basis of motivated behavior. Traditional and/or commonly used manners for quantifying odor preferences involve tracking the time a mouse spends within two or three chambers, each containing a different odor, with a manual stopwatch or through the use of costly video tracking software. Additionally, nose-poke based tasks are also available, yet often these only allow testing a limited stimulus set. Here we sought to develop an affordable and quantitative semi-automated apparatus to assay the odor preference behavior of mice to a wide stimulus set. This apparatus consists of a behavioral chamber enclosed within six walls, one being a removable door, with five 3D-printed nose poke ports on the other walls which hold plastic cups containing liquid odor and infrared beams to detect the nose pokes. Along with designing the apparatus, we also developed custom code written for the Arduino line of microcontrollers to collect the data and store it on a removable SD (secure digital) card, which could then be later transferred onto a computer for analysis. We validated the ability for this platform to monitor odor investigation behaviors in c57bl/6 mice. Prior to testing, each mouse was acclimated in the chamber for thirty minutes on two separate days without the presence of

odors. After the acclimation period, each mouse was again placed into the chamber, but with odors available to investigate. We found that all mice spontaneously nose-poke into the odor ports, with varying durations of poke hold times (sampling durations). We also found that mice continue to nose poke, to varying degrees, throughout the duration of a session. In conclusion, we designed and validated a novel device to quantify odor preference behavior in mice that has several distinct advantages over other available methods. We propose that this apparatus can be applied to a variety of future goals to test the neural basis of odor preferences.

Title: Neurophysiological mechanisms of the perception of natural odors in human

Authors: *I. ZYMA, S. TUKAIEV, S. KRYZHANOVSKYI, A. CHERNINSKYI, M. MAKARCHUK;
Dept. of Physiol. of Brain and Psychophysiology, Natl. Taras Shevchenko Univ. of Kyiv, Kyiv, Ukraine

Abstract: We conducted a comprehensive comparative neurophysiological study of neocortical mechanisms for the effects of olfactory sensation on functional activity of human brain (using EEG), based on the three-factor model of perception (attention, hedonic value, gender). 687 healthy volunteers (347 male and 340 female, students aged 18 to 24, with no documented manifestations of rhinal pathologies) participated in this study. EEG was registered during the rest state (5 min) and under odor stimulation (3;8 min) with essential oils (Lemon, Melissa, Ilang-ilang, Lavender, Rosemary, Bergamot, Pine, Mint, Anise, Artemisia, Valeriana, Rose essential oils). We estimated the spectral power density (SPD) and the levels of coherence of all the frequencies from 0.2 to 35 Hz. We demonstrated that the passive perception of odors, as well as the analytical odor detection, is accompanied by the activation of cortical neural networks. It stimulates the mechanisms of cortical-hippocampal loop (theta-waves), which leads to the expansion of cortical-cortical and cortical-subcortical interactions (coherence) and modulates mental, emotional and verbal activity (theta1,2-; alpha3-; beta1,2-; gamma-bands). Such effects appear due to the ability of smell perception to change excitability of brain networks (experiments with the use of photic stimulation effects). We revealed that prolonged resting states under background odoration by essential oils are accompanied by the development of a

specific combination of substantial (almost generalized) increase of coherence in alpha1- and alpha3-, beta1-bands. According to modern neurophysiology, this condition is described as a tonic alertness - perception of new information and readiness to react while relaxing. At the same time, increase of interfrontal coherence is described in the rest state right after the completion of external tasks. Positive evaluation of smell is associated with strengthening of functional brain activity, whereas negative or aversive evaluation - with its inhibition. We suggest that olfactory perception in humans is co-determined by the mental-psychological strategies of formation of introspective processes and behavior fulfillment that differ in men and women (insightful and intellectual, respectively). An important point in the structure of olfactory perception is the analysis of olfactory information in the first moment of detection, accompanied by a strong activation of cognitive memory circuits, emotions, semantic analysis, etc. At the same time, the mechanisms of "familiarity" evaluation and biological significance of the incoming sensory information turn on.

Title: Human olfactory segmentation: detecting targets among distractors

Authors: *S. CORMIEA[1], D. ROKNI[2], V. N. MURTHY[2], K. NAKAYAMA[1];
[1]Harvard Univ. Dept. of Psychology, Cambridge, MA; [2]Ctr. for Brain Sci., Harvard Univ., Cambridge, MA

Abstract: Many animals rely on their olfactory system to find food, seek mates and avoid danger. This involves detecting a particular odor of interest against a background of ever-changing distractors (analysis). However, previous studies on odor identification in mixtures found both humans and rodents performed poorly. From this, it was concluded that a mixture of odors perceived at the same time will combine to form a new percept, the individual components becoming irretrievable (synthesis). In contrast, we find that humans are able to reliably detect a monomolecular odor target against a background of distractors. We designed an olfactory match-to-sample task in which subjects were presented with one of 8 target odors at the beginning of

each trial. The target changed randomly from trial to trial, with each target occurring an equal number of times throughout the task. After a brief delay, subjects sniffed a mixture containing 1-7 components (this mixture was made up of the 8 odors in the task and contained the target odor 50% of the time). Subjects rated their target as present or absent and performance was above chance for mixtures of up to six components. These results are consistent with a recent paper (Rokni et al., 2014; Nat Neurosci 17:1225) that showed that mice could easily be trained to differentiate the target from the background in mixtures of up to 14 components. Though humans are often believed to have a poor sense of smell compared to other mammals, these results suggest that they have the ability to segregate a single odor against a background of variable distractors. Possibly more interesting is the fact that the target changes every trial which precludes the possibility that people are forming a template for search or focusing on one particular feature of their target odor.

Title: Classical olfactory fear conditioning non-selectively enhances olfactory bulb glomerular responses in awake behaving mice

Authors: *J. M. ROSS, M. L. FLETCHER;
Anat. and Neurobio., Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: The olfactory bulb (OB) glomerular layer is the first site of sensory input to the central nervous system and contributes to cortical processing of olfactory stimuli and subsequent behavioral output. Previous work from our lab in anesthetized animals suggests that olfactory fear learning induces plasticity observed at the post-synaptic glomerular level of the OB, presumably affecting downstream processing; however, the extent to which this occurs in awake animals is currently unknown. To address this, odor-evoked glomerular activity patterns were assessed in awake transgenic mice expressing GCaMP3 in excitatory post-synaptic OB cell populations. Mice were subjected to simple, classical fear conditioning by paired presentations of

an odor with footshock. Before and after associative conditioning, glomerular representations to a panel of similar and dissimilar odorants were imaged, allowing us to investigate glomerular activation to the trained stimulus as well as neutral, untrained stimuli. Our data demonstrates that glomerular odor responses in awake animals decrease with subsequent exposures to neutral odorants. However, fear learning produces robust reinstatement of representations for both trained and neutral odorants. By contrast, there were no similar representational changes in the control groups. Furthermore, the non-selective enhancement cannot be explained by a transient global fear state that enhances all incoming sensory information, as tone-shock trained mice do not exhibit increased glomerular responses when odor imaging trials immediately followed presentations of the previously conditioned tone. This suggests that non-discriminative olfactory fear conditioning non-selectively enhances odor-evoked activity in awake mice at the level of OB output neurons. This mechanism could potentially underlie behavioral generalization, the transference of fear responses from learned stimuli to related stimuli. Additionally, blocking muscarinic signaling with scopolamine during training attenuates both behavioral expression of fear learning and the associated physiological alterations, indicating an important role of acetylcholine in these related processes. Future directions include further characterizing changes that occur as a result of associative olfactory fear conditioning. All together, these studies will further our understanding of learning-induced plasticity at the initial stages of olfactory sensory processing and how neuromodulation influences this plasticity and shapes behavioural generalization in awake animals.

Title: Memory enhances search strategies during odor-guided foraging

Authors: *B. J. JACKSON[1], S. OH[1], V. GOPAL[2], A. SEMINARA[3], D. H. GIRE[1]; [1]Psychology, Univ. of Washington, Seattle, WA; [2]Physics, Elmhurst Col., Elmhurst, IL; [3]Lab. de Physique de la Matière Condensée, CNRS, Univ. Nice Sophia Antipolis, Nice, France

Abstract: Odor-guided searches are notoriously difficult due to the sparse and intermittent nature of odor plumes. The ability of rodents to form internal representations of their environment could allow them to apply learned spatial information to dynamic environments, creating a map that would act to lessen the cognitive load required to use the complex sensory cues in odor plumes and greatly increase the effectiveness of odor-guided searches. To investigate how rodents use learned spatial information to forage for food we constructed a large (2.5m x 1m) fully-automated open field arena. Two high-speed cameras detected minute changes in behavior as well as 3D body position, while an automated pellet delivery system allowed us to distribute food pellets at precise locations throughout the arena without being restrained to defined reward locations. Using this system we precisely monitored search behavior while controlling the amount of information each animal had about possible pellet locations. In our experiment Long-Evans rats foraged for sucrose pellets until all pellets had been eaten, or until ten minutes had elapsed. All behavior was done under red light, which rats cannot see, forcing them to rely upon olfactory cues to navigate. Rats completed one session of testing a day consisting of three discrete trials, with each trial containing three food locations. Rats were divided into two groups that differed in the amount of information available to them about pellet distributions. The first group was overtrained on a limited number of food locations that were consistent across trials. The second group was trained on unpredictable food locations that were novel each time the rat entered the arena. Efficiency in pellet procurement was based on rats travelling through the shortest Euclidean distance between successive pellets. Within a few days of training, rats in the first group displayed trajectories that were significantly correlated across trials, moving quickly and efficiently to procure pellets. Additionally, they consistently spent more time in the known pellet locations compared to areas of the arena where there was a low probability of finding food. In contrast, rats in the second group failed to develop a reliable or efficient pattern of pellet procurement, though they eventually found the pellets by relying more heavily on dynamic sensory cues. These results suggest that rats form distinct foraging strategies based on learned probabilities of resource locations. Further experiments will investigate the neural substrates of these strategies as well as employ an automated odor delivery system to examine the differential impact of predator odor-induced fear.

Title: Contribution of olfactory sensory neurons in respiration entrained brain oscillations

Authors: *A. H. MOBERLY, M. MA;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Oscillatory dynamics in populations of cortical and subcortical neurons are believed to serve critical roles in sensory information processing, motor coordination, learning and memory among other functions. However, the source of oscillations is elusive in many cases. A respiration entrained oscillation is a hallmark of rodent olfactory areas including the olfactory bulb and olfactory cortices, which follow respiratory rates from resting (2-4 Hz) to fast sniffing (up to 12 Hz). Olfactory sensory neurons (OSNs) in the nose are sensitive to mechanical stimulation and can thus relay airflow information throughout the olfactory system. Curiously, respiration-entrained activity has also been observed in non-olfactory areas. To determine if OSNs play a role in generating oscillatory dynamics in other brain regions, we monitored respiration and the neural activity in various brain regions (e.g. the whisker barrel cortex, hippocampus, and medial prefrontal cortex) under different conditions in freely behaving animals (n = 8). The preliminary results showed that the local field potentials from these brain regions are entrained by respiration during normal breathing and the correlation is reduced when the olfactory epithelium is ablated. Furthermore, upon optical activation of channelrhodopsin (ChR2)-expressing OSNs, the neural activity in various brain regions showed synchronization at different frequencies including beta and gamma. Our findings suggest that OSNs contribute to respiration-locked brain oscillation. Supported by R01 DC006213 from NIDCD, NIH.

Title: Multiunit activity in the granule layer of the cerebellum by olfactory stimulation during training of sexual behavior of male rats

Authors: *A. TAMARIZ[1], Z. S. HERNÁNDEZ-BRIONES[1], L. VÁSQUEZ[1], A. J. MARTÍNEZ-CHACÓN[2], P. CARRILLO[2], M. E. HERNÁNDEZ[1], G. A. CORIA-ÁVILA[1], J. MANZO-DÉNES[1], L. I. GARCÍA[1];
[1]Ctr. De Investigaciones Cerebrales, Xalapa, Mexico; [2]Univ. Veracruzana, Instituto de Neuroetología, Mexico

Abstract: Recent studies have demonstrated that non-contact stimulation of male rats by exposure to sexual cues of receptive females increases Fos-immunoreactivity (Fos-ir) in cells located in the granule layer of cerebellar lobes. However, such Fos-ir may correspond to the sensory stimulation evoked by visual, auditory or olfactory cues or also may be the result of enhanced motor activity. Because there is little information on the contribution of the cerebellum in sensory integration of smell, we recorded the multiunit activity in the cerebellum while males were exposed to olfactory sexual cues. Thus, we aimed to record the multiunit activity in the granule layer of lobes 6 and 7 of the cerebellum. Wistar males (250-300 g) were allowed to copulate during 1, 3 or 5 sessions with ovariectomized, hormone primed (estradiol+progesterone) females. One day after the last training session, males were exposed during 25 min to wood shaving, sprayed with either almond odor (Alm), urine of sexually receptive females (RF), or left unsprayed as control (Ctrl). Amplitude and frequency of records were obtained and compared between from sexually naïve and experienced animals. The distribution frequency between sexually naïve and experts males varied. Stud males showed greater amplitude and frequency as compared to naïve rats in the presence either of the three olfactory stimuli (Ctrl, Alm and RF). The amplitude and frequency was higher in rats with sexual experience as compared to naïve rats. In general, there were greater amplitude and frequency after exposure to RF odors, as compared with Ctrl and Alm exposure. These results suggest that the cerebellum is involved in the processing of olfactory cues associated with emotions and reward.

Title: Attentional influences on odor-guided behavior and information processing in the ventral striatum

Authors: *K. S. CARLSON[1], E. S. DAUSTER[1], M. A. GADZIOLA[1], D. W. WESSON[1,2]; [1]Neurosciences, [2]Biol., Case Western Reserve Univ., Cleveland, OH

Abstract: Cognitive processes, such as arousal, expectation, and attention, are well-known to modulate sensory processing, perception, and behavior. Little is known about the role of attention in the ventral striatum and secondary olfactory structures. This is particularly important given that, unlike in other well-studied sensory systems such as vision and audition, olfactory information bypasses the thalamus (a key regulator of incoming sensory information), to directly influence olfactory cortical structures. How, then, is the same external olfactory stimulus represented in an intrinsically different manner by the neurons, dependent upon whether or not the animal is paying attention to the cue? To investigate attentional influences on behavior and odor information processing, we designed a novel two-alternative choice behavioral task to precisely and systematically manipulate odor-directed selective attention, in which the subject must shift its attention to the relevant (rewarded) modality when presented with concurrent olfactory and auditory cues. Our results to date show 1) the validation of this novel, robust, stimulus-controlled psychophysical task to quantify odor-directed attention in rodents, 2) that rats can direct their attention to the olfactory modality, and that odor-directed attention dictates accuracy, 3) attentional shifting is subject to significant plasticity with experience, and 4) initial insights into the attentional modulation of odor information processing in the ventral striatum. These results provide the first of their kind look into how attention shapes odor-guided behavior and olfactory information processing.

Title: Investigating the neural correlates of olfactory-mediated memory consolidation in the sleeping human brain

Authors: *L. K. SHANAHAN, E. GJORGIEVA, J. A. GOTTFRIED;
Northwestern Univ., Chicago, IL

Abstract: Odors have been shown to be key players in targeted memory reactivation (TMR), a technique used to modulate memory consolidation during sleep. During olfactory TMR, when an odor is presented during a declarative memory task, and then again during subsequent non-REM sleep (i.e., reactivation), performance for the targeted memory task is often enhanced upon waking. Although the neural mechanism underlying these memory improvements is unclear, researchers speculate that olfactory TMR biases memory replay toward targeted memories. Here, we have designed a novel olfactory TMR paradigm to test the hypothesis that odors evoke memory replay in the sleeping human brain. First, subjects learn the locations of category-specific pictures during fMRI scanning. Next, subjects learn to associate pictures with category-specific odors. Then, during simultaneous EEG-fMRI recording, we present a subset of category-specific odors during non-REM sleep. So far, we have used multivariate pattern classification of fMRI data to demonstrate that category-specific pictures evoke unique signatures of neural activity during learning. Moreover, preliminary data suggest that reactivation may improve memory outcomes in a category-specific manner. In future analysis, we will search for odor-evoked category-specific fMRI activity during the reactivation phase to directly test the hypothesis that olfactory stimuli promote replay of targeted memory traces. By investigating the neural correlates of olfactory TMR, our work will provide valuable insights into the neural mechanism underlying odor-mediated memory consolidation.

Title: Switching between distinct neural ensembles mediates sensing and unsensing of a sensory stimulus

Authors: *D. SAHA, C. LI, W. PADOVANO, Z. CHEN, B. RAMAN;
Biomed. Engin., Washington Univ. In St. Louis, Saint Louis, MO

Abstract: Sensory systems can rapidly signal the presence of a sensory stimulus encountered by an animal. In addition to being rapid, the stimulus-evoked neural responses are usually elaborate, temporally patterned and tend to outlast the duration of the triggering stimulus. The need for such dynamical neural responses is puzzling, especially considering that the behavioral response initiations can be equally fast, and delayed only by few hundreds of millisecond after stimulus onset. This apparent mismatch between the complexity in the neural encoding and the behavioral decoding raises the following fundamental question: Are the temporally patterned neural activities important for controlling the behavioral output? Here, we investigated this issue in the insect olfactory system. Our results revealed that in the insect antennal lobe, due to circuit interactions, distinct neural ensembles were activated during and immediately following the termination of every odorant. Such non-overlapping response patterns were not observed even when the stimulus intensity or identities were changed. In addition, we found that ON and OFF ensemble neural activities differed in their ability to recruit recurrent inhibition, entrain field-˘potential oscillations and more importantly in their relevance to behavior (initiate vs. reset conditioned responses). In sum, our results reveal a general approach where recurrent inhibition actively controls stimulus ‘recognition’ and ‘derecognition’.

Title: Super-Fly-gym: An open-source, closed-loop stimulation and behavior tracking system for whole brain imaging in adult *Drosophila melanogaster*

Authors: *K. YANG[1], W. LI[1], R. S. MANN[2], E. M. C. HILLMAN[1,3];

Abstract: The adult Drosophila is an important model for neuroscience research and offers the ability to evoke and track complex behaviors in animals with brains small enough to fit within the field of view of a microscope. However, handling, mounting, stimulating and tracking behavior of adult flies in the context of acquiring real-time recordings of neural activity poses unique engineering challenges.
Despite the demonstration of prior Fly-walker systems, current solutions are large, difficult to implement, and incompatible with a number of imaging and electrophysiology configurations. They can also be challenging and cost-prohibitive for labs to construct. Therefore, there is a demand for an inexpensive and simple closed-loop experimental setup capable of delivering stimuli and tracking behavior to investigate the neuronal circuits in *Drosophila melanogaster*. Here, we detail a compact, low-profile, Arduino-based open source platform for monitoring locomotive behavior of a fly walking on a floating ball for less than $100. The platform is compatible with various stimulus delivery systems, including a multi-channel olfactometer that we have also implemented and integrated in the platform.
The current setup has been used with Swept Confocally Aligned Planar Excitation (SCAPE) microscopy, enabling whole-brain, high speed, volumetric imaging of neural activity in the adult fly brain during complex behaviors. A complete parts list, assembly guide and software for the behavioral rig will be provided online.

Title: Evaluating various properties of odor-evoked neural responses

Authors: *S. NIZAMPATNAM, D. SAHA, B. RAMAN;
BME, Washington Univ. In St Louis, Saint Louis, MO

Abstract: In the insect olfactory system, odorants are detected by olfactory receptor neurons (ORNs) in the antenna. The ORN signals are then relayed to the downstream antennal lobe, where spiking activities distributed across an ensemble of projection neurons are thought to represent both odor identity and intensity. Several features of these neural responses such as firing rates, spike latency, temporal patterns of spiking, or some combination of these features have all been proposed as approaches for encoding stimulus-specific information. Here, we evaluated which set of these odor-evoked response features can robustly encode stimulus-specific information. Surprisingly, our results reveal that all aspects of stimulus-evoked PN responses can change depending on recent stimulus history. Decoding information based on any of the proposed coding schemes does not allow the same stimulus to be recognized under a variety of experimental conditions. We propose a simplified framework that overcomes the limitations of the existing coding schemes and reveal how odor identity can be decoded independent of stimulus history. Finally, we illustrate how the existing architecture of the early olfactory circuits supports the implementation of this coding scheme.

Title: Effects of olfactory stimulation on activation of cerebellar Purkinje cells during training of sexual behavior of male rats

Authors: *Z. S. HERNÁNDEZ[1], M. PÉREZ-POUCHOULEN[2], L. VÁSQUEZ[1], A. TAMARIZ[1], P. CARRILLO[3], G. CORIA-AVILA[4], J. MANZO[4], L. GARCÍA[4];
[1]Doctorado Investigaciones Cerebrales Univ. V, Xalapa, Mexico; [2]Dept. of Pharmacol., Univ. of Maryland Sch. of Med., Baltimore, MD; [3]Inst. de Neuroetología, [4]Ctr. de Invetigaciones Cerebrales, Univ. Veracruzana, Xalapa, Mexico

Abstract: Previously we demonstrated that olfactory stimulation in sexually naïve male rats significantly increased the number of Fos-munoreactive (Fos-IR) neurons in the granule layer in each lobe of the cerebellum. Neutral olfactory stimuli (almond odor) and sexually explicit (female odor) seemed to be equally important for sexually naïve male rats. However, sexually experienced male rats expressed Fos-ir neurons in the granule layer only after exposure to female odor. In this study we analyzed and compared the expression of Fos-ir in the Purkinje layer of the cerebellar vermis of male rats with different degrees of sexual experience and after exposure to almond or female odors. Wistar males (250-300 g) were allowed to copulate during 1, 3 or 5 sessions with ovariectomized, hormone primed (estradiol+progesterone) females. One day after the last training session, males were exposed during 60 min to wood shaving sprayed with either almond scent, urine of sexually receptive female, or left unsprayed as control. Then, animals were sacrificed and the cerebellum processed for immunohitochemical and immunofluorescence reactions to detect the Fos protein and Purkinje neurons. The results indicated that the expression of Fos in Purkinje neurons decreased with sexual experience, regardless of the exposure to different odors. Accordingly, the expression of Fos-ir Purkinje neurons is opposed to that observed in the granule cells. We suggest that long-term depression in the Purkinje layer is essential for memory consolidation and learning process that underlies olfactory-modulated experience.

Title: Objective chemosensory testing in subjective salty hypergeusia; report of three cases

Authors: *N. KHANGURA[1], A. R. HIRSCH[2];
[1]Aureus Univ. Sch. of Med., Chicago, IL; [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Introduction
Rapid adaptation in those with primary complaints of chemosensory dysfunction has not been described. Three cases are presented.
Methods: Case Studies:
Case 1: A 49 year old left (L)-handed (familial) woman, five years prior to presentation sustained a subdural hematoma, and diffuse intracranial hemorrhage with loss of smell and taste. She noted

olfactory windows of a second or two and rapid adaptation to smells. She would detect a whiff of an odor which would then rapidly dissipate. While performing “scratch and sniff” smell tests, she was able to detect and identify the odor on the initial sniff, but then the odor would immediately disappear despite recurrent scratching and sniffing.
Results: Anosmia on all olfactory tests including: Brief Smell Identification Test (BSIT): 6. Quick Smell Identification Test (QSIT): 0. Alcohol Sniff Test (AST): 0. Sniff Magnitude Ratio: 1.01. Olfactometer Butanol Threshold: L 1.00, Right (R) 1.00. Olfactometer Identification: R 6.0, L 5.0. Suprathreshold Amylacetate Odor Intensity: Straight Line. Suprathreshold Amylacetate Odor Hedonic: straight-line. Sniff-N-Sticks: Threshold: L>1, R >1, dirhinous >1. Dirhinous: Discrimination: 9, Identification: 4. Retronasal Smell Index (RSI): 0.
Case 2: A 59 year old R-handed man, one year prior to presentation developed an upper respiratory infection (URI) followed by loss of smell and taste. While performing a scratch and sniff test, he would detect a whiff of an odor which he could identify, but within a second would disappear. Recurrent vigorous scratching of the strip would not cause the odor to reappear.
Results: Olfactory testing: BSIT: 9 (normosmia). RSI: 2 (abnormal). CT scan of brain and sinuses: normal.
Case 3: A 53 year old R-handed man, five months prior to presentation, developed a URI with a sudden loss of smell and taste. He noted olfactory windows, whiffs, twice a day. While performing the olfactory testing he would detect an odor initially, but it would rapidly fade away.
Results: Chemosensory testing: olfaction: BSIT: 10 (normosmia). QSIT: 3 (normosmia). Olfactometer Identification: L: 8, R: 8 (anosmia). Pocket Smell: 2 (hyposmia). Pyridine Snap Smell Threshold: L<2.0, R<2.0 (anosmia). AST: 30 (normosmia). RSI: 2 (abnormal). MRI of the brain with or without infusion: normal

Discussion

Rapid adaptation may be an independent aspect of olfactory function different from identification or threshold. Tests which can be completed with a single short sniff (i.e. Scratch-N-Sniff) or with very low intensity (AST) may demonstrate false negative findings of normosmia due to rapid adaptation. Assessment of olfactory adaptation as a diagnostic tool is warranted.

Title: Olfactory preferences are a matter of taste: retronasal learning requires taste cortex.

Authors: *M. BLANKENSHIP[1], M. GRIGOROVA[2], D. KATZ[3], J. X. MAIER[4];
[1]Biol., Brandeis Univ., Cambridge, MA; [3]Biol. Dept., [2]Brandeis Univ., Waltham, MA; [4]Dept. of Neurobio. and Anat., Wake Forest Sch. of Med., Winston-Salem, NC

Abstract: The mammalian olfactory system operates dually: odors in the environment are sampled through nasal inhalation (called orthonasal), and odors present in the mouth and nasal cavity are sampled through exhalation and mastication (retronasal). Understanding how animals use olfactory information from both modalities is important for understanding flavor perception and food seeking behavior. In this work, we ask whether the mode of odorant experience affects the acquisition of olfactory preferences in rats. Animals are trained to associate one of two ortho- or retronasally delivered odors with a sweet-water reward using a highly controlled olfactometer system. We then optogenetically inactivate cortical taste area gustatory cortex (GC) during testing to assess the involvement of the taste system in the expression of olfactory preference. We found that retronasal presentation of odors rapidly induces odor preference, and this preference is specific to the modal context in which it occurs; retronasally learned preferences are not expressed if animals are tested in the orthonasal olfactory mode. However, orthonasal preferences are "rescued," and even expressed more strongly than retronasally learned preferences, if learning includes both a retro- and orthonasal component. This retro- and retro-facilitated preference expression is eliminated during GC optogenetic inactivation. Taken together, these findings suggest that retronasal-taste associations occur directly and rapidly, while orthonasal-taste associations occur more slowly or indirectly through retro-facilitated second order learning. GC is required for this expression of retro- and retro-facilitated odor preferences even in the absence of taste stimulation, highlighting the intrinsic connection between taste and retronasal smell as orally-sourced chemosensory streams.

Title: Leptin modulates olfactory-driven feeding-related behaviors by a direct action on the olfactory bulb

Authors: *M. BENDAHMANE, M. C. OGG, J. M. ROSS, M. L. FLETCHER;
The Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Food intake in healthy animals is tightly controlled by internal and external signals. Internal signals such as circulating nutrients, hormones, and locally released neurotransmitter signals directly modulate neuronal circuits to induce, maintain or stop food intake. External cues, such as the sensory input provided by the sight, taste, texture and the smell of foods also affect food choice and consumption. In our study, we aim to understand the cross talk between the feeding system and the olfactory system, one of the major determinants for the palatability of food. There is increasing evidence showing the effects of the nutritional status signals on olfactory behaviors and the olfactory system physiology. However, a direct link between the modulation of the olfactory system and feeding behaviors is still poorly understood. The goal of our study is to determine the effect of direct olfactory bulb (OB) leptin olfactory-guided food-related behaviors. To accomplish this, we compared the effects of systemic versus direct OB leptin application on olfactory sensitivity and olfactory-guided food-finding abilities in fasted mice. Overall, we find that in fasted mice OB leptin increases latency to find food compared to vehicle controls and is similar to that of fed mice. Interestingly, ad libitum food consumption was not reduced by OB leptin infusions suggesting that the effect of leptin on the OB may serve to decrease food salience during food finding behaviors, but not directly modulate food consumption. Current experiments are focused on comparing these findings to that of system leptin injections to help further distinguish between leptinergic effects on sensory processing and feeding circuits.

Title: Citalopram induced chemosensory dysfunction

Authors: *N. OKEKE[1], S. KATCHY[2], A. R. HIRSCH[3];
[1]Caribbean Med. Univ., Willemstad, Netherlands Antilles; [2]Univ. of Nigeria, Enugu, Nigeria;
[3]Smell and Taste Res. Fndn., Chicago, IL

Abstract: Introduction: The selective serotonin reuptake inhibitor, citalopram's impact on smell and taste has not heretofore been reported. Such a case is described. Methods: Case study: A 52 year old right handed female was nasute until five years prior to presentation when she began citalopram and shortly thereafter noticed total smell and taste loss. Having been on citalopram for years, she discontinued citalopram three years prior to presentation and within three days of discontinuation her taste and smell returned and stayed normal for two months. She then began venlafaxine and her chemosensory ability then gradually faded to the current anosmic and ageusic state. Results: Chemosensory testing: Dirhinus Olfaction: Pocket Smell Identification Test: 1 (hyposmia) Brief Smell Identification Test: 6 (anosmia) Alcohol Sniff Test: 0 (anosmia). Olfactometer Identification Test: Left 6, Right 6 (anosmia) Retronasal Smell Index: 1 (abnormal). Gustatory testing: Phenylthiocarbamide Disc Taste Test: 5 (hypogeusia). Fiberoptic Endoscopy (normal). Discussion: Impaired chemosensory function with citalopram, and improvement upon its discontinuation, is strong evidence that this is the primary pathologic factor inducing taste and smell dysfunction in this patient. When citalopram is initially given, it induces an increase in serotonin which may stimulate 5HT receptors in the periglomerular cells of the olfactory bulb. Alternatively, an increase in serotonin may lead to direct inhibition of mitral cells in the olfactory bulb, both disrupting the chain of olfaction and the ability to fine tune different odors. Retronasal smell is linked directly to about 90% of taste and would explain why the patient also complained of a loss of taste with onset of anosmia. Since olfactory loss complaints are not routinely reported by hyposmic patients, routine smell and taste evaluation of patients prior and during citalopram use is warranted.

Abstract: Male zebra finches have only one song in their repertoires, but how they sing can vary depending on social context. Most well-known are the subtle acoustic differences between female-directed and undirected (solitary) singing, which seem to reflect the male's state of arousal. Here we analyze singing behavior above the level of the motif (the smallest repeating song unit) and show evidence for complex yet stereotyped rhythmic structure at larger timescales. We present preliminary results for how social context affects the structure of singing behavior, as well as how and when this higher-level structure develops beyond the sensitive period for song crystallization.

Title: Word-form feature combinatorics in the human auditory ventral stream

Authors: *I. DEWITT[1,2], J. WITTIG, Jr.[3], J. COCJIN[3], W. THEODORE[4], S. INATI[5], K. ZAGHLOUL[3], J. P. RAUSCHECKER[2], B. HORWITZ[1];

Abstract: The organization of the auditory ventral stream, the neocortical auditory pattern recognition pathway, has been proposed to operate as a hierarchical feature network, wherein elemental features are hierarchically recombined into increasingly complex sensory representations. Owing to combinatorial explosion, unsupervised learning, and network constraints, neurons in the system are mooted to only learn well-formed representations of feature combinations common to the sensory environment. To probe the operation of this network, we constructed auditory word-form stimuli that contained equivalent lower-order features (phonemes) but which varied in their regularity with respect to the natural statistics of embedded higher-order feature combinations (di-, tri-, tetraphones). Under a strictly feedforward model, stimuli with embedded higher-order feature combinations that are inconsistent with the natural statistics of the sensory environment would be expected to elicit a diminished neural response, compared to stimuli with regular higher-order feature statistics. Conversely, models that incorporate feedback (e.g., predictive coding) posit stimuli with irregular higher-order feature statistics to elicit increased neural response, proportional to expectancy error. To observe neural sensitivity to phoneme sequence probabilities (phonotactics), we presented auditory word-form stimuli to healthy subjects in a functional MRI (fMRI) scanner (Experiment 1) and to temporal lobe epilepsy patients implanted with intracranial electroencephalography (iEEG) arrays (Experiment 2). Preliminary analyses of fMRI data, consistent with feedback models, found increased blood oxygenation-level dependent (BOLD) signal in anterior-lateral planum temporale (PT) in response to irregular higher-order feature statistics. Preliminary analyses of iEEG data similarly found increased high-gamma power response in mid-superior temporal gyrus (STG), a site adjacent to anterior-lateral PT but on the lateral surface of superior temporal cortex. Together, our findings indicate the auditory ventral stream encodes sequence event probabilities extracted from the long-term natural statistics of the heard environment. Results support feedback-inclusive models, in which expectancy error is processed early in the ventral stream, at the transition from anterior-lateral PT to mid-STG.

Title: Slow rhythms in conspecific vocalisations are over-represented in the primary auditory cortex of common marmosets

Authors: *T. BANNO[1], W. SUZUKI[2], N. MIYAKAWA[2], T. TANI[3], N. ICHINOHE[2,3];
[1]Dept. of Otorhinolaryngology:Head and Neck Surgery, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA; [2]Dept. of Ultrastructural Res., Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan; [3]RIKEN BSI, Saitama, Japan

Abstract: A 3- to 8-Hz rhythm is a typical feature of human speech and is known to be critical for speech comprehension. Interestingly, macaque monkeys communicate with a rhythmic oral gesture within this range and they prefer a gesture produced in the natural rhythm over unnatural ones. These findings suggest the importance of rhythm perception in primate social communications and that the neural representations of vocal rhythm are fundamental to elucidate neural mechanisms of social communication. To address this issue, we conducted electrophysiological recordings from the primary auditory cortex (A1) of anesthetized marmosets, a New World monkey known to have various rhythmically modulated calls. We synthesized sounds having rhythms spectro-temporally matched to three representative marmoset call types and examined neural responses to the real and synthetic calls. We found that the A1 neurons were largely divided into two groups; one that responded both to the real and synthetic calls and the other that responded only to the real calls. The responsiveness to the synthetic calls was dependent on the characteristic frequencies of the cells, which were defined by the frequency tuning peak of the units, suggesting that the frequency is an important acoustic feature that evokes the A1 neurons. For the former cell group, we further examined their sensitivities to the rhythmic modulations by changing the rhythms in amplitude and frequency of the synthetic sounds independent from each other. The A1 neurons showed various types of tuning to these rhythm combinations and they covered entire parametric space of our stimulus set as a population. However, a large proportion of the cells (~40% of units) preferred the combinations of slow rhythms <8 Hz, which is naturally found in marmoset calls. These results indicate that the marmoset A1 neurons over-represent temporal rhythms that are commonly observed in conspecific vocalizations and human speech. Our findings suggest common neural mechanisms underlying vocal communications in humans and an ancestral primate and the usefulness of marmosets as a primate model for speech comprehension.

Title: Voice perception and recognition after lesion to face selective posterior temporal sulcus

Authors: ***J. GUO**[1], L. GARRIDO[2], R. LIU[3], T. SUSILO[4], J. BARTON[3], B. DUCHAINE[1]; [1]Dartmouth Col., Hanover, NH; [2]Brunel Univ. London, London, United Kingdom; [3]Univ. of British Columbia, Vancouver, BC, Canada; [4]Victoria Univ. of Wellington, Wellington, New Zealand

Abstract: Oron & Yovel (2015) found the face-selective area in posterior temporal sulcus (pSTS-FA) shows a strong response to human voices. These findings raise the question of what role, if any, pSTS-FA plays in voice processing. Here we examine whether the ability of perceive and recognize human voices is impaired when pSTS-FA is lesioned. We tested a woman in her early fifties named Faith, who had a right occipitotemporal resection for epilepsy in 2012 which left her severely prosopagnosic. Her lesion overlaps with the typical location of right pSTS-FA, and a dynamic localizer revealed that the resection disrupted nearly all of her right pSTS-FA. Faith has not noticed a change in her voice processing since the surgery. To formally assess her voice processing, we used ten behavioral tasks. Faith performed normally with tasks assessing voice discrimination, voice identity recognition (three tasks), voice identification, old-new vocal identity discrimination, and voice gender perception. Faith's scores in two vocal expression tests were low-normal in our first round of testing, so we tested her with a third vocal expression test. On that test, her z score of -0.94 compared with 18 college-aged participants indicates her vocal expression recognition is normal. Our results indicate that vocal perception and recognition can remain intact following a lesion to right pSTS-FA. These findings suggest that the strong voice activations in right pSTS-FA do not reflect computations contributing to the representation of voices but may instead reflect the integration of voice information with other social information.

Title: The effect of language familiarity on the cortical analysis of speech-specific temporal structure

Authors: *T. OVERATH, J. H. PAIK;
Duke Univ., Durham, NC

Abstract: Human speech is structured over multiple timescales. Phonemes, syllables and words carry information at scales ranging from a few tens of milliseconds to seconds, respectively (Rosen, 1999). Recently, we investigated the processing of such temporal structure in human auditory cortex by measuring BOLD signal changes to speech shuffled at different timescales in a foreign language (German); we showed that superior temporal sulcus (STS) is sensitive to temporal structure that is specific to speech but independent of linguistic lexical analysis (Overath et al., 2015). In the current study we addressed the role of temporal information in the transformation from speech-specific acoustic analysis to speech-specific linguistic analysis. We directly compared responses to English and Korean speech quilts to investigate the extent to which the previous findings are influenced by linguistic analysis.
We recorded four bilingual English-Korean speakers (all female) reading from a book. 4 s long speech quilts were then created with 30, 120, 480, and 960 ms segment lengths in English and Korean; we also included 4 s long original (unaltered) speech stimuli in either language. Imaging data was acquired on a GE MR 750 3T system using a high-resolution (2x2x2 mm) EPI sequence. Participants listened to the speech stimuli and identified which of the four speakers they heard via a button box.
We applied the bilateral group functional ROI in STS from Overath et al. (2015) to probe the responses to the English and Korean speech quilts as a function of segment length. Korean speech quilts showed a parametric increase similar to the one observed before (Overath et al., 2015), while the effect was significantly stronger and more left-lateralized for English speech. In addition, activity in inferior frontal gyrus (IFG) showed an increase as a function of segment length only for English speech quilts.
The results suggest a transition from speech-specific acoustic analysis to speech-specific linguistic analysis that arises in left STS and is mediated by frontal cortex (IFG).

Title: High-resolution intracranial recordings provide direct electrophysiological evidence for music and speech-selective neural populations in human auditory cortex

Authors: *S. V. NORMAN-HAIGNERE[1], J. FEATHER[1], P. BRUNNER[2,3], A. RITACCIO[2,3], J. H. MCDERMOTT[1], N. KANWISHER[1], G. SCHALK[2,3];

Abstract: The functional organization of human auditory cortex remains unresolved. Previously, we used 'voxel decomposition' to infer canonical components of the human cortical response to natural sounds, measured with fMRI. This analysis inferred distinct components selective for music and speech, which were localized to different non-primary regions of human auditory cortex. These components plausibly correspond to distinct underlying neural populations; but there is no direct electrophysiological evidence for such organization, and little is known about the temporal response properties of these putative neural populations. To address these questions, we recorded intracranial responses from a patient implanted with one of the highest resolution electrocorticographic (ECoG) arrays used to study auditory cortex to date (1 mm diameter electrodes, spaced 3 mm apart). We measured broadband gamma (70-140 Hz) responses to a diverse collection of 165 sounds. These sounds included many of the sounds people commonly hear, and have previously been used to characterize auditory cortex with fMRI. We then applied a decomposition method to infer canonical response time courses, whose weighted combination explained the ECoG response across all sound-responsive electrodes ($N = 52$, $p < 0.001$). This

analysis revealed 5 reliable components, two of which exhibited clear selectivity for music and speech, respectively, despite the lack of any functional constraints used to infer them. Notably, we also observed clear evidence for music and speech selectivity in the response of individual electrodes. The degree of this selectivity substantially exceeded that typically observed in fMRI voxels. Responses in three other patients with lower-density grids (2.3-mm diameter, 4-mm spacing) were qualitatively similar, but the degree of category selectivity was reduced. Collectively, these findings provide some of the first direct electrophysiological evidence for distinct neural populations selective for music and speech, and demonstrate the utility of high-density electrode recordings in revealing cortical tuning in humans. Ongoing work is investigating the temporal properties of the different components revealed by our analysis and their relationship to acoustic and semantic properties of music and speech.

Title: Perceptual boundaries for species-specific vocalizations in the common marmoset (Callithrix jacchus)

Authors: *M. S. OSMANSKI, X. WANG;
Johns Hopkins Univ., Baltimore, MD

Abstract: One of the most basic questions in cognitive neuroscience concerns how continuous, variable sensory inputs are organized into discrete, behaviorally significant perceptual categories with clearly defined boundaries. This phenomenon was first described, and remains best characterized, for human speech, although there is a wealth of evidence showing that many species display categorical perception of their own species-specific communication calls. The common marmoset (*Callithrix jacchus*) is a small, arboreal New World primate with a rich vocal repertoire. While several different classes of vocalizations have been described for this species (i.e., “twitter”, “phee”, “trill”, etc.), we know surprisingly little about how these vocalizations are

actually perceived by these animals, including the perceptual boundaries for classifying particular call types. Further, almost nothing is known about the neural underpinnings of categorical perception for species-specific vocalizations in marmosets. We began to address these questions by training marmosets using operant conditioning techniques to discriminate among several variants of synthesized ("virtual") vocalizations. We created a series of virtual vocalizations for each call type that progressively deviated away from the mean population value for single, or pairs of, acoustic parameters (e.g., dominant frequency, FM rate, etc.). Results from behavioral experiments utilizing these stimuli showed that marmosets appear insensitive to changes along one acoustic parameter axis for a given call type over a range of up to 2 SD of the population mean for that call type. Furthermore, marmosets showed less sensitivity to variations in their species-specific vocalizations compared to similar variations in simpler acoustic stimuli (e.g., pure tones, sFM tones, etc.). These findings suggest potential categorical specializations for vocal perception by marmosets. Finally, we examined changes in neural activity in several regions of auditory cortex (core and lateral belt) while marmosets engaged in the above discrimination tasks. Title: Attentional modulation of phoneme related potentials in EEG responses to multi-talker speech

Authors: *S. VYSYARAJU, B. KHALIGHINEJAD, G. CRUZATTO DA SILVA, N. MESGARANI;
Electrical Engin., Columbia Univ., New York, NY

Abstract: Humans are able to selectively attend to a speaker in multi-talker environments. Recent human electrophysiology studies have shown a preferred encoding of attended speaker features in non-primary auditory cortices. Nonetheless, it is not clear how the attended speaker is segregated from the background throughout the auditory pathway, and what specific

transformations are applied to the acoustic features of attended and unattended speakers. Previous studies using Electroencephalography (EEG) technique have successfully characterized the attentional modulation of speech envelop. These model-based approaches however suffer from the limitations imposed by the assumed structure and regularization of the model, in addition to a lack of direct relation between the neural data and the acoustic properties of speech sounds. Here, we employ a novel analysis method, phoneme related potential (PRP), to study the attentional modulation of phonetic feature representation of attended and unattended speakers. We recorded EEG data from 30 native speakers of American English. Participants listened to stories read by a male and a female speaker. Participants were asked to attend a target speaker in each experiment block. We segmented the neural responses into time-aligned sequences of phonemes and calculated the average neural response to each phoneme (PRP). We used discriminability of phoneme categories to quantify the phonetic representation of each speaker at different time intervals. We observed that the earlier component of the neural representation (100 ms) encodes both attended and unattended speakers, however, the later components only showed the phonetic features of the attended speaker. We used Multidimensional Scaling (MDS) analysis to visualize the neural representation of phonemes over time, and found a strong separation of phonetic features of the attended speaker organized primarily by the manner of articulation features.
Characterizing the representational properties of attended and unattended speaker throughout the auditory pathway provides a descriptive account of how a speaker's voice is selectively attended to, and establishes a direct link between the physical properties of speakers' voices and their neural transformation and modulation in the auditory pathway.

Title: Role of auditory cortex in feedback-dependant vocal control in marmoset monkeys

Authors: *S. ELIADES, J. TSUNADA;
Otorhinolaryngology: Head and Neck Surgery, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA

Abstract: Human speech is a sensory-motor process requiring constant self-monitoring to ensure accurate vocal production. This auditory feedback monitoring allows one to quickly adjust speech production in order to compensate for perceived changes in vocal output. Although many animal species show similar feedback-dependent vocal control, the underlying neural mechanisms remain largely unknown. Previous work has demonstrated neural sensitivity in the auditory cortex to altered feedback during vocal production. However, the functional role of this cortical activity during vocal production is not known. We investigated the contribution of the auditory cortex to feedback-dependant vocal control during self-initiated vocalizations in marmoset monkeys. Using real-time frequency-shifted feedback, we found that marmosets exhibited feedback-dependent control of their vocalization acoustics. Pairing frequency-shifted feedback with electrical microstimulation of auditory cortex, we found that stimulation induced changes in vocal production and compensation. Finally, we examined vocalization-related auditory cortex activity using chronic recordings from implanted multi-electrode arrays and found a variable relationship between site-specific microstimulation effects and neural responses. These results demonstrate that marmosets are a good model for studying feedback-dependent vocal control, and suggest a causal role of auditory cortex neural activity in the vocal production and control process.

Title: Exploring the effect of intelligibility on cortical entrainment

Authors: *L. S. BALTZELL, V. RICHARDS, R. SRINIVASAN;
Cognitive Sci., UC Irvine, Irvine, CA

Abstract: It has been suggested that cortical entrainment plays an important role in speech perception by helping to parse the acoustic stimulus into discrete linguistic units. However, whether or not the intelligibility of speech contributes to the entrainment response remains an open question. For example, Howard & Poeppel (2010) showed that the entrainment response to

time-reversed speech did not differ from the entrainment response to forward speech, suggesting that the entrainment response reflects acoustic rather than linguistic neural processes (see also, Zoefel & VanRullen, 2016). In contrast, Deng & Srinivasan (2010) used a non-linear frequency transform (the Hilbert-Huang Transform) of the neural data to show that showed that the entrainment response to time-reversed speech was significantly smaller than the entrainment response to forward speech, suggesting that intelligibility reflects linguistic neural processes (see also, Peelle et al., 2013). In these studies however, stimuli were acoustically altered in order to manipulate intelligibility, making it difficult to compare across "intelligible" and "unintelligible" conditions. Furthermore, a lack of matched behavioral tasks across conditions introduce an attentional confound. In the current study, we use semantic priming to manipulate the intelligibility of vocoded speech. Specifically, vocoded target sentences are preceded by clear speech (non-vocoded) prime sentences that are either matched or mismatched to the vocoded target. On each trial, a target vocoded sentence is preceded by a clear speech prime and followed by a vocoded snippet, and listeners are asked to determine whether or not the snippet was cut from the target. The length of these snippets were adaptively varied based on listener response in a 2-down/1-up tracking procedure. The two factors we varied were (1) whether or not the prime and target were the same, and (2) whether or not the snippet was drawn from the target. Despite the fact that matching the prime and the target substantially increases the intelligibility of the target, our analysis of the coherence between the broadband stimulus envelope and the neural response suggests that the difference in entrainment between "matching" and "mismatching" targets is modest if present at all. This result suggests that when acoustic confounds are removed and attentional confounds are mitigated, linear coherence between the stimulus envelope and neural response does not depend on intelligibility. We are in the process of implementing the Hilbert-Huang transform, but at present do not have results.

Title: Regional homogeneity of intrinsic brain activity correlates with auditory-motor integration for voice control

Authors: *H. LIU, Z. GUO, X. HUANG;
Dept. Rehabil. Medicine, The First Affiliated Hospital, Sun Yat-Sen Univer, Guangzhou, China

Abstract: It has been well documented that speakers produce rapid compensatory vocal adjustments for errors they perceive in their auditory feedback. The fact that they differ greatly in the degree to which they compensate for perceived errors, however, has received much less attention. The present study investigated whether intrinsic brain activity during resting can predict an individual's behavioral and cortical responses to pitch-shifted auditory feedback during vocalization. This relationship was investigated by correlating the regional homogeneity (ReHo) of resting-state fMRI signals with the magnitudes of vocal and event-related potential responses (N1 and P2) to pitch shifts of -200 and -500 cents. Behaviorally, the magnitudes of vocal responses were significantly correlated with the ReHo values in the bilateral superior temporal gyrus (STG) and right supplementary motor area (SMA) for both -200 and -500 cents, the right primary motor cortex (M1) for -200 cents, and the left premotor cortex (PMC) for -500 cents. For both pitch shift sizes, there were significant ReHo-N1 correlations in the left inferior frontal gyrus (IFG), right STG, bilateral M1, and the left SMA. Significant ReHo-P2 correlations were observed in the bilateral IFG, right STG, left SMA and M1 for -200 and -500 cents, the left PMC for -200 cents, and the right SMA for -500 cents. These findings provide the first evidence that regional homogeneity of intrinsic brain activity can predict behavioral and cortical responses to pitch errors in voice auditory feedback.

Title: Neural coding of species identity in birdsong prosody

Authors: M. ARAKI, M. M. BANDI, *Y. YAZAKI-SUGIYAMA;
Okinawa Inst. of Sci. and Technol. (OIST) Grad. Univ., Okinawa, Japan

Abstract: In the animal kingdom, vocal communication is used to establish social identity and to exchange information. In bird song, these functions are transmitted in prosodic melodies composed of syllables punctuated by silent gaps of variable length. Such vocal characteristics,

which are unique to each species, are thought to be learned primarily through auditory exposure of juveniles to adult tutors. However, this hypothesis remains untested because the developmental mechanisms governing neuronal coding of species-specific vocalizations remain unclear. We identified a class of neurons in zebra finch brain that encode durations of silent pauses between syllables, called temporal gaps, that are unique to each species. We recorded neuronal responses from the primary auditory forebrain in zebra finches and identified two types of neurons, one responsive to temporal gaps and durations of syllables, whereas the other was responsive to song morphology, acoustic features of syntactic elements. Remarkably, gap-responsive and morphology-sensitive neurons showed a double functional dissociation, and the former were even responsive to temporal gap structures in white noise. Moreover, both behavioral learning of song gap durations and their neuronal encoding properties in juvenile birds were resistant to abnormal auditory experiences with other tutor species or no tutor experiences during development. Interestingly, young zebra finches cross-fostered by Bengalese finch parents, learned Bengalese finch song morphology transposed onto zebra finch temporal gaps. Collectively, these results demonstrate innate neuronal encoding of prosody in birdsong and reveal distinct acoustic processing channels for phonology and morphology in vocal communication learning. Innate encoding of silent gaps in birdsong suggests a species-specific neuronal bar code for song learning that may contribute to formation and maintenance of conspecific social networks in highly speciose acoustic environments.

Title: Attentional modulation of speaker-phonetic features in primary and non-primary human auditory cortices

Authors: *J. A. O'SULLIVAN[1], S. A. SHETH[2], G. M. MCKHANN[2], A. D. MEHTA[3], N. MESGARANI[1];
[1]Electrical Engin., Columbia Univ., New York, NY; [2]Dept. of Neurolog. Surgery, The Neurolog. Inst., New York, NY; [3]Dept. of Neurosurg., Feinstein Inst. for Med. Res., New York, NY

Abstract: Humans posses the ability to segregate one speaker from another, even when there is no spatial separation between them. The neural mechanisms underlying this ability are poorly understood. Invasive human neurophysiology studies have shown a spectrotemporal representation of speech in superior temporal gyrus (STG) that rapidly changes depending on the attentional focus of the listener. Recent findings have also revealed a selective representation of phonetic features in STG. However, how this selective encoding is modulated by attention in a multi-speaker environment has not been characterized. In addition, the representation of speech in primary auditory areas remains unexplored due to their inaccessibility from the surface. Here, we used invasive depth and surface recordings to investigate the neural encoding of phonetic features in both single- and multi-speaker environments. Subjects listened to a male speaker and a female speaker, in both isolation (single-speaker; SS), and mixed together (multi-speaker; MS). By segmenting the speech into a time-aligned sequence of phonemes, we obtained the neural response to each phone. In the SS condition, we observed a progression of phonetic responsiveness over time: primary auditory areas responded at short latencies (~50 to 175ms), and non-primary areas at longer latencies (~175 to 300ms). We observed a similar pattern for the attended speaker; however, for the unattended speaker, longer latency responses were more strongly suppressed than short latency responses. Electrodes exhibited varying degrees of selectively for the male or female speaker in the SS condition. In the MS condition, these electrodes maintained their selectivity, with some responding preferentially for a particular speaker even when they were not being attended to. In order to establish a mechanistic description of how the neural responses are modulated by attention, we compared the responses in the SS and MS conditions over time. The difference of these responses indicates when a brain region either failed to represent the attended speaker features (SS > MS), or to suppress the unattended speaker features (SS < MS). We characterized the error patterns by showing a direct relation between the feature selectivity of an electrode, and the amount of overlap between the two speakers with regards the features that the electrode was sensitive to. Moreover, electrodes that responded at shorter latencies tended to exhibit more errors than longer latency electrodes. These results provide a descriptive account of how the features of an attended speaker are progressively processed along the auditory cortical pathway in a multi-speaker environment.

Title: Coordination of vocal interactions by marmoset monkeys in naturalistic social environments

Authors: *J. TSUNADA, B. BALLINTYN, S. J. ELIADES;
Dept. of Otorhinolaryngology, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA

Abstract: Vocal communication is important in day to day life, and plays a key role in maintaining group cohesion and social bonds. Successful vocal communication, however, requires coordination of vocal interactions with group members according to the social context. Marmosets (*Callithrix jacchus*) exhibit many human-like social vocal behaviors including a rich vocal repertoire. Previous experiments in isolated laboratory conditions have revealed rule-based antiphonal vocal interactions between marmosets. However, marmosets' interactive vocal communication in complex social environments remains largely unstudied. In this study, we asked what social rules marmosets use for vocal communication in complex, naturalistic social contexts. We recorded vocalizations from an entire group of marmosets housed in a colony environment and tracked their vocal interactions in order to determine which animals or groups responded to other's vocalizations and in what order. The pattern and frequency of vocal interactions was measured using Markov chain analysis, focusing particularly on the marmoset twitter call which is presumed to have a role in social communication. We found that twitter call production is non-random, but rather produced as part of interactive vocal exchanges. Surprisingly, we also found that co-housed family groups participate in twitter exchanges no more often than individual animals, suggesting the role of twitter calls as an inter-group communicative signal. We also found that individual animals exhibited biases to which animals they responded to. These results are the first quantitative measurements of marmoset vocal interaction in the social environment of a marmoset colony and demonstrate complex social communication. These findings will have important implications for future studies of vocal communication, and can potentially be paired with physiologic studies to determine the neural basis of interactive social behaviors.

Title: Ensemble neural recordings from awake behaving songbirds via microdrive-coupled tungsten microarrays

Authors: *W. E. WOOD, F. THEUNISSEN;
Dept. of Psychology, Univ. of California, Berkeley, Berkeley, CA

Abstract: We present a novel chronic neural recording setup based on a combination of experimental techniques. This new setup allows large-scale electrophysiological recordings in awake behaving songbirds using 16 channel tungsten microarrays coupled to small manual screw drives. Neural signals are then filtered and digitized by a small digital signal processing chip carried in a backpack between the animal's wings, thus distributing the weight of the neural implant between the head and the back and decreasing noise artifacts via earlier digitization of the signal. We use this novel recording technique to obtain neural responses of ensembles of auditory neurons in the avian auditory cortex while the bird is actively engaged in vocal communication and song production. In particular, we focus on error-matching of the bird's own song during the song learning process across the auditory lobule. It is likely that understanding neural representations of higher-level percepts that are attentionally regulated and encoded in a distributed fashion will require ensemble neural recordings of awake behaving animals, such as is demonstrated here. The same recording technique could be used in other small animals to investigate neural computations during complex behaviors.

Title: High intensity sound stimulation changes electrical properties of hippocampal CA1 pyramidal neurons.

Authors: *A. O. CUNHA[1], R. M. X. LEÃO[2];
[1]Univ. of Sao Paulo, Ribeirao Preto, Brazil; [2]Dept. of Physiol., Univ. of Sao Paulo, Ribeirão Preto, Brazil

Abstract: Auditory information induces plastic changes in limbic structures leading to the control of the emotional aspects of sound stimulus. We have previously demonstrated that high intensity sound stimulation (HISS) for 10 days inhibits Schaffer-CA1 hippocampal long-term potentiation in measured in hippocampal slices from Wistar rats. In order to understand the mechanistic basis of this effect we analysed electrical properties of CA1 pyramidal neurons and both excitatory and inhibitory neurotransmission. HISS consisted of two daily acoustic stimulations (1 minute of 120 dB broadband noise) for ten days. Animals were observed before, during and after HISS and individuals that presented seizures were discarded from this study. One week after the last stimulus, animals were killed and their brains were removed and sliced for electrophysiology. We observed that CA1 pyramidal neurons from chronically stimulated animals presented lower input resistance, and smaller membrane time constant, but similar resting membrane potentials and action potential threshold. Furthermore, we observed a decrease in the depolarization sag after a hyperpolarization in cells from stimulated animals suggesting a decrease in h current. On the other hand, both basal excitatory and inhibitory neurotransmission were not affected by HISS. Altogether, our findings show that cells HISS induce changes in electrical properties of CA1 neurons compatible with a reduced membrane excitability which could account, at least partially, for the inhibition of LTP induced by HISS.

Title: Discrimination of synthetic vowel sounds consisting of multiple formants: a potential rat model for discrimination of speech sounds.

Authors: *G. OGAWA, M. KUDOH;
Physiol., Teikyo Univ. Sch. of Med., Itabashi-ku, Japan

Abstract: Our previous work revealed that rats are capable of discriminating synthetic vowels consisting of multiple formants. Further, bilateral lesions of the auditory cortices impair this ability in the case of multiple formants, though discrimination of vowels consisting of single

formants remains unaffected, suggesting an important role for the auditory cortex in distinguishing among vowels consisting of multiple formants. However, it is unclear whether rats use the formant frequency as an acoustic cue for the discrimination of vowel sounds in the same manner as humans. In the present study, we examined whether discrimination of synthetic vowels was dependent on the frequency of the 1st (F1) and 2nd formants (F2) of the vowels. Rats were trained to distinguish between two tones in a Skinner box using a go/no-go format. Rewarded (S+) and unrewarded (S-) sounds were presented randomly in each trial for four days. The discrimination test consisted of synthetic vowels created using a terminal analog system and composed in the first and second formants corresponding to the human vowels /e/ and /a/. Test performance was defined as the difference observed in the rate of licking between S+ and S- sounds. Analysis of Spearman's rank correlation revealed that test performance was positively correlated with the differences between F1 and F2 in S+ and S- vowels ($y=18.92x+26.97$, $r_s=0.49$), indicating that F1 and F2 are critical for the discrimination of vowels. Test performance was further correlated with the difference between the F2/F1 ratios of S+ and S- vowels ($y=36.85x+20.39$, $r_s=0.51$), indicating that the F2/F1 ratio is critical for the discrimination of vowel sounds in rats, a finding similar to that observed for humans. The results of the present study indicate the capacity for discrimination of synthetic vowel sounds in rats and provide evidence supporting use of the rat as an animal model for studying the discrimination of speech sounds in humans.

Title: Calretinin- and vasoactive intestinal polypeptide- positive interneuron responses in auditory cortex following fear conditioning

Authors: *E. M. MEYER, P. ZMARZ, G. B. KELLER, A. LÜTHI;
Neurosci., Friedrich Miescher Inst. For Biomed. Resear, Basel, Switzerland

Abstract: Calretinin (CR)- and vasoactive intestinal polypeptide (VIP)- positive interneurons in auditory cortex primarily connect to other interneurons, putting them in an ideal position to provide disinhibitory drive from within cortical layer 2/3. Previous work from our lab showed disinhibition of pyramidal cells during learning in an auditory fear conditioning paradigm is crucial for memory acquisition. Whether this disinhibiton persists during expression of fear, as

well as the involvement of CR^+ and VIP^+ interneurons, remains unclear. We are using 2-photon calcium imaging in awake head-fixed adult mice to investigate CR^+ and VIP^+ interneurons in auditory cortex in mice before conditioning and during fear expression. In this paradigm, pyramidal cells continue to show an increased calcium response specific to the conditioned stimulus during the memory test, whereas responses to a neutral control tone are unaltered. This shows that the disinhibitory effect facilitating learning described previously persists beyond memory acquisition. CR^+ interneurons as a population show a diverse response to auditory stimuli; a major amount of those neurons is typically increasing their responses to the conditioned stimuli after learning, whereas responses to a neutral control stimulus are unchanged, or even reduced. VIP^+ interneurons seem not to alter their response properties to auditory stimuli during the paradigm. Taken together, CR^+ interneurons form a potential source of inhibitory drive unto other interneurons, leading to disinhibition of pyramidal cells in auditory cortex during fear expression.

Title: Associative plasticity in the auditory cortex induced by fear conditioning

Authors: *O. ZELENKA, O. NOVAK, J. SYKA;
Inst. of Exptl. Medicine, Acad. of Sci. of the Czech Republic, Prague, Czech Republic

Abstract: The sensory cortex is able to modify its function based on preceding experience in order to optimize processing of behaviorally relevant stimuli. In the auditory cortex, tonotopic reorganization follows various types of learning. Fear conditioning leads to expansion of the regions representing the conditioned stimulus. However, the extent of this plasticity as described by classical electrophysiological approaches has been unclear at the level of subpopulations of neurons. We used two-photon calcium imaging in vivo to investigate associative plasticity in the auditory cortex with single-cell resolution. Further, we wanted to elucidate plastic changes in receptive fields of somatostatin-positive interneurons (SST), because SST cells can influence

tuning of principal cells by inhibitory inputs to their distal dendrites. In somatostatin/tdTomato mice with an implanted chronic cranial window and neurons expressing an ultrasensitive calcium indicator GCaMP6 in the auditory cortex, we measured coding properties of exactly reidentified neurons before and after fear conditioning. In subsets of SST-negative neurons, both shifts towards the CS+ and CS- were present. The shift direction was dependent on neuron´s best frequency before fear conditioning. In some neurons no tuning shifts were observed, even when they were spatially intermingled with the retuned neurons. This evidence contradicts the view of simple expansion of CS+ tuned regions. SST+ cells retuned in a different manner than SST- cells with an upward BF shift independent on initial best frequencies. Behaviorally, these changes were accompanied by selective spatial attention towards the conditioned stimuli. The adaptive purpose of these learning-induced physiological and behavioral changes can be possibly explained as an information processing optimization, improving the ability to discriminate between threatening (CS+) and non-threatening (CS-) stimuli. The orienting responses towards CS+ were more often followed by escape behavior, instead of conventional freezing reactions.

Title: Regularity-dependent changes in neuronal adaptation in the awake rat auditory cortex

Authors: *B. H. GAESE;
Goethe Univ. Frankfurt, Frankfurt, Germany

Abstract: Adaptation to stimulus context is an ubiquitous property of cortical neurons and is thought to enhance the efficiency of sensory encoding. In the auditory cortex, this has been further related to the behavioral importance of stimuli, with neurons responding weakly to frequently repeated tones and strongly to rare tones in oddball paradigms. Such history-dependent adaptation suggests a functional significance in the context of novelty detection or (automatic) attentional focusing on important stimuli, strongly related to the 'mismatch negativity' signatures recorded from the scalp in humans.
As the prediction of future stimuli (i.e. the degree of novelty) is strongly related to the regularity

of stimulation in the preceding tone sequence, we tested this hypothesis for "predictive coding" further by systematically varying the regularity (sequential arrangement and temporal pattern) of stimuli while recording from different areas of the auditory cortex (A1, AAF, VAF, and SRAF) in awake rats. Chronically implanted movable electrodes allowed for recording of activity from multiple single neurons and of local field potentials simultaneously. A total of 217 neurons were recorded from six animals.
Neuronal characteristics and adaptation behavior was found to be significantly different between auditory fields. Neurons in primary fields (A1, AAF, VAF) were narrowly tuned to sound frequency and showed less stimulus-specific adaptation while responses in the secondary field (SRAF) were broadly tuned an exhibited strong adaptation in most cases. Regularity-dependent differences in adaptation related to stimulus history, however, were observed in the secondary field only. Neurons showed significant differences in adaptation between regular or more random sequential patterns of stimuli (standard/deviant).
Dependence on temporal regularity was tested by using either rhythm-like temporal patterns (regular repetition rate) or different inter-stimulus intervals for standard and deviant stimuli in several oddball paradigms. General adaptation was not influenced by sole changes in temporal regularity. Only local interactions between adjacent stimuli could be observed as expected by the mechanism of adaptation (i.e. stronger adaptation for reduced inter-stimulus intervals). Taken together, this indicates strong differences in adaptation behavior between cortical areas and the importance of secondary cortical areas for encoding of regularity dependence. Such encoding of higher-order interactions in stimulus sequences is necessary for the detection of unexpected acoustic event in natural environments.

Title: Neural circuit mechanisms for recognizing and predicting self-generated sounds

Authors: *D. M. SCHNEIDER, R. MOONEY;
Dept. of Neurobio., Duke Univ., Durham, NC

Abstract: Almost every movement that we make produces sounds. Auditory guided behaviors such as learning to play a musical instrument are thought to depend upon the recognition of self-generated sounds and upon the accurate distinction of self-generated sounds from environmental sounds. To recognize self-generated sounds, the brain may take advantage of the fact that the sounds our movements produce are time-locked to those movements with a short temporal delay and have stable acoustic features from one execution to the next. Here, we ask whether the brain can take advantage of this tight statistical coupling to recognize and predict the acoustic outcome of an action. We developed an acoustic virtual reality (aVR) paradigm in which we can precisely control and manipulate the timing, spectral features and predictability of the sounds produced by a mouse's movements. Using multi-electrode array recordings from large populations of auditory cortical neurons, we find that after several hours of experience in aVR, neural responses to expected self-generated sounds are strongly suppressed, whereas neural responses to unexpected sounds are largely unaffected. This selective suppression of predictable self-generated sounds is absent in the auditory thalamus, indicating that it arises de novo in the auditory cortex. Longitudinal 2-photon calcium imaging of large populations of GCaMP6f+ excitatory neurons in layer II/III of the auditory cortex shows that predictive suppression of self-generated sounds arises in parallel with aVR experience. In ongoing experiments, we are imaging and manipulating the activity of genetically identified inhibitory populations within the auditory cortex to test their role in mediating predictive suppression of self-generated sounds. In addition, we are testing the idea that long-range projections from the motor to the auditory cortex may play a role in binding a particular movement to the sound it produces. Together, these experiments hold the promise of elucidating how the brain learns, stores, updates, and recalls memories about self-generated sounds, and how the brain uses these memories to guide behavior.

Title: Echoic memory for very short meaningless stimuli: barely heard but robustly encoded

Authors: *J. VISWANATHAN[1,2], F. RÉMY[1,2], S. J. THORPE[1];
[1]CerCo, CNRS UMR 5549, Toulouse, France; [2]Univ. of Toulouse III - Paul Sabatier, Toulouse, France

Abstract: Introduction: Humans are remarkably good at recognizing repeating patterns in meaningless auditory noise. Using the frozen noise paradigm (Guttman, N., and Julesz, 1963), it was recently shown that implicitly-encoded features in noise could be retained in memory for several weeks (Agus, Thorpe, & Pressnitzer, 2010). Recently, we explored the robustness of memory for these meaningless features (which could not be rehearsed) using a similar implicit learning paradigm. We found that participants had long-term memory for degraded versions of the learned sounds (sounds were degraded by changing their temporal origin or by scrambling using 20- and 10-ms bins). These previous results raised several questions regarding mechanism(s) of auditory noise learning, parameters affecting robustness of recognition as well as the role of the cyclic nature of the stimuli (learning context) in recognition. Methods: We addressed these questions using a novel auditory localization task, in which participants were presented simultaneously with cyclic Gaussian noise (CN) in one ear and non-cyclic Gaussian noise in the other ear, and were asked to localize the CN. Learning and testing sessions were 4 weeks apart. We collected EEG data during both sessions. During the learning session, some of the CNs were presented multiple times in the same ear. CNs were either 10, 80, 150, 340 or 500 ms in length, repeated 25 times. During the testing session, participants performed passive listening tasks, auditory localization tasks, as well as explicit recognition tasks. Results: Participants showed a performance increase when localizing old 10-ms CNs vs. novel CNs with 4, 8 and 16 repeats, 4 weeks after the learning session. This effect was sub-conscious; in an explicit recognition task, participants were unable to differentiate old from novel CNs (150 ms). The event-related spectral perturbations (ERSPs) induced by 10-ms segments of old CNs (500 ms) and 10-ms novel CNs were compared. The power of alpha waves in response to old CN segments was significantly lower than the power of alpha waves in response to novel CNs, both immediately after sound onset and in the N100 component. Discussion: These results show that participants could better localize very short segments of old vs. novel CNs, without any conscious awareness of this ability. Moreover, this memory for short temporal features in old CNs was independent of the cyclic context in which features were encoded. Finally, the difference in ERSPs between old and novel CNs indicate that new sounds elicited higher activation in the neural sources of the primary auditory cortex contributing to the N100 component.

Title: Cortical mechanisms of perceptual learning

Authors: *M. L. CARAS[1], D. WANG[2], D. H. SANES[1];
[1]Ctr. for Neural Sci., [2]New York Univ., New York, NY

Abstract: Auditory perceptual learning is defined as a long-term improvement in the detection or discrimination of acoustic stimuli. One broadly held hypothesis is that core auditory cortex plays a critical role in the perceptual learning process. To test this idea directly, we manipulated auditory cortical activity while Mongolian gerbils (*Meriones uniguiculatus*) trained on an aversive Go-Nogo amplitude modulation (AM) detection task. We reversibly attenuated auditory cortical activity bilaterally, via a low dose of muscimol, during perceptual training. Muscimol infusions impaired behavioral improvement while still permitting animals to generate psychometric functions. This finding suggested that either muscimol infusion prevented learning from occurring, or prevented its expression. To distinguish between these possibilities, we exposed the same animals to additional training sessions during which saline was infused into auditory cortex. Training paired with saline infusions improved detection thresholds. Together, these findings indicate that reducing auditory cortical activity during training prevents perceptual learning.

To establish a quantitative relationship between auditory cortical activity and perceptual learning, we implanted chronic microelectrode arrays into left auditory cortex of a separate group of naïve animals. We wirelessly recorded single and multi-unit activity as animals trained on the AM detection task described above. Neurometric sensitivity was tracked across days and directly compared to psychometric performance. As performance improved, we observed a significant correlation between simultaneously recorded neural and behavioral thresholds within individual animals. However, when recordings were made from animals while they were disengaged from the task, we found that neural thresholds remained relatively constant across days and were not correlated with behavioral performance. Collectively, our results suggest that auditory training leads to task-dependent enhancements of cortical sensitivity that ultimately support perceptual learning.

Title: True deviance sensitivity in awake freely moving rats

Authors: A. POLTEROVICH, *M. M. JANKOWSKI, I. NELKEN;
The Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: Stimulus-specific adaptation (SSA) is the decrease in responses to a common stimulus that does not generalize, or only partially generalizes, to other stimuli. SSA is usually measured using oddball sequences, in which a common (standard) tone and a rare (deviant) tone are randomly intermixed. The larger responses to a tone when deviant, however, do not necessarily represent true deviance sensitivity. They can be explained by the tone not being adapted when deviant due to its rarity. Another possible explanation is that the tone when deviant violates the expectation to hear a standard tone, thus the larger response to it is deviance detection. A common test for deviance sensitivity uses a 'deviant among many standards' control sequence, where many different tones serve as the 'standard', thus eliminating the deviance of the deviant. When the response to the same tone when deviant (against a single standard) is larger than the responses to the same tone in the control sequence, it can be concluded that true deviance sensitivity occurs. In anesthetized rats, responses to deviants and to the same tones in the control condition are comparable in size. We recorded local field potentials and multiunit activity from auditory cortex of awake, freely-moving rats, implanted with 32-channel drivable microelectrode arrays and using telemetry. We observe highly significant SSA (deviant>standard) in the awake state. Moreover, the responses to a tone when deviant were significantly larger than the responses to the same tone in the control condition. These results establish the presence of true deviance sensitivity in primary auditory cortex in the awake state.

Title: Auditory detection learning alters the cortical population response via muscarinic receptors.

Authors: *D. T. BLAKE[1], E. CARPENTER-HYLAND[2], J. GRIFFETH[3], A. V. TERRY, Jr[4], A. VAZDARJANOVA[5];
[1]Brain and Behavior Discovery Inst., Med. Coll Georgia/Augusta Univ., Augusta, GA; [2]Neurobio., Morehouse Sch. of Med., Atlanta, GA; [3]Neurol., [4]Pharmacol. and Toxicology, Augusta Univ., Augusta, GA; [5]Pharmacol. and Toxicology, Augusta Universtiy and Charles Norwood VAMC, Augusta, GA

Abstract: Plasticity in sensory cortex is critical for perceptual learning, and is hypothesized to involve acetylcholine modulating neuralresponses. Rats learned to detect a brief, pure frequency sound, and then performed detection for three behavioral sessions. The fourth day, acoustically activated responses were sampled in primary auditory cortex. Overall responsiveness became elevated, although the proportion of the response dedicated to the target decreased. On the third behavioral session in some animal groups, rats were treated with scopolamine to block muscarinic receptors, or mecamylamine to block nicotinic receptors. Either treatment significantly reduced performance on the third day, but neither treatment significantly affected performance on the fourth day. The muscarinic block group had signiticantly lower responsiveness in auditory cortex on the fourth day. However, a significant increase in strength in the late phase of the response emerged. This late phase response was selective for the target in frequency and intensity which suggests the muscarinic block interacted with an activity-dependent mechanism. Nicotinic receptor antagonism on the third day neither lowered day four responsiveness nor did it alter the late phase response. However, nicotinic antagonism had a larger acute effect on neural activity than muscarinic antagonism. Second messenger pathways intrinsic to muscarinic receptor activation may work to keep balance between the initial and late phase of the response. After three days of acoustic detection training, middle cortical lamina spiking responses show no improvement in neural signal despite significant detection learning.

Title: Cross-frequency coupling increases during adaptation of high-gamma responses in human auditory cortex

Authors: *U. MALINOWSKA[1], P. FRANASZCZUK[1,3], N. E. CRONE[1], D. BOATMAN-REICH[1,2];
[1]Neurol., [2]Otolaryngology, Johns Hopkins Sch. of Med., Baltimore, MD; [3]US Army Res. Lab., Human Res. and Engin. Directorate, Aberdeen Proving Ground, MD

Abstract: Introduction. Cortical high-gamma oscillations (>70 Hz) are implicated in human auditory perception and exhibit adaptation with stimulus repetition, also known as repetition suppression. Although high-gamma has been shown to be coupled in phase and amplitude with lower cortical frequencies including theta (4-7 Hz) during auditory perception, the role of phase-amplitude coupling in adaptation has not been investigated.
Methods. We examined effects of stimulus repetition on phase-amplitude coupling of theta and high-gamma using intracranial electrocorticographic (ECoG) recordings. ECoG recordings were acquired from five right-handed epilepsy patients (ages 24-56 yrs; 4 female) with subdural 8x8 electrode arrays (2.3 mm diameter electrodes; 9 mm spacing) implanted over lateral left temporal cortex, including superior temporal gyrus. The experimental paradigm was a 300-trial passive auditory oddball task comprising consecutively repeated (1-12 repetitions; 82% trials) tone or speech stimuli (1000 Hz, /ba/) and a second stimulus (1200 Hz; /da/) presented infrequently and non-consecutively while subjects watched a silent video. Time-frequency matching pursuit analysis of the ECoG time-series signals was performed to identify sites with statistically significant ($p<0.05$) increases in high-gamma power (70-150 Hz). Normalized repetition suppression index (RSI) values ranging from -1 to 1 were computed for all sites based on mean log power density estimates. At sites with positive RSI values, consistent with adaptation, phase-amplitude coupling was computed as the phase-locking value of theta (4-7 Hz) phase and high-

gamma amplitude across consecutive frequent stimulus trials (repetitions).
Results. A total of 29 sites located in traditional auditory areas showed high-gamma adaptation for speech (mean 6/subject; range 4-7). Of these, 23 sites (79%) showed repetition-related increases in phase-amplitude coupling. Phase-locking values increased by an average of 10% when measured over five consecutive trials. Similarly, 10 electrode sites in auditory cortex showed high-gamma adaptation for tones, eight (80%) of which also showed repetition-related increases in phase-amplitude coupling, with a mean increase of 11% in phase-locking values.
Conclusions. Our results indicate that repetition of simple and complex auditory stimuli is associated with attenuation of high-gamma response power (adaptation) and increased cross-frequency coupling at the same cortical sites, potentially reflecting optimization of the underlying cortical processing networks.

Title: Rapid adaptation to changing signal conditions in human auditory cortex

Authors: ***H. BAI**[1], L. K. LONG[2], T. NAGAMINE[1], A. D. MEHTA[3], N. MESGARANI[1]; [1]Electrical Engin., [2]Columbia Univ., New York, NY; [3]Feinstein Inst. for Med. Res., Manhasset, NY

Abstract: Humans are experts at perceiving spoken language, even in the presence of interfering sound sources. However, the dynamic neural mechanisms required to understand speech in noise are largely unknown. To understand how the auditory system adapts to extract speech during irregular additive and reverberant distortions, we used invasive technology to record auditory cortical responses in neurological patients as they listened to continuous speech stimuli while the background noise changed every three seconds. Analysis of the neural responses to the speech signal as the background noise changed revealed an adaptation phase after the onset of a novel noise. Directly after noise onset, the neural representation of speech features degraded, then

adaptation gradually restored these features. We quantified the degradation of the neural representation using discriminative analysis of phonetic features and stimulus reconstruction techniques. To explore possible mechanisms that could contribute to this dynamic response property, we constructed a neural network model to map the speech stimulus to the neural responses. A simple feedforward network model failed to replicate the temporal adaptation of neural responses to the changes in the background. We then incorporated feedback mechanisms into the model based on 1) synaptic depression models and 2) the statistical structure of neural co-activation patterns. We found that these mechanisms allowed the model to replicate the temporal dynamic properties of the neural response at noise transitions. The proposed model thus offers insight into biologically plausible computational mechanisms that can explain the robust speech perception observed in real-world hearing conditions.

Title: Hierarchical mismatch responses to auditory sequences in the human brain

Authors: *P. LEUNG[1], R. E. ROSCH[2], K. J. FRISTON[2], T. BALDEWEG[3];
[1]Inst. of Neurol., [2]Wellcome Trust Ctr. for Neuroimaging, [3]Ctr. for Developmental Cognitive Neuroscience, Inst. of Child Hlth., Univ. Col. London, London, United Kingdom

Abstract: The mismatch negativity (MMN) is a commonly observed evoked response to disruptions of regular stimulus sequences. Recently there has been an interest in understanding the mismatch responses to disruptions of regularities at different temporal scales. These short-term (stimulus to stimulus repetition) and longer-term (recurring patterns of stimuli) regularities can be modulated experimentally using novel variations of auditory oddball paradigms. Dynamic causal modelling (DCM) is a connectivity analysis of electroencephalography (EEG) data to make inferences about changes in coupling among cortical regions that explains observed EEG phenomena. DCM furnishes generative models for evoked response potentials, providing an advanced computational modelling analysis with biophysically plausible constraints on the model inversion based on empirical data.

Here we present an analysis of mismatch responses to a novel, hierarchically structured oddball paradigm. Healthy adults underwent EEG recordings during a task free auditory paradigm where both 'local' disruptions of repeated stimuli trains, and 'global' disruptions of recurring patterns were present. We conduct a DCM analysis to evaluate network-wide changes in cortical dynamics and further understand the cortical origin of the observed mismatch responses at the two different temporal scales. The experimental effects are modelled as changes in synaptic gain at different levels of the cortical hierarchy (primary auditory cortex, superior temporal gyrus, inferior frontal gyrus) and Bayesian model selection is used to identify the model that best explains the data. The approach presented here utilises recent advances in DCM for group studies (parametric empirical Bayes, Bayesian model reduction), which allows for computationally efficient inversion of large neuronal models for individual participants in order to evaluate the overall group effects.
The novel paradigm presented here reproduces the known MMN response, as well as identifying specific mismatch responses to longer temporal scale disruptions of regularity. DCM allows interpretation of the different evoked responses in terms of synaptic changes and the hierarchical deployment of underlying cortical sources. This approach provides a deeper mechanistic understanding of mismatch responses at different temporal scales, and delineates how the cortical hierarchy processes sequences of auditory stimuli.

Title: Contrast gain control in auditory thalamus

Authors: *M. LOHSE, B. D. B. WILLMORE, V. M. BAJO, A. J. KING;
Dept. of Physiology, Anat. and Genet., Univ. of Oxford, Oxford, United Kingdom

Abstract: Contrast gain control has been identified in the visual, auditory and somatosensory systems. Gain control is beneficial because the statistics of the sensory environment are constantly changing, meaning that neurons may not be able to accurately represent the range of stimulus values that occur at any moment unless they are able to adapt their dynamic ranges to match that range. Furthermore, adaptation to sound contrast may also provide a useful

mechanism for generating noise-invariant neural representations of complex sounds. In the auditory system, previous work has demonstrated robust contrast gain control in ferret auditory cortex (Rabinowitz/Willmore et al., 2011), and limited contrast gain control in the auditory midbrain (Rabinowitz et al., 2013). It is currently unknown whether the robust contrast gain control seen in cortex is computed locally in the cortex or whether it reflects a thalamic computation which is relayed to cortex. To determine the site of robust contrast gain control in the auditory system, we recorded with extracellular electrode arrays from auditory thalamus in anesthetized mice. We presented dynamic random chord stimuli at two different contrasts, and similar mean sound level. We fitted the neuronal responses with a linear spectro-temporal receptive field and sigmoid output nonlinearities for each contrast. To estimate the gain of each unit, we examined the parameters of the sigmoid output nonlinearities. We found that the auditory thalamus exhibits robust auditory contrast gain control, similar to that previously found in cortex, suggesting that the thalamus does indeed have a role in computing contrast gain control. We are currently conducting similar recordings in auditory thalamus while inactivating auditory cortex, to investigate whether the contrast gain control seen in auditory thalamus arises through cortico-thalamic feedback from primary auditory cortex or is implemented within the thalamus itself.

Title: Does long lasting exposure to non-traumatic industrial noise affect differentially the auditory cortex in adult vs. immature rats?

Authors: F. OCCELLI, B. GOURÉVITCH, *J.-M. EDELINE;
Paris Saclay Inst. Of Neurosci. Neuropsi, Orsay Cedex, France

Abstract: Over the last decade, an increasing number of studies have reported that noise exposure at non-traumatic sound levels (<85dB) can lead to important alterations in the responses of auditory cortex neurons. For example, studies have described reduced neuronal responses in the noise frequency band, alterations of tonotopic maps and even behavioral deficits (Norena et al 2006; Zhou & Merzenich 2012, Zheng 2012). Here, we evaluated the consequences

of long-lasting exposures (3 months, starting at 2 months old) to an industrial ("realistic") non-traumatic noise (80dB SPL, 8h/day) on the rat auditory system. We compared these data with those obtained from rats exposed for 3 months at the age of P5. Based upon Auditory Brainstem Responses, thresholds were higher for the young exposed animals compared with the young non-exposed ones, an effect that was no longer present 1 month later. This suggested that a potential TTS occurred after 3 months of exposure in young rats exposed at the age of P5. This potential TTS effect was not observed in adult rats. Analyzing the cortical evoked responses revealed several differences between the P5 exposed rats and the control rats, but only when the exposed P5 rats were tested in less than 24h after exposure. These differences were: First, the tuning was broader as quantified by the Q10dB, Q20dB and by the bandwidth at 75dB. Second, within the receptive field, the firing rate of auditory cortex neurons was higher in the exposed animals than in the control animals. Third, the percentage of neurons responding to a short gap of silence in a vocalization was much higher in exposed P5 rats than in control rats. In contrast, in the auditory cortex of adult animals (exposed at 2month old), there was no effect of the 3-months exposure whatever the stimulus (artificial or natural stimuli) and the parameter used to quantify the neuronal responses. Altogether, these results suggest that exposure to non-traumatic industrial noise has a larger impact when occurring at hearing onset than when occurring in adult animals. However, these effects do not seem to persist over time, they dissipated within a month.

Title: Rapid adaptation to the timbre of natural sounds

Authors: *E. A. PIAZZA[1], F. E. THEUNISSEN[2], D. WESSEL[3], D. WHITNEY[2];
[1]Princeton Univ., Princeton, NJ; [2]Dept. of Psychology, [3]Dept. of Music; Ctr. for New Music and Audio Technologies, Univ. of California, Berkeley, Berkeley, CA

Abstract: Timbre allows us to quickly identify threatening animal growls, pick out a friend's nasal voice among a crowd, and enjoy a rich variety of musical textures, from the bright buzz of

a muted trumpet to the crisp attack of a snare drum. Often defined as tone color, or the unique quality of a sound, timbre cannot be attributed simply to pitch, intensity, duration, or location. However, despite its critical contributions to our everyday auditory experiences, it is unclear whether timbre truly represents a meaningful auditory configuration rather than an arbitrary collection of low-level features: if so, listeners should adapt to timbre, and this adaptation should generalize across changes in lower-level features (e.g., pitch). Here, we used a range of complex sounds equated in basic auditory features to investigate timbre adaptation. For each of several sound classes (musical sounds, natural sounds, or isolated timbre dimensions), participants adapted to one of two sounds (e.g., clarinet and oboe, male and female voice) that formed the endpoints of a morphed continuum. After repeated exposure to one of the two adapter sounds, participants judged the identity of the various morphed sounds. We found consistent negative aftereffects resulting from timbre adaptation, such that adapting to sound A significantly altered perception of a neutral morph between sounds A and B, making it sound more like B. Importantly, these aftereffects were robust and invariant to changes in pitch, suggesting that they stem from adaptation to the global, spectro-temporal configuration of complex sounds and can survive the lower-level feature shifts that naturally vary (largely independently of timbre) in the environment. This adaptation, which is likely exploited by composers, could serve to enhance our sensitivity to novel or rare auditory objects, such as a new soloist in an orchestra or a new voice in a crowd.

Title: Auditory Categorization in the Rhesus Macaque

Authors: *A. GARCIA, M. MISHKIN, R. C. SAUNDERS;
Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Studies of auditory recognition memory in macaques strongly suggest that monkeys cannot encode sounds into long-term storage. Animals performing auditory delayed match-to-sample (DMS) paradigms require tens of thousands of trials to acquire the DMS rule at short intervals and then fall to chance levels when intervals are increased beyond 30 seconds. These findings directly contradict ethological observations which report the ability of free-ranging monkeys to accurately discriminate individuals' calls. However, one proposed avenue by which this discrimination may occur in the wild is not through traditional recognition structures in the medial temporal lobe, but through repeated exposure during development via the habit formation pathway of the neostriatum. Monkeys may acquire "caller identity" through constant group interactions in a troupe setting. Supporting this method of auditory stimulus acquisition, previous work in our lab has shown that animals can learn a simple, two-choice auditory discrimination task and retain which stimulus is rewarded for at least two weeks. In the present study, we sought to assess the cognitive limits of these learned habits by investigating whether monkeys could utilize a small set of stimuli to form a category of rewarded acoustic features, e.g. vocalizations. In a two-choice discrimination task, monkeys were trained on a series of three coo pairs from two unfamiliar monkeys. After achieving a 9/10 criterion on a given pair they were moved onto the next. Upon reaching criterion on all three exemplar pairs, the animals were given 140-trials of trial-unique coo pairs as a performance test to assess their ability to generalize across novel coos from the two callers. Preliminary data shows that, on average, monkeys performed significantly better on their performance tests than the first 140 trials on the first exemplar presented (70.0% for trial unique, 48.3% for pair 1, $p = 0.0047$). These findings suggest that these animals are capable of generalizing across similar auditory stimuli in a cognitively flexible fashion—despite being acquired in an incremental manner. Further work will need to be done to investigate whether this generalization depends on the cognitive memory systems of the medial temporal lobe or the habit system of the neostriatum.

Title: Origin of spontaneous activity in the auditory system following noise induced hearing loss

Authors: *C. H. PARSONS, N. D. SOBARUN, J. W. MORLEY;
Western Sydney Univ., Sydney, Australia

Abstract: Noise-induced hearing loss may induce a range of changes in the auditory system. For example, increased spontaneous activity, increased synchrony of spontaneous activity and cortical tonotopic map reorganization, have been shown to occur after noise-induced hearing loss. These changes within the auditory system have been proposed as a neural mechanism responsible for the perception of tinnitus. While increased spontaneous activity following noise-induced trauma has been observed in most auditory nuclei, it is not known whether it is generated at a particular site (or sites) in the auditory path and then propagated throughout the rest of the auditory system. In other words, is there a specific nucleus in the auditory pathway that is responsible for the generation of spontaneous activity? In this study, we unilaterally exposed Male Long Evans rats (aged 3-4 months) to a 115 dB SPL 16 kHz 1/10th octave bandpass noise for 1 hour. Unexposed rats served as controls. Hearing was assessed using auditory brainstem response audiograms, before and at different time-points following the noise trauma procedure. All noise-exposed animals in the study showed a frequency-specific, permanent threshold shift in their exposed ear, while hearing in their non-exposed ear was in the normal range. After 4-5 months we recorded spontaneous, extracellular activity from cochlear nucleus, inferior colliculus and auditory cortex. Recordings from these nuclei were made simultaneously, using 32 or 64 channel electrode arrays. Rats were anaesthetized with a mixture of ketamine and medetomidine. Baseline spontaneous activity was recorded for 10 minutes, followed by 5 minutes exposure to a series of noise bursts (80 dB SPL) to temporarily suppress spontaneous activity. We then recorded spontaneous activity for a further 20 minutes to observe the return of spontaneous activity to baseline. Our aim was to determine if spontaneous activity returned to baseline levels in one of the nuclei before the others. Controls and noise-exposed animals showed a reduction in spontaneous activity relative to baseline after 5 minutes of moderate noise exposure. Over the 20 minute recovery period, spontaneous activity in both groups returned to values approaching baseline. This occurred in all 3 nuclei under study.

Title: Mechanisms of movement-related changes in auditory thresholds

Authors: *J. SUNDARARAJAN, R. MOONEY;
Duke Univ., Durham, NC

Abstract: Movements can suppress neural responses to acoustic stimuli in the auditory cortex of humans and other mammals. An influential but largely untested idea is that this cortical suppression works to minimize responses to predictable acoustic consequences of movement, while enhancing sensitivity to novel stimuli. Notably, recent work has described a circuit that could mediate these suppressive effects: A subset of motor cortical neurons sends axons to the auditory cortex, where they synapse on inhibitory neurons that suppress the activity of excitatory cells. Moreover, this circuit is both necessary and sufficient to drive movement-related suppression of auditory cortical activity. However, how this cortical suppression influences auditory perception and whether this suppression functions predictively, as widely theorized, remain unknown. To explore these issues, we designed a virtual acoustic reality setup where head-fixed mice are trained using operant methods to detect and lick in response to tone pips of varying intensities while they are either at rest or running on a quiet treadmill. Using this approach, we observed that movement elevates tone detection thresholds. Furthermore, pharmacological inactivation of the auditory cortex also severely elevated tone detection thresholds, consistent with the idea that the auditory cortex is an important component of a circuit for detecting tones in our task. Currently, we are exploring whether movement-related suppression of auditory cortical activity accounts for movement-related changes in auditory thresholds.

Title: Inhibition of LTP in the hippocampal Schaffer-CA1 pathway by one minute of high-intensity noise

Authors: J. D. LARA[1], A. O. S. CUNHA[2], *R. M. LEAO[3];
[1]Physiol., Univ. of São Paulo, Ribeirão Preto, Brazil; [2]Physiol., [3]Univerisity of São Paulo, Ribeirão Preto, Brazil

Abstract: The acoustic stress and trauma caused by high intensity sound is an common occupational and environmental problem related with increasing exposure to loud sounds. Long-term potentiation (LTP) is a long lasting synaptic potentiation traditionally associated with learning and memory events, which can be altered by stressors agents. We recently demonstrated that rats submitted to two daily exposures to high intensity noise (110 dB for one minute) for 10 days presented a strongly reduced LTP in the Schaffer-CA1 pathway of the hippocampus. The aim of this study was to investigate the effect of acute stimulation with high-intensity noise on the hippocampal LTP. Wistar rats of 60-70 days were submitted to a single sound stimulus of intensities of 110 or 80 dB during 1 min. After 2, 24 and 48 hours of stimulation, rats were anesthetized with isoflurane, sacrificed, their brains removed and 400 μm slices of the dorsal hippocampus prepared using a vibratome. For induction of LTP, a train of three high frequency (HF) pulses at 100 Hz (1 second duration each) were given in Schaffer-collateral pathway and field excitatory posts-synaptic potentials were recorded in the stratum radiatum of CA1 region. Data are presented normalized by the baseline obtained before the HS train. We observed that a single stimulus of 110 dB for one minute significantly inhibits the post-tetanic potentiation (PPT) from 2.45 ± 0.27 (control) to 1.28 ± 0.10, 2 hours after the stimulus and reverted to normal values after 24 hours (2.19 ± 0.13). Regarding the LTP (80 minutes after HF train) we observed a significant decrease 2 hours after stimulation (1.08 ± 0.39) in comparison to control (1.32 ± 0.75), lasting 24 hours after stimulation (1.09 ± 0.86) and recovering 48 hours after (1.35 ± 0.10). The group of animals that received 80 dB present no changes in PTP (2.38 ± 0.21) and LTP (1.39 ± 0.09) 2 hours after stimulation. Our results showed that exposure to a brief 110 dB noise is sufficient to inhibit hippocampal LTP after 2 hours of the one-minute high-intensity noise exposure, with these effect lasting 24 hours and reverting 48 hours after the stimulation. Furthermore, we found that this effect was not observed in animals exposed to non-traumatic noise (80 dB). We concluded that a short event of high intensity noise has the potential to inhibit hippocampal synaptic plasticity, which could have consequences to cognitive and emotional aspects of the animal, and potentially for humans exposed to traumatic sound.

Title: Evolutionary origins of non-adjacent rule processing in primate brain potentials

Authors: *A. E. MILNE[1], J. L. MUELLER[2], C. MÄNNEL[3], A. ATTAHERI[1], A. FRIEDERICI[3], C. I. PEKTOV[1];
[1]Inst. of Neurosci., Newcastle Univ., Newcastle Upone Tyne, United Kingdom; [2]Inst. of Cognitive Sci., Univ. of Osnabrück, Osnabrück, Germany; [3]Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: There is considerable interest in understanding the ontogeny and phylogeny of the human language system, yet, empirical work at the interface of both fields is rarely conducted. Syntactic processes in language build on both sophisticated sensory processing and sequencing capabilities on the side of the receiver. While insights on the development of auditory perception and non-adjacent sequencing operations in the human brain have expanded, we lack knowledge on whether and how these processes are implemented in the brains of our primate relatives. In the present nonhuman primate study we used a paradigm initially developed to evaluate human infant and adult brain potentials associated with the processing of non-adjacent dependencies in auditory sequences. We measured scalp-recorded event-related potentials (ERPs) from two macaque monkeys listening to syllable triplets. Frequent standard triplet sequences were interspersed with infrequent voice pitch or non-adjacent rule deviants. Monkey ERPs revealed early pitch and rule deviant mismatch responses that are strikingly similar to those previously reported in human infants in response to the same stimuli material, suggesting similar automaticity in processes. This stands in contrast to adults' later ERP responses for rule deviants, indicating less automaticity in sequencing functions. The results reveal the evolutionary origins of non-adjacent sequencing operations in the primate brain and they provide evidence for evolutionarily conserved neurophysiological effects, some of which are remarkably like those seen at an early human developmental stage.

Title: Unsupervised learning and recognition of vowel sequences in the auditory cortex

Authors: *S. TEKI, B. D. WILLMORE, A. J. KING;
Dept. of Physiology, Anat. and Genet., Univ. of Oxford, Oxford, United Kingdom

Abstract: The ability to recognize and predict patterns in sensory input is a fundamental feature of the brain. Learning to process sequential information is particularly important in audition, and underpins speech recognition and language acquisition. In this study, we aimed to examine the neural representation of repeated auditory sequences in the auditory cortex of the ferret, following the experimental paradigm reported by Gavornik and Bear (2014). A sequence of four artificial vowels (Bizley et al., 2009), termed ABCD, with each letter denoting a unique fundamental frequency, was presented to an experimental group of ferrets (n = 2) on four consecutive training days. The control group of ferrets (n = 2) was presented with random permutations of the same sequence elements (e.g. CDAB, BCDA etc.). Sound presentation was delivered through headphones to the passively listening ferrets that were implanted with 16 channel multi-electrode arrays in the primary auditory cortex in each hemisphere. On the fifth day, both groups were presented the trained sequence as well as a novel sequence, obtained by reordering the same elements (e.g. DCBA). We measured local field potentials in response to the two sets of test stimuli. Using the same paradigm, other experiments tested the transfer of learning from a trained ear to an untrained ear, the temporal specificity and predictive aspects of learning, as well as the robustness of the sequence learning effects. Gavornik and Bear (2014) observed enhanced field potentials and multiunit spiking activity in response to the repeated sequence (ABCD) relative to the novel sequence (DCBA) in an experimental group of mice, but no difference in responses to the two stimuli in the control group. The present set of experiments aim to examine whether auditory cortical responses to repeated sequences show enhancement, as observed by Gavornik and Bear (2014) in the primary visual cortex, or whether they are suppressed, in line with previous reports of stimulus-specific adaptation in the auditory cortex (Ulanovsky et al., 2003). Title: Neural correlates of incidental learning in the mouse inferior colliculus.

Authors: H. CRUCES SOLIS[1,3], O. BABAEV[2,3], Z. JING[4], N. STRENZKE[4], *L. DE HOZ[1]; [1]Dept. of Neurogenetics, Max Planck Inst. of Exptl. Med., Goettingen, Germany; [2]Max Planck Inst. of Exptl. Med., Göttingen, Germany; [3]Intl. Max Planck Res. Sch. for Neurosciences, Göttingen, Germany; [4]InnerEarLab, Univ. Med. Ctr., Göttingen, Germany

Abstract: The auditory system is constantly processing the surrounding auditory world in order to filter the relevant sounds. The system must, thus, be able to compute the statistics of the acoustic environment. We hypothesize that the inferior colliculus (IC) is an important player in this process. We investigated the effect that sound exposure had on IC neuronal activity as well as on incidental learning.

Associative and random sound exposure was done in the Audiobox, an automated apparatus for continuous monitoring of behaviour where mice live in groups for several days. Food was available *ad libitum* in the home-cage while water could be obtained in a connected 'corner'. Incidental learning was triggered by exposing mice to 16 kHz pips for the duration of each of the >50 daily visits to the ‘corner’ (exposed group). Sound was, thus, triggered by the mouse entering the corner and was associated with the water area but played no role in water availability. A 'random' group was exposed to 16 kHz pips in a similar temporal pattern but randomly in the Audiobox home-cage. The amount of sound exposure was the same as in the ‘exposed’ group but the tone was not associated with anything in particular. A third 'control' group had no specific sound exposure but lived in the Audiobox for a comparable amount of time (6-12 days).

Acute recordings in the central nucleus of the IC of these mice revealed an upward shift in best frequency along the tonotopic axis and a frequency-unspecific increase in evoked multiunit activity in 'exposed' mice with respect to controls. In the 'random' group the best frequency shift was significantly milder than in 'exposed' animals. Mice in the ‘exposed’ group had stronger spontaneous activity and a broader bandwidth at the base of the tuning curve. The same sound exposure had no visible effect in upstream structures such as the cochlear nucleus. Muscimol inactivation of auditory cortex revealed that the expression of the described changes was not the result of corticofugal input.

Associative and random exposure resulted also in different levels of incidental learning. The 'exposed' group showed stronger latent inhibition of the exposed sound than either of the other two groups as well as wider ranges of generalization in pre-pulse inhibition.

We conclude that adult experience results in plastic changes in sound processing at subcortical levels and that these changes correlate with patterns of incidental learning. We hypothesize that the IC is one neural substrate of auditory incidental memory.

Title: Effect of fear conditioning on stimulus specific adaptation to complex sounds in freely moving animals

Authors: *A. YARON[1,2], M. JANKOWSKI[2], R. BADRIEH[3], I. NELKEN[2];
[1]Neurobio., Neurobio., Jerusalem, Israel; [2]the Edmond and Lily Safra Ctr. for Brain Sci., [3]Neurobio., Hebrew university, Jerusalem, Israel

Abstract: Stimulus-specific adaptation (SSA) is the reduction in responses to a common stimulus that does not generalize, or only partially generalizes, to other stimuli. Previous studies have demonstrated stimulus specific adaptation (SSA) in primary auditory cortex of many mammalian species to a variety of sound stimuli. SSA has been studied mainly in sounds with no behavioral relevance. We hypothesized that a behaviorally meaningful sound should show less adaption compared to the same sound when it doesn't have a behavioral meaning.
To test this hypothesis, we used discriminative fear conditioning in rats, using two word-like stimuli. One stimulus (derived from the word "Danger": CS+) was coupled with foot shock whereas the other stimulus (derived from the word "Safety": CS-) was presented without a concomitant foot shock. In order to verify learning, rats were tested for the amount of freezing to the two stimuli on the day following conditioning. In addition, we used pseudo-conditioning (using the same stimuli without foot shock) and reverse conditioning (using 'Safety' as CS+ and 'Danger' as CS-).
We monitored neural responses to the auditory stimuli using a chronic implantation of multi-electrode arrays in the auditory cortex of the rats. We recorded responses telemetrically in freely

moving animals before, during, and after conditioning.
To test SSA, we recorded auditory responses to oddball sequences composed of the word stimuli in the days following conditioning. Our results show that in the animals conditioned to the word stimuli, SSA of the CS+ stimulus became smaller whereas SSA of the CS- stimulus increased. These results may suggest the sounds that are important behaviorally adapt less, presumably in order to remain highly detectable by the auditory system.

Title: Developing an objective test for tinnitus in humans

Authors: *C. A. WILSON[1,3], M. SEREDA[4], J. I. BERGER[2], A. R. PALMER[2], D. A. HALL[4], J. DE BOER[2], M. N. WALLACE[2];

Abstract: Gap-induced pre-pulse inhibition of acoustic startle (GPIAS) (behavioural test for tinnitus in animals) relies on a short gap in continuous background noise providing a cue to inhibit the response to a loud startling stimulus. Impaired GPIAS following tinnitus induction has been shown in a number of species, as well as in humans with tinnitus. Inhibition to detect the gap was originally thought to be caused by the tinnitus 'filling' the gap but there have been suggestions that another mechanism is involved. Preliminary work in humans measuring the eye blink reflex responses showed gap detection deficits in tinnitus subjects, but the underlying mechanisms of this effect were unclear (1). The eye blink response is not specifically related to the auditory system and subsequently has a relatively long latency (>40ms) that is subject to attentional modulation. We have developed a variation of the GPIAS method in which we measure GPIAS in guinea pigs using the reflex pinna movement. The post-auricular muscle reflex (PAMR) is the human analogue of the pinna reflex and may represent a route for developing an objective tinnitus test. The PAMR is a short-latency (10-12ms) response that involves two or three synapses in the brainstem and is more tightly linked to auditory input and less susceptible to attentional modulation. However, gap-induced pre-pulse inhibition (PPI) of the PAMR has not previously been demonstrated. In the present study, we measured gap-induced

PPI of the PAMR in 45 normal-hearing subjects. PAMR responses were recorded simultaneously with the eye blink reflex electromyographically with surface electrodes placed over the insertion of the post-auricular muscle to the pinna. Gap detection was evaluated with 1 kHz background sounds, presented monaurally to the right ear at 70 dB SPL, and startling stimuli comprising very brief broadband noise bursts presented at 105 dB SPL. The embedded gaps ranged from 20-100ms with the position of the gaps ranging from 20-500ms from the end of the gap to the onset of the startle stimuli. Eye direction has been shown to have a dramatic effect on the amplitude of the PAMR reflex (2). Therefore we investigated the effect of eye position - looking forward or to the right - on the amplitude of the PAMR reflex response. The data suggests that the PAMR is susceptible to gap-induced PPI, and the amplitude of the response is greater when the subject is looking to the stimulus presentation side. Future studies will establish whether deficits in gap detection using the PAMR are characteristic of subjects with tinnitus.

Title: Accuracy of arm position sense in sighted and visually-impaired people

Authors: *K. OH[1,2], B. I. PRILUTSKY[1,2];
[1]Applied Physiol., [2]Ctr. for Human Movement Studies, Georgia Inst. of Technol., Atlanta, GA

Abstract: One of the most vital parts of our daily activities is to position the arm or the hand at desired locations accurately and this is also true for the visually-impaired people. Comparing the ability of these two groups can be an important key to understanding how visual experience affects arm position sense. Only few studies have compared the arm position sense between sighted and blind subjects, and the obtained results are conflicting and depend on the experimental design. Colley and Colley (1981) who tested arm position sense in the a horizontal plane have showed that the lack of early visual experience negatively affects the arm spatial representation, however, studies in which the arm position sense was investigated in the sagittal plane obtained opposite results (Gaunet and Rossetti, 2006; Rossetti et al., 1996). On the other hand, Gaunet and Rossetti (2006) and Rossetti (1996) have also reported that deprivation of early

visual experience decreased the ability for memorizing proprioceptive targets. Therefore, bilateral arm matching tasks, during which the subjects do not need to remember target locations, is a way to avoid influences of memorizing proprioceptive targets. In this study, We conducted experiments in which three different bilateral arm-matching tasks in horizontal workspace were performed by two groups of right-handed subjects: blindfolded sighted group (n=10) and visually-impaired group (n=7). In experimental tasks, a robot moved the subject's right hand to one of four targets in random order, and the subject was instructed to matched with the left arm 1) the joint angles (the shoulder and elbow), 2) the distance and direction of hand movement from the initial position, or 3) the distance and mirrored direction of hand movement from the initial position. Accuracy (defined as the mean error) across all the targets was significantly lower in visually-impaired subjects, which is consistent with previous studies performed in the horizontal plane. In addition, accuracy in task 2 was much lower than in the other tasks. There was no interaction between the task and vision condition. Several possible explanations for the latter result will be discussed. We concluded that accuracy of position sense depends on visual experience.

Title: Encoding of contralateral and ipsilateral hand movements by high-gamma and theta bands of local field potentials in the globus pallidus of monkeys

Authors: *O. YOKOYAMA[1,2], Y. NAKAYAMA[1], E. HOSHI[1,2];
[1]Frontal Lobe Function Project, Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan; [2]AMED-CREST, AMED, Tokyo, Japan

Abstract: The basal ganglia form a circuit with the motor areas in the frontal cortex ("motor" loop). It has been considered that the coordinated work of the functions subserved by the brain areas constituting the circuit is critical in planning and executing movement. However, specific roles played by the respective areas and underlying neural mechanisms have not been fully clarified. In this study, we recorded local field potentials (LFPs) from the globus pallidus (GP) of monkeys (*Macaca fuscata*) performing a button-press movement with either the right or left hand. We found a movement-related power increase in the high-gamma (80-120 Hz) and theta (3-8 Hz) bands. In a subset of these power changes, a greater modulation was observed during contralateral hand movement than during ipsilateral one (contralateral representation). In another subset, a comparable power modulation was observed during contralateral and ipsilateral hand movements (bilateral representation). In contrast, only a few ($\leq 2\%$) of the changes showed a greater power modulation during ipsilateral hand movement than during contralateral one (ipsilateral representation). Compared with our previous findings on the caudal cingulate motor area (CMAc) and supplementary motor area (SMA) (Yokoyama et al., 2016), the bias toward the contralateral hand representation by the high-gamma and theta bands was evident in the GP. Further, the movement-related power increase in the GP began and formed a peak later than that in the SMA did. These findings suggest a specific contribution made by the GP in controlling hand movement: the GP, receiving signals biased toward the contralateral hand movement at a later timing than the SMA, may contribute to movement execution of the contralateral hand by detecting, coordinating and/or terminating developing movement-related neuronal activity.

Title: Lower limb support preference when initiating reach to grasp movements during locomotion

Authors: *G. C. BELLINGER[1], K. A. PICKETT[2], A. H. MASON[1];
[1]Dept. of Kinesiology, [2]Program in Occup. Therapy, Dept. of Kinesiology, Univ. of Wisconsin - Madison, Madison, WI

Abstract: Reach to grasp movements are often executed while walking, but few studies have investigated the potential for coordination between the upper and lower limbs. Previous research has studied the gait cycle at object contact, but reach onset towards a lateral target is when

humans need to account for dynamic stability. The current study explored preferred gait patterns during execution of a prehensile movement toward a target. *Methods:* Ten right-handed healthy young adults (3 males, $M = 23.57$ years) with normal or corrected-to-normal vision participated in the study. Ten markers were placed on the chest and right arm. Three-dimensional motion capture data was collected at 120 Hz using a VisualEyez camera system. Gait was analyzed using a GAITRite instrumented walkway and the two systems were temporally synced. The targets were three dowels placed 20 cm apart from each other on a support surface to the right of the mat. Participants stood 4.5 m from the center target and were instructed to walk towards the object, pick it up, and continue walking. Participants completed 10 trials for each of the 3 object locations as well as 10 walk-through trials. The markers on the radial styloid process and the sternum were used to determine relative wrist position during each trial. The 10 walk-through trials were used to find the average lateral displacement of the wrist during normal arm swinging. The initiation of intentional reach was then defined as the point at which the wrist extended more laterally than the average of the walk-through trials plus two standard deviations for each participant. It is difficult to determine when the contralateral swinging of the arms becomes intentional anterior reach, but our definition ensures that the participant was executing the secondary task during our time point of interest. The gait phase (ipsilateral single support, contralateral single support, double support) was then determined at reach onset for each of the 30 trials. *Results:* The percentage of trials in which the reach was initiated during ipsilateral single support ($M = 42.76$) did not significantly differ from contralateral single support ($M = 32.14$) ($p = 0.354$), but it did significantly differ from double support ($M = 25.10$) ($p = 0.037$). There was variability between the 10 subjects. Although some individuals demonstrated a preference for one single support phase, or an avoidance of the other, during initiation of intentional reach, there does not appear to be a pattern generalizable to all healthy right-handed young adults. The results suggest that ipsilateral versus contralateral support at reach onset is not a critical variable in planning these combined tasks.

Title: Neurons in the globus pallidus, supplementary motor area, and caudal cingulate motor area are differentially involved in contralateral and ipsilateral hand movements in monkeys

Authors: *Y. NAKAYAMA[1], O. YOKOYAMA[1,2], E. HOSHI[1,2];
[1]Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan; [2]AMED-CREST, AMED, Tokyo, Japan

Abstract: The basal ganglia form a loop circuit with the motor areas in the frontal cortex. This circuit is considered to play a crucial role in planning and executing movement. However, the specific roles each area plays still remain elusive. In the present study, we recorded neurons in the globus pallidus (GP) while monkeys (*Macaca fuscata*) performed a button-press movement with either the right or left hand. Three types of movement-related neuronal activity were observed: (1) with only the contralateral hand (contralateral neuron), (2) with only the ipsilateral hand (ipsilateral neuron), and (3) with either hand (bilateral neuron). The proportion of contralateral neurons was larger than that of ipsilateral neurons, and quantitative analyses also revealed that neuronal selectivity was biased toward contralateral hand movement. In comparison with neurons in the caudal cingulate motor area (CMAc) and supplementary motor area (SMA) (Nakayama et al., 2015) and with muscles, the movement-related activity in GP tented to begin later than that in CMAc, SMA, and even the prime mover muscle (flexor carpi ulnaris muscle). These results suggest that GP neurons play a major role in contralateral hand movement and that while CMAc and SMA are amply involved in initiating a hand movement, GP neurons mainly contribute to detecting, coordinating, and/or terminating an unfolding hand movement.

Title: Modulation of corticospinal output associated with convergence of multiple effectors

Authors: *R. J. IBEY, D. ANDREW, W. R. STAINES;
Kinesiology, Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Unilateral voluntary muscle activation leads to increased excitability of the homologous muscle representation in the ipsilateral primary motor cortex (M1). Excitability changes also arise in the upper limb M1 during lower limb contractions. The increase seen during homologous muscle activation is largely attributed to transcallosal connections, but the changes with distal non-homologous muscles is not well established and is thought to be due to secondary motor areas such as the supplementary motor area (SMA). The purpose of this study was to examine the neural mechanisms that contribute to the increase in excitability of M1 during isometric contractions of the contralateral homologous upper limb muscle and ipsilateral lower limb muscle both individually and in combination. We explored the convergence of these effectors probing intracortical inhibitory and excitatory networks (SICI, LICI, ICF), interhemispheric inhibition (IHI) (M1-M1) and the connection between SMA and M1 using transcranial magnetic stimulation (TMS). We hypothesized that intracortical inhibition of the resting forearm muscle representation will be reduced by both wrist and ankle contractions due to transcallosal and SMA connections respectively. We also hypothesized SMA will have a distinct functional role contributing to excitability changes during ankle contraction. We delivered focal TMS to healthy right-handed subjects targeting the M1 representation of the right extensor carpi radialis (ECR) muscle at rest and during three movement conditions: Isometric contraction of (1) left ECR at 10% MVC, (2) right TA at 30% MVC, and (3) left ECR at 10% MVC + right TA at 30% MVC. Motor evoked potentials (MEPs) were recorded using surface electrodes on ECR, FCR and FDI bilaterally and tibialis anterior (TA) on the right leg. Subjects' limbs were secured in manipulandums to isolate the muscle of interest. EMG was continuously recorded from the active muscle to monitor the force of contraction throughout each trial. Contractions were continuously held, and feedback was provided visually, during each trial while 10 MEPs were sampled over the ECR representation for each TMS condition. Preliminary results show there is an overall increase in excitability of the target motor representation during all conditions in comparison to rest. Contraction of the lower extremity individually and in combination increases excitability to greater extent then low-level homologous muscle activation. This appears to be modulated by GABA-mediated inhibitory networks. This data suggests another means for up-regulating excitability of primary motor cortex with potential clinical applications.

Title: Effects of applying differential fore-aft resistance on propulsive force generation during walking

Authors: *A. NAIDU[1], C. P. HURT[2], D. A. BROWN[2];
[1]Rehabil. Sci., [2]Physical Therapy, Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: **PURPOSE**: Inability to generate appropriate forces in the fore-aft direction leads to disrupted walking patterns seen in individuals poststroke. These forces are a reflection of lower-limb muscle strength, correlated with hemiparetic severity, and walking speed. During walking, impairment in paretic-limb propulsion causes adaptation of compensatory strategies that favor greater non-paretic limb propulsion, to maintain speed. However, these strategies lead to interlimb-force asymmetry producing asymmetric, slow, and inefficient gait patterns. Recent studies have found that application of fore-aft resistance can improve both paretic and non-paretic propulsion. However, selective modulation of resistance, in the form of applying differential resistance, to improve weaker paretic-limb propulsion has not been investigated. To validate the application of such differential resistance, our primary purpose is to test the application of differential fore-aft, limb-loading resistance during walking in nonimpaired individuals. Secondarily, these results will then be compared with a similar paradigm in individuals poststroke. **HYPOTHESIS:** Application of fore-aft differential resistance will lead to interlimb propulsive-force asymmetry. To maintain speed, the left limb working against greater resistance will generate greater propulsion due to increased proprioceptive load-feedback integration. **METHODS:** Nonimpaired individuals were asked to maintain a constant velocity (1m/s) while walking inside a novel robotic device called the KineAssist interfaced to a split-belt force treadmill. Each treadmill belt is governed by a unique force vs velocity relationship which was manipulated to create different resistance levels between the limbs. Four differential force levels were applied to increase the difference in resistance applied to one leg versus the other. Kinetic and kinematic data for each differential condition were collected, and analyzed. **RESULTS:** Data from 10 participants (Mean age 39 ± 11) was analyzed. All participants maintained a relatively constant speed (1.03±0.09 m/s, R= 0.68 ± 0.33). Seven participants experienced progressively greater propulsive force in the leg exposed to greater resistance. Three participants experienced greater propulsion in the lower resistance condition. The average slope for all ten legs that experienced greater propulsive forces was 0.23 N for every N of applied differential resistance. **IMPLICATIONS**: We will further develop this method to provide a unique strength training environment for individuals poststroke, to improve the paretic-limb's propulsive-force generation during walking.

Title: The influence of transcranial random noise stimulation on motor skill acquisition and learning in a golf putting task

Authors: *L. LIMA DE ALBUQUERQUE[1], K. M. FISCHER[1], A. L. PAULS[1], M. A. GUADAGNOLI[1], Z. A. RILEY[2], B. POSTON[1];
[1]Dept. of Kinesiology & Nutr. Sci., Univ. of Nevada, Las Vegas, Las Vegas, NV; [2]Indiana Univ. – Purdue Univ. Indianapolis, Indianapolis, IN

Abstract: Transcranial random noise stimulation (tRNS) is a non-invasive brain stimulation technique that can increase cortical excitability and motor performance in simple tasks. However, the ability of tRNS to improve motor performance in a complex, multi-joint task is unknown. The purpose was to determine the influence of tRNS on motor skill acquisition and learning in a golf putting task in young adults. The study was a sham-controlled, double-blind, between-subjects experimental design. Twenty-four young adults were allocated to either a tRNS group or a SHAM stimulation group and each subject participated in 2 experimental sessions on 2 consecutive days. In the first session (practice session), both groups performed 6 trials of a golf putting task in a baseline testing block, followed by 4 practice blocks of 15 trials, and a post-testing block (6 trials) that was performed five minutes after the last practice block. In the second session (retention session), a retention testing block (6 trials) was performed 24 hours after the practice session. The golf putting task involved accurately performing putts to a small target positioned 3 meters away from the subjects. tRNS or SHAM stimulation was applied during the practice blocks. tRNS was applied to the scalp area overlying the 1st dorsal interosseus muscle representation area of the primary motor cortex for 20 minutes at a current strength of 2mA. SHAM stimulation was applied in the same manner according to established blinding procedures in which the current was ramped up and down over a period of 60 seconds. The endpoint error (primary outcome measure) during the golf putting task was quantified as the absolute distance of the final endpoint of each put relative to the target, whereas the endpoint variance (secondary outcome measure) was quantified as the sum of the variances of the *x* and *y* endpoints for each trial block. For the testing blocks, the endpoint error was significantly reduced in both groups between the baseline block and the post-test block ($P = 0.000$), but there was no difference between groups. Similarly, endpoint variance was not different between groups, but decreased significantly for both groups between the baseline block and the post-test block, and between the baseline block and retention block ($P = 0.000$ and 0.018, respectively). For the practice blocks, there were no significant differences in the rate of decrease in endpoint error or endpoint

variance between the tRNS and SHAM groups. The findings indicate that a single application of tRNS applied during practice of a complex golf putting task does not increase the rate of motor skill acquisition or the amount of motor learning experienced by young adults.

Title: Characterization of involuntary arm movements elicited by lower extremity efforts in pediatric hemiplegia

Authors: *R. L. HAWE, J. P. A. DEWALD;
Physical Therapy and Human Movement Sci., Northwestern Univ., Chicago, IL

Abstract: Altered interlimb coupling, clinically referred to as associated reactions, is a common motor deficit in children with hemiplegia. When an individual exerts a high level of effort with their lower extremities, involuntary movements can be observed in their upper extremity. These movements can interfere with functional tasks, disrupt balance, and cause cosmetic concerns and stigma for children and their families. The aim of this research was to quantify involuntary movements in the paretic and non-paretic upper extremity lower extremity tasks.
Eighteen children with hemiplegia and 10 typically developing age-matched participants were recruited for this study. Participants were seated with their leg attached to a push/pull loadcell. Their upper extremity was secured to a robotic device used to create a haptic environment in which the weight of their limb was negated and haptic springs were used to provide stability at rest while still allowing for movement in all planes. Participants performed maximal and sub-maximal (25, 50, and 75%) isometric knee flexion and extension torques with visual feedback, with the instruction to relax their upper extremity. Fingertip excursions and EMG activity at the shoulder and elbow were recorded. Each arm was tested separately with each lower extremity. Knee flexion and extension of both the paretic and non-paretic lower extremities elicited increased amounts of fingertip excursion and EMG activity in children with hemiplegia. The

amount of excursion and muscle activity scaled with effort level. Increased movement was also observed in the non-paretic upper extremity. Preliminary work has been done to examine the role of injury timing on involuntary arm movements by comparing children with prenatal (n=10), perinatal (n=5), and postnatal (n=3) lesions. Preliminary findings suggest that arm movements in the paretic arm are greatest in peri- and post-natally acquired lesions, however, involuntary arm movement on the non-paretic side is greater in prenatal lesions.
By quantifying altered interlimb coupling patterns in pediatric hemiplegia, we can better understand the underlying mechanism and gain insight into how the motor system is reorganized after early lesions.

Title: Electrophysiological correlates of interference during discrete bimanual coordination

Authors: *P. C. DESROCHERS, A. T. BRUNFELDT, F. A. KAGERER;
Dept. of Kinesiology, Michigan State Univ., East Lansing, MI

Abstract: Bimanual movements are common in daily life and require a high degree of coordination. Incongruous bimanual movements can cause interference between the hands as each hand attempts to perform independent action. Since little is known about neurophysiological signatures of interference between the hands, this study examined changes in electroencephalography (EEG) during a bimanual center-out task. Twenty-one right handed participants moved two robotic manipulanda simultaneously from two home positions to two target positions located 10 cm forward or backward of the home positions. Hand position was represented by a cursor on a screen that occluded the view of the hands. Seven blocks of 60 trials each were administered. In the first block, hand feedback was displayed for both hands. In the second block, visual feedback of the left hand was removed. In blocks three through six, right hand visual feedback remained veridical for the control group (n=11), whereas the experimental group (n=10) adapted to a 40 degree visual feedback rotation in the right hand. Both groups were instructed to continue moving the invisible left hand straight to the targets. In the final block, right hand feedback was veridical again for both groups. EEG was time-locked to movement onset for each trial. The signal was filtered and artifacts were rejected. EEG was segmented from 500 ms before to 1000 ms following movement onset. Averaged segments were evaluated for

spectral power at alpha (8-13 Hz) and beta (13-30 Hz) frequencies, and compared between channel pairs over the left and right hemispheres (F3-F4, C3-C4, P3-P4, FC5-FC6, CP5-CP6). Preliminary behavioral results showed that the experimental group adapted to the perturbation of the right hand, with substantial aftereffects in the final block. The left, invisible hand deviated from its straight path due to interference from the perturbed right hand. EEG results showed consistently reduced spectral power in the left hemisphere in both groups, suggesting greater activation in neural populations controlling the visible hand. Additionally, across both hemispheres in late adaptation, the adapting group showed lower power at parietal sites in alpha, and fronto-central sites in beta. Finally, in the adapting group, power was lower in late adaptation in the non-dominant hemisphere, particularly at parieto-central sites in alpha, and fronto-central sites in beta. These results suggest that hemispheric differences in brain electrical activity may reflect interference during simultaneous discrete bimanual movements, and may indicate modification of neural activity that occurs as bimanual movements become more stable.

Title: Gating sensory inputs in the ipsilateral somatosensory cortex during unimanual force generation

Authors: *Y. LEI, M. A. PEREZ;
Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL

Abstract: It is well known that increasing levels of force with muscles on one side of the body increases the excitability of the ipsilateral primary motor cortex. The involvement of the

somatosensory cortex ipsilateral to a contracting hand (iS1) during increasing levels of unilateral force generation remains unknown. Here, we examined somatosensory evoked potentials (SSEPs) by recording electroencephalographic signals from iS1 and stimulating the ulnar nerve (3x above perceptual threshold) at rest and during 30% and 70% of isometric maximal voluntary contraction (MVC) into index abduction with the dominant ipsilateral hand. We found that in the iS1 the amplitude of the P25/N33 but not the P14/N20 and N20/P25 SSEP components decreased during 30% and 70% of MVC to a similar extent compared to rest. To further understand the mechanisms involved in changes in SSEPs in the iS1 we tested interhemispheric inhibition from contralateral to iS1 (IHI) and short-latency afferent inhibition (SAI) at rest and during 30% of MVC with the dominant ipsilateral hand. During SAI testing the ulnar nerve was stimulated 15-40 ms before a motor evoked potential was elicited by stimulating the primary motor cortex using transcranial magnetic stimulation with the coil oriented in the posterior-anterior (PA) and anterior-posterior (AP) direction. Notably, IHI decreased in the P25/N33 component and SAI increased with the TMS coil in the PA but not AP direction during 30% of MVC compared with rest. Our findings suggest that intracortical pathways, likely those involving PA synaptic inputs, contribute to modulate iS1 activity during increasing levels of unimanual force generation in intact humans.

Abstract: Introduction:
Healthy aging is associated with distinct structural and functional brain alterations leading to an age-related decline in motor behavior and a general loss in postural stability. Non-invasive brain-stimulation techniques such as transcranial direct current stimulation (tDCS) can help to facilitate motor behavior in young and old adults. More specifically, tDCS over the leg motor cortex (M1 leg area) enhances postural control and improves individual balance ability. In the present study, we wanted to investigate the effects of facilitatory anodal tDCS (a-tDCS) applied over M1 leg area on learning a complex whole-body dynamic balancing task (DBT) in young and old adults. We hypothesized that in both age cohorts, a-tDCS during DBT enhances learning performance compared to sham tDCS (s-tDCS).
Methods:
In total, 32 older and 28 younger adults were enrolled in two consecutive DBT training sessions. Using a randomized, parallel, design, 20 minutes of tDCS were applied while participants performed the DBT for the first time. Task performance and error rates were compared between a-tDCS and s-tDCS for each age group, separately as well as between both s-tDCS groups. Additionally, we investigated how well DBT task performance can be predicted from the individual kinematic profile, which captured different aspects of task execution.
Results:
Both age groups successfully increased their level of DBT performance on both training sessions. However, the comparison of both s-tDCS groups revealed that younger adults showed superior DBT learning on TD 1 and TD 2 as compared to the elderly. In our younger study sample, a-tDCS over M1 leg area significantly promoted balance performance in a DBT relative to s-tDCS, which was indicated by higher performance and smaller error rates. In the older age cohort, between-group analyses revealed no difference between a-tDCS and s-tDCS group regarding their level of task performance and associated error rates. A regression analysis revealed that the DBT performance level in both age groups can be well predicted by the individual kinematic movement profile.
Conclusions:
Our findings provide novel evidence for the ability of tDCS to improve dynamic balance learning in a younger age cohort. However, in our older age cohort, the concurrent application of tDCS over M1 leg area did not elicit DBT performance enhancement which may relate to a variety of factors such as timing or stimulation parameters. Additionally, our data showed that the kinematic profile can predict the level of DBT performance, which may provide new insights for the individualized approaches of treating balance and gait disorders.

Title: Influence of sex on asymmetries in pain sensitivity, proprioception, and strength

Authors: *J. H. KING, A. R. KARDUNA;
Human Physiol., Univ. of Oregon, Eugene, OR

Abstract: Abnormalities in the sensory and motor systems, including hypersensitivity to pain, poor proprioception, and weakness, are associated with the progression and/or development of several chronic upper extremity disorders. Given the low success rate in treating chronic upper extremity disorders, both researchers and clinicians have grown increasingly interested in the aforementioned abnormalities, and generally utilize a patient's uninjured limb as a reference; that is, deficits and subsequent treatment strategies are quantified based on the assumption that prior to injury, a patient had bilateral similarities. To date however, little work supports the validity of this assumption despite the fact that significant asymmetries may exist, and that these asymmetries may be particularly evident in males versus females. Therefore the aim of this project is to investigate the influence of sex on asymmetries in pain sensitivity, strength, and proprioception across the joints of the upper extremity. We hypothesize that similar to research on the special senses males will demonstrate greater asymmetries than females. Eight right-hand dominant subjects (four females), with a mean age of 30 ± 7 years, have participated in this ongoing study. Bilateral measures of pain sensitivity, proprioception and strength were collected across the joints of the upper extremity in a randomized and counterbalanced manner during a single session. Asymmetry scores were calculated as the difference between the right and left limbs, with the right limb serving as the reference limb. Pain sensitivity was assessed by using a hand-held pressure algometer to apply gradual pressure perpendicular to the skin. Proprioception was assessed by using an active positioning-active repositioning protocol. Strength was assessed using maximum voluntary isometric contractions performed against a mounted dynamometer. Our preliminary findings suggest that side-to-side differences in pain sensitivity, strength, and proprioception, may be present in the upper extremity of right-hand dominant persons. If these asymmetries are confirmed within a larger subject pool, the validity of using a patient's or research participant's uninjured limb as a reference becomes questionable and a correction factor may need to be developed. Moreover, our preliminary findings are also one of the first functional studies to suggest that males may have greater strength and proprioception asymmetries than females, especially at distal joints. If males are shown to have greater asymmetries within our larger subject pool, future studies using bilateral measurements may need to account for sex.

Title: Predicting the behavior of each individual: kinematic parameters during sensorimotor adaptation determine the magnitude of interlimb transfer and after-effects in right- and left-handers

Authors: ***A. G. RENAULT**, H. Z. LEFUMAT, L. BRINGOUX, C. BOURDIN, J.-L. VERCHER, F. R. SARLEGNA;
Inst. Des Sci. Du Mouvement Etienne-Jules M, Marseille, France

Abstract: The human nervous system displays such a plasticity that we can adapt our motor behavior to various changes in environmental or body properties. However it remains unclear what determines generalization of sensorimotor adaptation across effectors: here we aimed at uncovering the factors which drive generalization. We specifically examined the capacity of human adults to adapt to prismatic glasses while reaching to visual targets with their dominant arm and assessed the level of transfer to the non-dominant arm. As shown in several previous studies (Cohen 1973; Choe & Welch 1974; Redding & Wallace 2008), we first observed that subjects adapted to the prismatic deviation: indeed, dominant arm movements were initially perturbed but quickly became as accurate as in the pretest, no-prism condition. More interestingly, transfer of adaptation to the non-dominant arm was not systematically observed for all subjects as we observed large inter-individual differences. Some subjects showed transfer in the opposite direction of the perturbation, i.e. in an extrinsic coordinate system, and some subjects showed transfer in the same direction as the perturbation, i.e. in an intrinsic coordinate system. As suggested by recent findings on a slightly different, force-field adaptation task (Lefumat et al. 2015), we hypothesized that kinematic parameters may explain such differences. A stepwise forward multiple regression analysis showed that a few kinematic parameters measured during the adaptation phase with the dominant arm such as peak acceleration, mean and variability of initial reach direction predict transfer to the non-dominant arm. The magnitude of the after-effects observed on the dominant arm can also be predicted based on variability of initial reach direction, number of trials to adapt and peak acceleration. Our findings are consistent with recent studies which reported that individual characteristics such as motor variability impact sensorimotor adaptation and its generalization. For instance, Wu et al. (2014)

reported that the more variable a subject is during a pre-adaptation phase, the faster he is for learning a novel arm-reaching task and Lefumat et al. (2015) found that the more variable a subject is when adapting to novel limb dynamics, the greater interlimb transfer is. Overall, our findings support the view that kinematic parameters can determine the coordinate system used by subjects to transfer what is learned during adaptation.

Title: Lateralized motor control processes determine asymmetry of interlimb transfer

Authors: *R. L. SAINBURG[1,2], S. Y. SCHAEFER[3], V. YADAV[4];
[1]Penn State Univ., University Pk, PA; [2]Neurol., Penn State Col. of Med., Hershey, PA; [3]Biomed. Engin., Arizona State Univ., Tempe, AZ; [4]Mechanical Engin., Stonybrook Univ., Stonybrook, NY

Abstract: This experiment tests the hypothesis that interlimb transfer of motor performance is dependent on recruitment of hemisphere specific motor control processes during opposite arm practice. Participants performed a single-joint task, in which reaches are targeted to 4 different distances. While the speed and accuracy was similar for both hands, the underlying control mechanisms used to achieve scaling of movement speed with distance were systematically different between the arms: The dominant arm scaled the amplitude of the initial acceleration profiles to achieve variations in peak velocity, and the non-dominant arm relied to a greater extent on modulation of the duration of the acceleration profiles. These differences were previously shown to depend on left and right hemisphere processes, respectively (Schaefer, Haaland, & Sainburg, 2007). We predicted that initial practice with the dominant arm should transfer to produce greater contributions of acceleration amplitudes to peak velocities in the non-dominant arm, and practice with the non-dominant arm should transfer to increase the contributions of acceleration duration to peak velocities in the dominant arm. Our findings support these predictions, results that cannot be accounted for by explicit cognitive mechanisms,

asymmetries in task errors, or asymmetries in responses to environmental perturbations. We conclude that interlimb transfer of motor performance depends on initial training of lateralized motor control mechanisms in the contralateral hemisphere that are exploited during opposite arm performance.

Title: Sensorimotor postmovement and foreperiod β-band modulations by unilateral kinematic-errors in two bimanual coordination tasks

Authors: *J. ALAYRANGUES, F. TORRECILLOS, A. JAHANI, N. MALFAIT;
AMU & CNRS Inst. De Neurosciences De La Timone, Marseille, France

Abstract: In a previous EEG study (J.Neurosci. 35:12753-65) we examined how β-band sensorimotor oscillatory activity is influenced by kinematics errors. We applied unpredictable visual or mechanical perturbations while participants reached to a visual target with their dominant arm. Along with the attenuation of the post-movement β-rebound observed at the end of the perturbed movements, we described how β-activity is modulated during the foreperiod of the movements that immediately follow a perturbed reach. Interestingly, the pre- and post-movement periods exhibit different error-related modulations that point to distinct functional roles in behavioral monitoring and adaptation. The attenuation of the β-rebound seems to relate to salience-processing independent of adaptation processes, whereas foreperiod β-power modulation seems to reflect motor-command adjustments activated after a movement-execution error is experienced. Here, we assess how foreperiod and post-movement β-activities are influenced by unilateral kinematic errors experienced during bimanual reaches. Specifically, we contrast oscillatory responses observed in two tasks involving similar movements but different coordination. In a “cooperative” coordination task, participants have to control a single cursor with both hands to hit a unique target. In contrast, in a “parallel” task they have to reach with two independent cursors (each controlled by one hand) two different targets simultaneously. During both tasks, in catch-trials mechanical perturbations are unpredictably applied to one of the arms, with equal probabilities. Consistent with our previous findings, we observe postmovement and

foreperiod β-band modulations in response to unilateral kinematic-errors. More interestingly, we show that the β-activities observed during these two periods exhibit different sensitivities to the nature of the bimanual task. Specifically, while the β-rebound exhibits similar error-related attenuation in both tasks, the foreperiod β-activity is differently modulated depending on the mode of coordination: In the parallel task, β-power is modulated over the hemisphere contralateral to the perturbed arm, whereas in the cooperative task the modulation is visible over the right hemisphere regardless of the side of the perturbation. These findings are consistent with the contrasting behavioral responses observed in the two tasks. In the parallel task, on-line motor correction and adaptive processes are manifest for the arm submitted to the perturbation only. In contrast, in the cooperative condition correction and motor-command adaptation are observed bilaterally.

Title: Practice-induced changes in EEG during asymmetric bimanual skill learning

Authors: *S.-W. PARK, H. TAM, D. STERNAD;
Biol., Northeastern Univ., Boston, MA

Abstract: Identifying the spatiotemporal pattern of cortical activity during skill learning has been problematic, because electroencephalography (EEG) has multiple sources of noise, especially for larger-scale movements. However, recent advances in algorithms for EEG artifact removal facilitated this study that recorded EEG during a bimanual task. We aim to identify spatiotemporal patterns during acquisition and consolidation of an asymmetric bimanual motor skill. Eight healthy right-handed subjects rotated their forearms in the horizontal plane and moved their right arm to a target cue as fast as possible, without disturbing the continuous

rhythmic movements of their left arm. Subjects performed 150 discrete movements triggered at random phases of the ongoing oscillations in the left arm. The task goal was to achieve high peak velocity in the cued movement, while minimizing perturbations of the continuous rhythmic movement. Subjects practiced for 10 daily sessions. Cortical activity during performance was measured using 64-channel EEG electrodes in the 1st, 6th and 10th practice sessions. For comparison, EEG was also recorded during symmetric bimanual cued discrete movements. Prior to the analyses, noise and artifacts were eliminated using the adaptive mixture independent component analysis (AMICA). Event-related potentials (ERP) were aligned with the visual cue onset with an epoch size of [-300, 500ms]. The time of the ERPs was quantified in both the asymmetric and symmetric conditions. To quantify the change of interhemispheric interaction, coherences between a pair of EEG electrodes in bilateral frontal, motor, and parietal regions were analyzed in the alpha and beta frequency regions (8 and 20 Hz, respectively). Behavioral results showed that the performance of both arms significantly improved: peak velocity of the cued discrete movement increased and the perturbation of the rhythmic movement decreased, although it did not reach zero. EEG results showed that the signal at C3 (left hemisphere) differed between the symmetric and asymmetric condition at ~200ms following cue onset, but this difference disappeared after 10 practice sessions. Interhemispheric coherence at the beta rhythm increased in the first part of practice, but only in the asymmetric condition. We found that ERP and interhemispheric coherence change over the course of asymmetric bimanual skill learning with different time scales. We suggest that 1) increased interhemispheric coherence at the beta frequency range was associated specifically with acquisition of the asymmetric bimanual skill and 2) long-term practice shapes the cortical activation in the contralateral motor area.

Title: Increased visual load impairs motor control during a reactive driving task

Authors: *C. KIM, E. A. CHRISTOU;
Univ. of Florida, Gainesville, FL

Abstract: Increased cognitive load impairs driving performance. There is evidence that information processing can lengthen reaction time. Although driving requires constant motor control, it is currently unclear to what extent increased information processing (cognitive load)

alters motor control during driving. The purpose of this study was to determine whether increased cognitive load alters motor control during a reactive driving task. Eight young adults (23.2±3.2 years, 5 women) performed a simulated reactive driving task. Participants controlled the gas pedal during a visuomotor task and responded to a sudden visual stimulus by moving their foot from the gas pedal to the brake pedal. Their goal was to apply a 40 N force on the brake pedal as quickly and as accurately as possible. We varied cognitive load by changing the visual load. The visual scenario involved following multiple cars. During the low visual load condition, participants reacted to a single visual stimulus displayed at a fixed location in the center of the visual field (red lights of the car directly ahead). During the high visual load condition, participants reacted to a visual stimulus that could appear in one of five possible locations (red lights from one of the cars, the rest were blue). Participants were not to respond if all car lights turned blue. Therefore the low visual load condition represents a simple reaction time task, whereas the high load visual condition represents a choice Go/NoGo reaction time task with distractors. Motor control was quantified with the brake force error (RMSE) and variability (SD of brake force). Cognitive load was quantified as the length of the premotor response time (from stimulus onset to tibialis anterior muscle activity onset). Participants reacted 85% slower during the high load condition. Premotor response time was 580±60 ms during the high load condition and 315±20 ms during the low load condition ($t=17.7$ $P<0.01$). We found that brake force control was related to premotor response time. Participants with increased premotor response time during high load condition exhibited the greatest increases in brake force error ($R^2=0.7$ $P<0.01$) and variability ($R^2=0.63$ $P<0.02$). As expected, we found that increased visual load lengthens information processing time, as evidenced by a longer premotor response time. The novel finding is that healthy young adults who require longer processing time of visual information exhibit the greatest deterioration in motor control during a reactive driving task. Therefore, it appears that greater information processing requirements could influence motor control and contribute to higher car accident rates in visually complex situations.

Title: Aging and working memory on manual asymmetry during visuospatial motor tasks

Authors: *T. S. FLINK;
Gannon Univ., Erie, PA

Abstract: Working memory and its effects on manual asymmetry during motor tasks in young and older adults was explored. Twenty young (M = 21, SD = 3 years) and twenty older (M = 70, SD = 6 years) right-handed adults participated in three tasks. For the memory task (Task A), participants studied and recalled the location of twenty-five distinct shapes on a board. The number of successfully recalled shapes was recorded. For the motor task (Task B), participants were required to pick up objects of different shapes from a table and place them into matched holes on the board. The shapes were aligned in the proper order and position on table that matched the exact location to their corresponding holes in the board. For the motor plus memory task (Task C), individuals selected the shapes from the table and placed them into their proper holes on the board. Unlike Task B, the order and location of the shapes on the table were randomized so that participants would be required to remember the proper locations of the holes during movement. Time to completion was recorded for Tasks B and C for the right and left hands, the laterality quotient (LQ = (R-L)/(R+L)*100) was computed. No significant difference in number of shapes recalled between young and older adults was observed for Task A. For Task B, participants in both groups were more lateralized for use of their right hand on this task, but no significant difference was found between groups for LQ. Finally, for Task C, a significant difference between groups for LQ was observed, $t(38) = 2.59$, $p = 0.013$. Young adults were highly lateralized for use of the right hand for this task (LQ = -5.15), whereas older adults displayed a more balanced performance between the right and left hands (LQ = 0.33). The reduced manual asymmetry in older adults compared to young adults for Task C may be attributed to the addition of visuospatial working memory in this task that was not present in Task B. These results support the hemispheric asymmetry reduction in older adults (HAROLD) model, which suggests that reductions in manual asymmetry in older adults may be due to neural compensatory mechanisms as a result of cognitive declines in working memory with age.

Title: Prior expectation facilitates corticospinal excitability before sensory evidence accumulation

Authors: *I. C. WEINBERG, J. DUPONT-HADWEN, S. BESTMANN;
Sobell Dept. of Motor Neurosci. and Movement Disorders, Univ. Col. London, London, United Kingdom

Abstract: Recent accounts reject the historical dissociation between the study of decisions about which movement to make and the study of how those movements are planned and executed (Cisek, 2007). Instead, multiple actions are proposed to be planned simultaneously during the decision and gradually eliminated. Recent work has shown that such parallel planning extends even to the corticospinal tract, with decision factors modulating corticospinal activity whilst the decision is ongoing (Michelet et al., 2010; Klein-Flugge and Bestmann, 2012). Separate streams of research have studied how an expectation or prior is incorporated into decisions. In sensory and parietal areas, a prior expectation increases baseline activity in advance of the evidence accumulation phase of the decision (Puri et al., 2009; Rao et al., 2012). An interest in the influence of ongoing decision activity in motor areas motivated us to study how prior expectation affects motor areas, with the hypothesis that an expectation to move would boost excitability before stimulus onset.

Human subjects were asked to make left or right button presses in response to the direction of motion of a noisy moving dot stimulus. Before each dot stimulus, subjects saw the accurate probability the stimulus would indicate a rightward movement so that they formed a prior expectation about the movement direction on a trial-by-trial basis. We used single pulse Transcranial Magnetic Stimulation over left primary motor cortex to record right-hand motor evoked potentials (MEPs) and thus measure corticospinal excitability (CSE) during the reaction time. We recorded most MEPs at the time of stimulus onset in order to measure the impact of a prior expectation before the appearance of new sensory evidence.

We find that reaction times are shortest when the prior expectation was strongest and longest in the condition with a neutral (50:50) prior. Similarly, a strong prior improved accuracy. At stimulus onset, as hypothesised, MEPs were biased by prior expectation. CSE was greatest with strong prior expectation to move the right hand. The reaction time and MEP effects correlate on a subject-by-subject basis, suggesting a mechanistic role for the corticospinal facilitation. On incorrect trials, the trend linking prior expectation and MEP size was reversed, suggesting that an incorrect representation of prior expectation in the corticospinal tract contributes to error. These data suggest that the motor system activity reflects not merely an ongoing sensory decision but also probabilistic information in advance of the decision.

Title: Voluntary reduction of force variability via modulation of low-frequency oscillations

Authors: *S. PARK, A. CASAMENTO-MORAN, B. YACOUBI, E. A. CHRISTOU;
Applied Physiol. and Kinesiology, Univ. of Florida, Gainesville, FL

Abstract: Force control has been associated with the modulation of force oscillations below 0.5 Hz. These low-frequency oscillations increase with voluntary effort and are strongly associated with the increase in force variability. It is currently unknown whether a voluntary reduction in force variability with similar effort would result in a reduction of low-frequency oscillations. The purpose of this study, therefore, was to determine the force oscillations that change with a voluntary reduction in force variability. Fifteen young adults (28.3 ± 3.9 years) were asked to match a force target of 15% MVC with ankle dorsiflexion. Participants performed six contractions with no guidelines. We selected one contraction with the least variability. Participants were then asked to perform 6 additional contractions but this time they were asked to constrain their force output within a range, which was provided visually with two dotted guidelines above and below the targeted force. That range represented half of their initial minimal variability as measured during the no guideline condition. From the force output we quantified the following outcomes: 1) mean force; 2) standard deviation (SD) of force; 3) power spectrum of force from 0-2 Hz (0.1 resolution). Participants exhibited the same mean force during the no guideline and guideline conditions ($p = 0.973$). In contrast, the SD of force decreased 36.5% during the guideline condition ($p < 0.05$). Low-frequency oscillations in force from 0.1-0.2, 0.2-0.3, and 0.5-0.6 Hz significantly decreased during the no guideline condition ($p < 0.05$). Decreased force variability during the no guideline condition was associated with decreased low-frequency oscillations in force from 0.1-0.2 Hz ($R^2 = 0.373$, $p < 0.05$) and 0.5.-0.6 Hz ($R^2 = 0.459$, $p < 0.01$). These findings demonstrate that visual guidelines provide an effective tool to reduce force variability without changing the mean force. Most importantly, we provide novel evidence that healthy young adults decrease force variability by reducing low-frequency oscillations in force. It is possible, therefore, that low-frequency oscillations can be voluntarily modulated to decrease force variability.

Title: Planning and execution of movements revealed by *In vivo* calcium imaging in mice

Authors: *J. E. DAHLEN[1], E. HWANG[2], M. MUKUNDAN[2], T. KOMIYAMA[2];
[1]Dept. of Neurosciences, [2]Univ. of California San Diego, La Jolla, CA

Abstract: During the planning of a movement, collection of evidence allows for environmental stimuli, internal states and projected consequences to be taken into account prior to making confident, robust movements. How are these transformations and associations represented among various regions of the brain comprising the sensorimotor pathway? Previous studies recording neural activity from the primary (M1) and secondary (M2) motor cortices have revealed fundamental principles about their activity during movement behaviors, showing changes in activity during and immediately prior to (i.e. in preparation for) movements. Activity prior to movement in each of M1 and M2 likely plays an integral role in preparing the motor cortex for proper movement execution. To this end, we developed a novel sensorimotor discrimination task for head-fixed mice. In this task, mice discriminate between two visual stimuli, plan and withhold a movement until instructed to move by an auditory cue. We performed in vivo two-photon imaging of a genetically encoded calcium indicator (GCaMP6) in M1 and M2 during the performance of this task. We observe that both M1 and M2 in mice (also known as the caudal and rostral forelimb areas, respectively) are active during the preparation and execution of movements, with M2 showing more cells active during movement preparation M1. Additionally we show that we can reliably identify neurons projecting between M1 and M2 allowing us to

study information flow between these two motor areas. Lastly, this work is currently being extended to demonstrate the behavioral effects of optogenetically inactivating each of M1 or M2.

Title: Performance monitoring of action policies in mice

Authors: *R. F. OLIVEIRA, R. M. COSTA;
Champalimaud Ctr. for the Unknown, Lisbon, Portugal

Abstract: When a musician performs a difficult piece, actions have to be performed with striking accuracy. Previous work has shown that after a self-paced action sequence has been rehearsed, the trial-to-trial variability in performance decreases (precision increases). Furthermore, if the action is complex the modulation of behavior and neural variability is contingent to the relevance of each dimension (e.g. speed, duration) to the task. However, it is unclear whether animals can monitor and report their performance on a particular trial before the outcome is presented or not. We train mice to execute 4 or 5 sequential presses in order to obtain a cached reinforcement. After training, animals are asked to wait for 8 secs before the outcome is known; animals can wait to know the outcome or abort the trial and start again. Mice abort more trials after incorrect than correct sequences. Logistic regression analysis shows that the probability of current trial abortion depends on the recent history of trial abortion (with slow dynamics) and current trial performance (with faster dynamics). Furthermore, optogenetic inactivation of of Anterior Cingulate Cortex shifts the confidence estimation in mice. These results show that mice learn to perform sequences of movements within narrow constraints and that they are capable of monitoring their own performance in the absence of outcome. Moreover, the data shows that variables with different time dynamics are involved in assessing action performance.

Title: EEG oscillatory modulations (10-12 Hz) discriminate for voluntary motor control and limb movement

Authors: *E. R. SYMEONIDOU[1,2], M. OLIVARI[1], J. VENROOIJ[1], H. H. BÜLTHOFF[1], L. L. CHUANG[1];
[1]Human Perception, Cognition and Action, Max Planck Inst. for Biol. Cybernetics, Tübingen, Germany; [2]IMPRS for Cognitive and Systems Neurosci., Tübingen, Germany

Abstract: The oscillatory suppression of sensorimotor-mu power (i.e., 10-12 Hz) is a robust EEG correlate of motor control. Simply imagining voluntary limb movement can result in consistent suppression of mu-power, especially in contralateral electrode sites. This is typically exploited by neuroprostheses (e.g., BCI-controlled wheelchairs; Huang et al., 2012) that seek to restore movement to spinal-cord injury patients. In some examples, levels of mu-suppression have also been treated as an index of motor control effort (e.g., Mann et al., 1996). However, mu-suppression in contralateral sites can also be observed during passive limb movements, namely in the absence of voluntary control effort (Formaggio et al., 2013). In this study, we investigate whether patterns of oscillatory EEG activity across contralateral (C3) and ipsilateral (C4) sites discriminate for voluntary control and limb movement. In our study, EEG measurements were taken of ten participants who were required to either actively follow or resist the deflections of a control-loaded side-stick, this respectively required voluntary control in the presence and absence of limb movement. In contrast, they were also tested in conditions with passive or no limb movements, which respectively required them to simply hold on to a moving or stationary side-stick. A repeated-measures 2 x 2 x 2 ANOVA for the factors of electrode site (contralateral vs. ipsilateral), control (active vs. passive), and movement (movement vs stationary) revealed the following. To begin, there was a significant main effect of lateralized mu-suppression. Suppression of mu-power is larger in the contralateral site compared to the ipsilateral site ($F(1,9)=5.10$, $p=0.05$). More importantly, three significant interactions were found, movement x control ($F(1,9)=13.1$, $p<0.01$), electrode x movement ($F(1,9)=5.78$, $p=0.04$) and for electrode x control ($F(1,9)=5.81$, $p=0.039$). Limb movement resulted in selective mu-suppression of only the contralateral electrode. Voluntary control resulted in mu-suppression in both contralateral and ipsilateral electrodes, albeit to a lesser extent in the ipsilateral site. Overall, active resistance against side-stick deflections resulted in the largest levels of mu-suppression. The current results suggest that active voluntary resistance can result in high levels of mu-suppression that do not exhibit strong lateralization. This might go unnoticed in brain-computer-

interface and experimental paradigms that estimate control effort by contrasting contralateral to ipsilateral mu-suppression.

Title: Temporal and kinematic consistency predict sequence awareness

Authors: *J. W. MINK, M. JAYNES, M. SCHIEBER;
Dept Neurol, Univ. Rochester Med. Ctr., Rochester, NY

Abstract: Many human motor skills can be represented as a hierarchical series of movement patterns. Conscious awareness of underlying sequence patterns can improve performance through decreased cognitive load and increased neural efficiency. However, despite the performance benefit, not all individuals will become aware of underlying patterns in a sequential task. Furthermore, it is unknown which factors predict awareness of a pattern at the level of the motor response. Subjects (n=30) tapped a finger sequence with changing stimulus-to-response mapping and a common movement sequence. We instructed subjects to tap the sequences as quickly and accurately as possible but made no insinuation of the common motor sequence. Thirteen subjects (43%) became aware that they were tapping a familiar movement sequence during the experiment. We found no effect of age, musical experience, error rate, or inter-key-interval (IKI) on awareness of the pattern in the motor response. However, a Concordance analysis of the IKI pattern in each repetition of the sequence reveled that subjects who attained awareness tapped with greater temporal consistency. A generalized Procrustes analysis of the velocity-acceleration plot of each fingertip also revealed more awareness in subjects who tapped with greater kinematic consistency. Temporal or kinematic consistency was necessary for awareness of the underlying pattern in this tapping task, but consistency did not guarantee awareness. It is likely that tapping consistency indicated a more stable internal sequence

representation, but cognitive engagement with the representation was necessary to bring the sequence pattern to conscious awareness. These findings predict benefit for movement strategies that limit temporal and kinematic variability during motor learning.

Title: Reduced sequence awareness in dystonia despite normal performance

Authors: *M. JAYNES, J. W. MINK;
Univ. of Rochester Med. Ctr., Rochester, NY

Abstract: Dystonia is a neurological disorder characterized by involuntary movements and abnormal postures. The abnormal movements may affect multiple body parts or may be isolated to a single body part. Some forms of dystonia are limited to performance of a specific task, as in musician's focal hand dystonia. Dystonia has been associated with impaired motor learning in sequential tasks. However, it is unclear if impaired motor learning is characteristic of all subtypes of dystonia, and whether differences in motor learning are markers of underlying neural circuit dysfunction, or simply secondary to performance differences. Musicians with task-specific focal hand dystonia (FHD) (n=9), non-musicians with other forms of dystonia (n=11), and healthy controls (n=30) tapped a finger sequence with changing stimulus-to-response mapping but with an unchanging movement sequence. We instructed subjects to tap the sequences as quickly and accurately as possible but gave no clues to the common motor sequence. Compared to controls, there were no differences in performance measures of inter-tap-interval, temporal consistency, or kinematic consistency in subjects with dystonia. There were

also no performance differences between musicians with FHD non-musicians with dystonia. Thirteen (43%) healthy controls had awareness that they were tapping an unchanged movement sequence, but only two subjects with dystonia (10%) demonstrated awareness. In addition, the strength of this awareness was reduced in subjects with dystonia compared to healthy controls. Reduced sequence awareness in people with dystonia in this motor task is not attributable to differences in key performance measures. Furthermore, performance measures did not differ across subtypes of dystonia. These findings suggest that there is a fundamental difference in cognition of motor sequence performance in patients with dystonia, regardless of etiology, and that this impairment is due to neural circuit differences that are independent of motor execution.

Title: Contributions of peripheral versus central mechanisms to motor slowing

Authors: *M. T. BÄCHINGER[1], F. THOMAS[2], N. WENDEROTH[1];
[1]ETH Zürich, Neural Control of Movement Lab., Zürich, Switzerland; [2]Univ. Konstanz, Konstanz, Germany

Abstract: Finger tapping of an over-trained sequence at submaximal speed causes significant motor slowing that can be observed after approximately 20s. The objective of our present study is to (i) disambiguate whether peripheral or central mechanisms lead to this progressive decrease in performance and (ii) whether neurophysiological markers can be linked to the observed behavioural changes. Three experiments were conducted. All of them compared after-effects evoked by short periods of finger tapping (10s tapping followed by a 30s break) to after-effects evoked by longer periods (30s tapping followed by a 30s break). In general, tapping for 30s resulted in significant slowing when the first 10s were compared to the last 10s. **Exp. 1** used supramaximal peripheral nerve stimulation (PNS) in 10 subjects to test whether motor slowing could be explained by changes at the neuromuscular junction (peripheral fatigue), however, none of the investigated parameters (maximal M-wave, peak twitch force) changed significantly

relative to baseline values, neither after 30s nor after 10s of tapping. Thus, it is unlikely that motor slowing results from peripheral fatigue. In **Exp. 2** we used electroencephalography (EEG) in 17 subjects and found that EEG alpha power was strongly reduced immediately after tapping but recovered during the subsequent 30s of rest. Importantly, alpha rhythm was significantly more suppressed after 30s tapping than after 10s tapping (repeated measures ANOVA, tapping x time interaction; $p<0.05$). In **Exp. 3** we used transcranial magnetic stimulation in 13 subjects and found that short interval intracortical inhibition (SICI) was strongly decreased immediately after tapping but recovered during the subsequent 30s rest. Analogous to the alpha rhythm, SICI was significantly smaller after 30s tapping than after 10s finger tapping (linear mixed effects model, tapping x time interaction; $p<0.05$). Our results suggest that central rather then peripheral processes cause motor slowing, which is typically observed when sub-maximal movements are repeated over a longer time interval. Moreover, both the EEG alpha rhythm and SICI measured during the rest immediately after tapping dissociated the 30s from the 10s tapping condition. More specifically, we found that even though motor cortex was strongly disinhibited, it could not prevent motor slowing. This points towards a compensatory role of cortex suggesting that the potential inhibitory influence on motor performance might arise from other brain areas.

Title: Testing the proactive inhibition account: a tms study.

Authors: *L. BATTELLI[1], S. C. FICARELLA[2];
[1]Ctr. for Neurosci. and Cognitive Systems, Italian Inst. of Technol., Rovereto, Italy; [2]Aix-Marseille Univ., Marseille, France

Abstract: Background/Aim: In everyday life, environmental cues are used to predict upcoming events to which we need to respond. In cueing paradigms, when a non-informative warning signal (WS) precedes the target, Response Times (RTs) are faster, an effect called “alerting benefit” (Fernandez-Duque & Posner, 1997). However, for short Stimulus Onset Asynchronies (SOAs), the time interval between the WS and the target, RTs are longer, when compared to uncued trials, an effect known as “paradoxical warning cost” (Jaffard et al., 2007; Boulingues et al., 2008; 2009). One possible explanation of this effect is that, when a WS appears before the target (cued trials) a proactive volitional inhibition mechanism is activated to prevent the

execution of unwanted responses to the WS (Braver et al., 2007). One explanation is that proactive inhibition takes ~300ms to deactivate, explaining the lengthening of RTs for SOAs shorter than 300ms. In this study, we tested this hypothesis using a different cueing paradigm, with two possible SOAs (100 vs. 250ms). **Methods:** 27 participants performed three blocks of cued, uncued and mixed cued/uncued trials while we used single pulse TMS to measure motor evoked potentials (MEPs) at baseline (trial onset) and at target presentation. **Results:** Results show a beneficial effect of the cue, eliciting shorter RTs on cued trials, irrespectively of SOA and block condition. We find an effect of the SOA with a pattern comparable to previous studies (slower RTs for shorter SOA); however, the effect was present on both cued and uncued trials, irrespective of the block. We found higher response-related MEPs at target presentation on cued trials only, suggesting that the WS was boosting cortico-spinal excitability. This effect was influenced by the SOA, with higher muscle-specific MEPs, in the longer SOA condition. **Conclusions:** Together, these results suggest that the cue provided beneficial effects, shortening RTs and increasing cortico-spinal excitability, an effect that was stronger when participants were given more time to prepare the response. While previous studies reported reduced cortico-motor excitability during the SOA (Hasbroucq et al., 1997; 1999; Touge et al., 1998), and in line with the proactive inhibition account, others have found increased MEPs (Mars et al., 2007; Van den Hurk et al., 2007; Van Elswijk et al., 2007). We suggest that, even in conditions of uncertainty, where proactive inhibition should normally be activated, if the target follows the WS by a short interval and speed is stressed, proactive inhibition might not be activated, since it would not allow to respond to the target as quickly as necessary.

Title: Cortical influence on movement is associated with distinct neuronal activity dynamics

Authors: *J. A. MIRI, C. L. WARRINER, T. M. JESSELL;
Neurosci., Columbia Univ., New York, NY

Abstract: The role of primary motor cortex in the control of movement remains enigmatic. Inactivation of motor cortex has suggested that this role may be limited to dexterous or idiosyncratic movements, yet motor cortical neurons fire in patterns consistent with an active role in directing muscle activity during a broad range of motor behaviors. To provide further insight into the function of motor cortex, we have examined its influence on skilled forelimb movements as well as on untrained locomotor behaviors thought to be more reliant on spinal pattern generating circuits. We developed a behavioral paradigm in which head-fixed mice are trained through an incremental shaping procedure to reach toward and grasp a joystick before pulling it a set distance - a precision pull task. Unilateral motor cortical injection of muscimol (75 ng), as well as ablation of motor cortex, markedly diminished task performance, demonstrating a requirement for motor cortex in task execution. To quantify movements, we recorded the activity of forelimb muscles with chronically implanted EMG electrodes. Rapid optogenetic silencing of motor cortical output using *vGAT*-targeted activation of inhibitory interneurons during precision pull caused muscle activity time series to deviate from controls in less than 10 ms. Such deviations were not observed during untrained treadmill locomotion. Thus, motor cortex can operate in distinct control modes depending on behavioral context, consistent with interpretations of previous lesion results. To probe the mechanism of this differential influence, we performed population-level analysis of activity recorded in motor cortex during precision pull and locomotor behaviors. We found that the firing rate of motor cortical neurons on average scales similarly with muscle activity in both behavioral contexts. However, the correlations among neuronal firing patterns change dramatically, well beyond the changes seen in muscle activity. These population changes in neuronal correlation indicate that motor cortical firing patterns occupy distinct subspaces of an overall neuronal activity space in which each cardinal dimension represents the firing rate of an individual neuron. Such changes could plausibly transform the functional impact of motor cortex on downstream circuits. Collectively, these findings clarify the real-time involvement of motor cortex in movement control and provide insight into the neuronal activity dynamics that underlie this context-specific role.

Title: Computational model of sensorimotor cortex.

Authors: *T. D. SANGER;
Biomed. Engin., USC, Los Angeles, CA

Abstract: Candidate computational models based on known neural connectivity in vertebrates exist for the cerebellum, basal ganglia, and spinal cord. There is no hypothesized model for the computational function of the cortex. We hypothesize that there exists a universal computational structure that serves the many different purposes of the different cortical areas. The structure is based upon dynamic propagation of activity across cortex. Propagation is seen in vertebrate and invertebrate neural sheets, and it creates the internal dynamics that are necessary for prediction, control, and interaction with the external world. The simplest model of propagation dynamics is given by a density flow described by da/dt = -b(x,t) * da/dx, where b(x,t) is the local rate of flow, and a(x,t) describes the activity at point x in the cortex at time t. We show that for visual sensory processing these dynamics describe and predict the movement of visual objects, whereas for motor processing these dynamics allow compliant linear and oscillatory motions. The local flow rate b(x,t) changes more slowly than a(x,t), and it can be learned by observing the changes in state a(x,t). b(x,t) itself is also a type of state, because it describes the current dynamics of the environment or control outputs. Therefore a different cortical area could model or control these dynamics using a flow of the form db/dt = -c(x,t) * db/dx. Extrapolation of this process leads to a hierarchy of dynamic descriptors, each operating on progressively coarser time-scales. For example, for vision a(x,t) describes the velocity of points in the image, b(x,t) describes how objects change velocity or direction over time, and c(x,t) describes the sequence of different movements. Because b(x,t) and c(x,t) operate at progressively slower time-scales, coarser representations of the state x can be used giving a sequential abstraction of the original sensory data. In the motor domain, control progresses from more abstract sequences c(x,t) through velocities b(x,t) and down to specific positions or postures a(x,t). We simulate this hierarchical model using a network of interconnected spiking neurons implemented on a graphics processing unit (GPU). The network controls a robot in order to learn and perform 3-dimensional visually-guided reaching in real-time. We propose a candidate structure by which the dynamic flow algorithm may map onto the known ultrastructure of primary sensory-motor regions of cortex. These results provide the first hypothesis for cortex that can describe the hierarchical functions of different regions using a single consistent computational structure.

Title: Model-free optimal feedback mechanisms of human sensorimotor control

Authors: *Z.-P. JIANG[1], T. BIAN[1], D. M. WOLPERT[2];
[1]Departrment of Electrical and Computer Engin., New York Univ., Brooklyn, NY; [2]Dept. of Engin., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Recent work has shown that in the human sensorimotor learning tasks, the central nervous system (CNS) regulates, and even amplifies, the motor variability instead of minimizing its effects (Wu et al., 2014). The importance of motor variability is also illustrated by showing that the ability to increase the motor variability is impaired in patients with Parkinson's disease (Pekny et al., 2015). Here, we develop a novel learning theory known as adaptive dynamic programming (ADP; see Jiang and Jiang, 2013) that can justify the necessity of regulating the motor variability in motor learning, and explain several recent experimental discoveries. This theory exhibits three important features. First, sharing some similar aspects with reinforcement learning (RL), our learning framework is a data-driven, non-model-based approach, and hence serves as an ideal candidate for studying the model-free learning mechanism in the human sensorimotor system. Second, our theory confirms that the motor variability, usually thought as a consequence of the internal noise, plays an important role in sensorimotor learning. Similar to the exploration noise in RL, the active regulation of motor variability promotes the search for better control strategies in each learning cycle, and as a result improves learning performance. Finally, in contrast to RL, both stability and optimality of the human sensorimotor system are taken into account in our learning model. To illustrate our learning theory, we conducted simulations to study the learning behavior of human arm movements in a divergent field (DF). Our simulation reveals that our algorithm, even without identifying the specific model of the environment, can still regain a stable and optimal behavior in the DF after enough learning trials. Moreover, during the learning process, the stiffness increases significantly along the direction of the divergence force. Our simulation also successfully recreates the savings phenomenon, indicating that model-free learning may be the cause of savings. In conclusion, we conjecture that human sensorimotor system may use an ADP-type mechanism to control movements and to achieve successful adaptation to uncertainties present in the environment.

Title: An action selection model based on sensorimotor associations and rewards for recoverable biased potentials

Authors: *T. NISHIZAWA, T. URAKAWA, O. ARAKI;
Tokyo Univ. of Sci., Tokyo, Japan

Abstract: Before a monkey begins an action, neural activities representing motion directions appear at the dorsal premotor (PMd) and the parietal cortices (potential action; PA) (Cisek et al., 2005; Klaes et al., 2011). Even if the direction is not shown to the monkey, the corresponding PA to the imaginary direction is evoked (Klaes et al .,2011). In this previous experiment, the monkey had to select the motion direction following an alternative rule which indicated the same (direct) or opposite (inferred) direction to a visual cue. Thus, the monkey must keep both directions in mind until the rule was shown. After learning, the PA for the inferred direction was larger than for the other (biased potentials). In the following free choice task with no rule, where the monkey was able to freely select either direction, the biased potentials were almost observed and the inferred direction before the free choice task was actually selected. Interestingly, a reward schedule which prevents biased behaviors made the PA evenly balanced. However, when the reward policy returned to even, the biased potentials occurred again in only a few days. Klaes et al. (2012) proposed a neural field model, which learned each state of biased or balanced PA in the experiment. However, this model does not refer to the fast recovery to biased potentials. To explain the whole process from biased potentials to balanced and to biased ones again, we hypothesized two learning systems. In our model, one learned rules for sensorimotor associations by long-term experiences, and the other learned the associations to make short-term rewards as much as possible. The former system is implemented in synaptic weights from the PFC to the PMd, and the latter is in those from PFC to the basal ganglia (BG) relevant to the reward system. We proposed a neural network model that consisted of 5 kinds of layers (PMd, PFC, PPC, BG, and M1), adding BG with modified PFC to the previous model of PA (Cisek et al., 2006). Our results showed that PFC-PMd learned biased connections heavily weighted on the inferred directions to balance the input signals of direction. The reward schedule made PFC-BG system contribute to moving towards the direct one to compensate the biased activity from PFC-PMd system, and the PA became balanced. After the reward control stopped, the biased potentials occurred again because rapidly-updating PFC-BG weights approached uniform in strength. As a system's behavior, the rate of selecting an inferred direction was 72.5% in the biased state, 48.8% in the balanced one, and finally returned to 61.9%. Our study suggests that two leaning

systems, long-term sensorimotor associations and short-term adjustments, compete for the selection.

Title: Post-Movement activity in M1 contributes to retention when movements become repetitive

Authors: *R. HAMEL[1], P.-M. BERNIER[1], M. TREMPE[2];
[1]Kinanthropologie, Univ. De Sherbrooke, Sherbrooke, QC, Canada; [2]Sports Studies program, Bishop's Univ., Sherbooke, QC, Canada

Abstract: Post-movement activity in the primary motor cortex (M1) has been shown to play an important role for the retention of motor memories (Hadipour-Niktarash et al., 2007). Yet, it remains unclear whether M1 contributes to memory storage early during visuomotor adaptation – when motor commands are adjusting – or late during adaptation – when motor commands tend to repeat (Taylor et al., 2014). Hence, the objective of the present study was to determine whether the contribution of M1 to the retention of motor memories changes during a practice session.
A visuomotor adaptation paradigm was used in which participants (n = 55) reached toward visual targets while compensating for a rotated visual representation of their hand. Three separate groups had to execute a total of 500 reaching movements in which the visual rotation was slowly incremented from 1 to 25° in the first 250 trials and remained constant at 25° for the last 250 trials. A fourth group executed the aforementioned 250 first trials, but the visual rotation increased from 25° to 31°, decreased to 19° and increased back to 25° in the last 250 adaptation trials. Single-pulse transcranial magnetic stimulation (TMS) was used to disrupt M1 activity immediately at movement offset. Participants of the Early TMS group received a TMS pulse after each of the first 250 adaptation trials. Participants of the Late TMS and Var TMS groups both received a TMS pulse after each of the last 250 adaptation trials. Participants of the No TMS group received no TMS pulse. Adaptation was assessed by measuring the direction of hand movement at peak velocity and retention was assessed 24h after the initial session.
Verbal reports after the experiment revealed that none of the participants consciously perceived the gradually-introduced visuomotor rotation. Results showed that participants of all groups similarly adapted to the visuomotor rotation on the first day (p = 0.48). However, participants of

the Late TMS group showed impaired retention when compared to the No TMS, Early TMS and Var TMS groups ($p < 0.05$), which did not differ from each other ($p > 0.9$). This suggests that the contribution of M1 to retention is more important during the late phase of adaptation when motor commands tend to repeat.

Title: The neural substrates of error processing in face of a visuomotor rotation

Authors: *G. AVRAHAM[1,2,3], A. SHKEDY-RABANI[4,3], O. GROWEISS[4,3], I. NISKY[2,3], L. SHMUELOF[4,3];
[1]Ben-Gurion Univ. of the Negev, Beer Sheva, Israel; [2]Dept. of Biomed. Engin., [3]Zlotowski Ctr. for Neurosci., [4]Dept. of Brain and Cognitive Sci., Ben-Gurion Univ. of the Negev, Be'er Sheva, Israel

Abstract: The human sensorimotor system has a remarkable capacity to adapt to changes in the environment. It is generally accepted that adaptation to sensorimotor perturbations takes place through an error-based mechanism: a sensory prediction error (e.g., the difference between the predicted and the perceived feedback) leads to updates of an internal model, which then modifies the control policy to affect subsequent trials. Such an error-based framework suggests that, following the experience of an error, one or multiple brain networks process the error and update its internal models. Here, we localize the areas that show sensitivity to the presence of errors and to their size while controlling for possible online correction confounds. Lying inside a 3T MRI scanner (Philips), eleven participants made fast out-and-back reaching movements with their dominant wrist. Participants were instructed to position the reversal point of the movement on a target. Visual feedback from the cursor was given only at the reversal point. Following a familiarization session with no perturbations, visual feedback of the reversal point began to

rotate with respect to the direction of wrist movement. The perturbation was varied according to a random walk algorithm. In 20% of the trials, participants did not receive feedback about the reversal point (no error trials). Each participant performed four experimental runs. To extract activation patterns on a trial-by-trial basis, a slow event-related fMRI design with ITI of 6-10 seconds was chosen. Behavioral results show that the random walk perturbation led to comparable directional errors throughout the entire experiment. However, the directional errors were smaller than the applied rotation, indicating a trial-by-trial adaptation. Furthermore, analysis of the trajectories revealed that the participants did not make online corrections or error-related adjustments between the trials. Contrasts of the error and no-error trials revealed a network of areas that include the posterior parietal cortex, primary and premotor cortices, lateral occipital areas, and areas in the anterior lobe of the cerebellum. A parametric analysis in search of areas that show sensitivity to the size of the error revealed areas in the right premotor cortex and in the anterior lobe of the cerebellum. Isolating the error processing component in visuomotor adaptation learning is vital for studying the neural networks that are associated with the modulation of error sensitivity in face of consistent perturbation and with the retrieval of recent motor memories.

Title: Good brain-state for high performance of the visuomotor tracking task - A Simultaneous EEG and fMRI study

Authors: *H. SHITARA[1,2], S. HOROVITZ[1], T. HANAKAWA[3], L. LI[1], N. THIRUGNANASAMBANDAM[1], H. CHO[1], D. MUESSGENS[1], S. KORKMAZ[1], M. HALLETT[1];
[1]Human Motor Control Section, NINDS, NIH, Bethesda, MD; [2]Dept. of Orthopaedic Surgery, Gunma Univ. Grad. Sch. of Med., Maebashi, Japan; [3]Dept. of Advanced Neuroimaging, Integrative Brain Imaging Center, Natl. Ctr. of Neurol. and Psychiatry, Kodaira, Japan

Abstract: Several studies have shown that brain states before stimulus presentation correlated with the performance of memory and cognitive tasks. However, it is still unclear whether brain states before performing motor task affects the performance. Moreover, the relationship between mental-state, including the motivation and arousal before performing a task, and the performance of the motor task is unclear. To address this issue, we performed simultaneous EEG and fMRI recording during a visuomotor tracking task in 17 right-handed healthy participants. Participants were asked to track a target with a joystick using the left hand. Performance was quantified as the distance between the target and the cursor (small distance meaning good performance). EEG data were recorded with 32-channel cap. The power in the α and β band were extracted for each dataset. A asymmetry (F3 minus F4) and β/α ratio were used as the parameters of mental-state. FMRI data were acquired on 3 Tesla MRI with a head coil and analyzed with AFNI. A asymmetry and β/α ratio were also used as regressors for the fMRI. There was a significant negative correlation between the α power at FP2, F4, FC6 and performance($P< 0.001$). The α power at P3 and Pz and β power at FP1, P4, P7, O1, and Oz were significantly positively correlated with performance($P< 0.001$). The β/α ratio was significantly correlated with performance ($P< 0.0005$). There was no significant correlation between the α asymmetry and performance. B/α ratio during task preparation was correlated with performance, showed significant correlations with fMRI activity in the left paracentral gyrus, pons, the right thalamus and the right middle frontal gyrus (unc $P<0.001$). The fMRI activation in the left lingual gyrus was significantly positively correlated with performance (FWE $P<0.05$). The EEG result showed that high power of the α range at the right Brodmann area(BA) 8, 10, and 44, and low power of the α range at the left BA39 and the right BA7 and β power at the right BA 17, 39, the left BA 10, 18, and 37 were correlated with high performance of the task. The high β/α ratio, associated with excitement or tense state, was correlated with bad performance. Using regressors of performance and the β/α ratio might be able to separate the motor related areas from the mental state-related areas. FMRI results showed high brain activity of the left precentral gyrus and pons, the right thalamus and the right middle frontal gyrus correlated with high performance related mental state and the low brain activity of the left visual cortex correlated with high performance, not related mental-state. Interestingly, these areas of fMRI activation were corresponding to the EEG activations.

Title: Role of dopamine in motor adaptation with reward and punishment.

Authors: *G. QUATTROCCHI[1], J. MONACO[1], A. HO[1], F. IRMEN[1], W. STRUBE[1], D. RUGE[1], S. BESTMANN[1], J. M. GALEA[2];
[1]UCL Inst. of Neurol., London, United Kingdom; [2]Univ. of Birmingham, Sch. of Psychology, Birmingham, United Kingdom

Abstract: Seeking reward and avoiding punishment are powerful motivational factors known to shape human behaviour. Despite this, little is known regarding their influence on error-based motor learning (motor adaptation), traditionally thought as an implicit process unaffected by motivational feedback. Recently we have shown a double dissociation where punishment accelerated visuomotor (VM) adaptation, whereas reward increased retention (Galea et al., 2015). However, the underlying neural mechanisms of these effects are not known. We used a pharmacological approach to test for the role of dopamine (DA) during adaptation with reward- (R) or punishment- (P) based monetary feedback.
Healthy young subjects performed a VM adaptation reaching task under different feedback (R/P/neutral) and drug (levodopa, LD/haloperidol, Halo/placebo, Pl) conditions, in a double-blind placebo controlled design. Experiment 1 (Exp1) examined whether the positive effect of reward on retention could be enhanced by increasing dopamine through LD (100 mg), with four groups (n=16 each): reward-LD, reward-Pl, punishment-LD, and punishment-Pl. Experiment 2 (Exp2) investigated whether the influence of reward could be impaired by blocking DA receptors through halo (2.5 mg), with three groups (n=16 each): reward-halo, punishment-halo, neutral-Pl. During adaptation, the screen-cursor was rotated 40^o clockwise and reward, punishment, or neutral feedback was provided (between-subject design). Next, both the perturbation and visual feedback were removed to assess retention. This was followed by a washout with visual feedback and finally re-adaptation to the 40^o perturbation.
Exp1 replicated our previous results that reward increases retention. Surprisingly, we didn't find any effect of LD, possibly due to the effect of reward not being dopaminergic, or LD being ineffective in healthy young participants. The latter would be in line with previous studies, reporting a beneficial effect of LD on movement acquisition in elderly but not young subjects (Floel et al., 2005 and 2008). Indeed, in Exp2, haloperidol significantly reduced the positive effect of reward, with retention being indistinguishable from the punishment and neutral groups.

Our results support the hypothesis that the dopaminergic system underpins the positive effect of reward on motor retention and highlight the behavioural and neurobiological difference between reward and punishment-based feedback during motor learning. We suggest that DA stimulation (LD) may be still useful to enhance reward-based motor retention when the DA system is challenged such as in aging or in stroke (Hosp & Luft, 2013).

Title: Low-frequency oscillations in force slow reaction time

Authors: *A. CASAMENTO MORAN, S. PARK, B. YACOUBI, E. A. CHRISTOU;
Univ. of Florida, Gainesville, FL

Abstract: A fast reaction time is essential in many activities of daily living (e.g. reacting during driving) and sports (e.g. receiving a tennis serve). The anticipation of an event (stimulus) can influence the speed of the reaction time. It is unclear whether specific frequencies in the motor output are advantageous for producing faster reaction times. The purpose of this study, therefore, was to determine whether reaction time can become faster with the selection of specific frequencies during a dynamic force task. Ten healthy young adults (22.4 ± 3.1 yrs, 5 men) performed a dynamic force task with the ankle and reacted to a visual stimulus. The target force for the dynamic force task was 15% MVC, and each trial lasted 37 seconds. Participants fluctuated around the targeted force at a self-selected frequency with an amplitude no greater than ± 5% MVC. They reacted to an unanticipated visual stimulus (screen turning green) by exerting an ankle dorsiflexion force. Reaction time was quantified as the time interval between the stimulus onset and the onset of the tibialis anterior (TA) muscle activity. The frequency components of the force output were quantified with a power spectrum 10 seconds prior the stimulus onset (0.1 Hz resolution). We considered low-frequency oscillations the frequencies below 0.5 Hz. The self-selected oscillatory force frequency during the anticipation of the visual stimulus was 0.8 ± 0.48 Hz. Participants who selected lower frequencies exhibited slower reaction times (R^2=0.46; P<0.05). Similarly, contractions with greater power below 0.5 Hz were

associated with slower reaction times (R^2=0.54; P<0.01). In contrast, greater power in faster frequencies (1-3 Hz) was associated with faster reaction times (R^2=0.44; P=0.03). These findings provide novel evidence that low-frequency oscillations in force (<0.5 Hz) during the anticipation of a visual stimulus slow reaction time. Interestingly, low-frequency oscillations in force have been associated with greater force variability, and have been viewed as an unwanted signal to the motor command. It is possible, therefore, that modulating force at higher frequencies is advantageous for producing faster reaction times.

Title: Identification of EEG biomarkers in essential tremor drug discovery: a preclinical study

Authors: *V. DUVEAU, B. MANDÉ-NIEDERGANG, R. MAURY, C. DUMONT, B. POUYATOS, C. ROUCARD, Y. ROCHE;
SynapCell, La Tronche, France

Abstract: Essential tremor (ET) is one of the most common form of movement disorders. It is characterized by the apparition of postural tremor and intensifies when one tries to use the affected muscles. ET typically involves a tremor of the arms, hands or fingers. In the case of stronger symptoms, first line medication is beta-blockers such as propranolol or the anti-epileptic primidone. Second line medications are the anti-epileptics topiramate, gabapentin and levetiracetam given as an add-on therapy with the first line drug. Despite the wide possibility of medications, a large number of patients are not adequately relieved. There is therefore an urgent need to find new specific treatments for ET.
The most widely used animal model of essential tremor is generated by the administration of the beta-carbolin (harmaline) in mice. Harmaline induces long-lasting tremors in mice by increasing neuronal synchrony and rhythmicity in the olivocerebellar system. In this model the classical read-out is the recording of tremor frequency that occurs between 8 to 10Hz.
In this work we investigated the impact of harmaline-induced tremor on cortical, cerebellar and thalamic oscillations using quantitative electroencephalography (qEEG), and the sensitivity of these activities to the reference drugs.
We found that administration of harmaline (10, 20, 30mg/kg) in male C57BL/6 mice dose-

dependently increased the cortical power in the 15-60Hz range, along with action tremors. This power increase appeared within a few minutes after treatment and remained stable for at least 4h. This oscillation was also seen in the thalamus and in the cerebellum along with a strong increase of the gamma power for this latter. Pre-treatment with 20mg/kg propranolol, one of the first-line medications used in ET patients, 20 minutes before the administration of harmaline 20mg/kg strongly attenuated the tremors and reversed the 35-60Hz oscillation to control levels for the three structures investigated.
In this study, we identified specific EEG biomarkers of ET in three different brain structures after harmaline injection using qEEG methods. We then showed the pharmaco-sensitivity of these EEG biomarkers to several reference drugs used in the clinic.
The EEG biomarkers identified in the rodent harmaline model might constitute a powerful preclinical tool for the drug development for ET.

Title: Visual perception of communicative hand actions in the parietal cortex

Authors: ***B. A. URGEN**, G. A. ORBAN;
Dept. of Neurosci., Univ. of Parma, Parma, Italy

Abstract: A growing body of research in action perception suggests that the parietal node of the action observation network has dedicated regions for different classes of actions including manipulation, interpersonal, skin-displacing, locomotion, and climbing (Jastorff et al., 2010, Abdollahi et al. 2013, Ferri et al., 2015). The aim of the current study is to extend this work with two new classes of actions that are communicative in nature. The stimuli are 2.6 sec video clips showing a male or female actor performing 3 classes of actions with hands or fingers: (1) direct

communication, (2) indirect communication, (3) manipulation. Each class has 4 exemplars, and each exemplar has 4 variants (16 video clips per action class). The direct communication actions include waving, clapping, displaying “no” sign, and displaying “right here” sign, and are targeted toward a male or female actor. The indirect communication actions include writing, drawing, erasing, and sculpturing, performed on two substrates, sand or dough. The manipulation actions are grasping, dropping, dragging, and pushing, and targeted toward a small or a big object. Two types of control stimuli are used: static controls (SC), which are static frames from the first, middle or last part of each video clip, and dynamic controls (DC), which consist of optical flow of each video clip with a noise pattern. 15 subjects were presented the stimuli while they were scanned with fMRI. The activation maps for each class were computed by the conjunction of the contrasts (action – SC) and (action – DC) ($p = 0.01$), masked by (action – fixation) ($p = 0.01$). Manipulation actions activate left phAIP, PFt, and PF in parietal cortex consistent with previous work. Direct communication actions activate only left PF in parietal cortex, lacking phAIP. Indirect communication actions activate not only phAIP and PFt more extensively than manipulation actions but also DIPSA and DIPSM in parietal cortex bilaterally. The PFt cluster also overlaps with SMG, an area specialized in observation of tool actions (Peeters et al. 2013). These results extend previous work on phAIP by suggesting that interaction of hand not only with an object (with the goal of displacing) but also with a substrate (with the goal of transforming) could activate phAIP, as it is activated in manipulation and indirect communication but not direct communication. The results also show that indirect communication actions activate right parietal regions as strongly as the left ones unlike manipulation actions. In sum, these results are consistent with recent evidence that parietal cortex is activated differentially for different action classes. Supported by ERC grant Parietalaction.

Title: A brain-computer interface for motor rehabilitation with multi-modal feedback in a chronic stroke patient

Authors: *G. EDLINGER[1,2], C. GUGER[3];
[1]Guger Technologies OG, Graz, Austria; [2]g.tec medical engineering GmbH, Schiedlberg,

Austria; [3]g.tec medical engineering GmbH, g.tec neurotechnology USA, Inc., Schiedlberg, Austria

Abstract: Brain-computer interfaces (BCI) are able to measure brain activation and to generate a control signal for external devices in real-time. This is especially well suited for motor rehabilitation since motor imagery BCI systems allow to analyze sensorimotor regions of patients and can control feedback devices that allow the patient to re-gain motor functions. In the current study patients with sub-acute stroke were trained for 25 sessions with 30 minutes each to imagine left or right hand movement. An avatar on a computer screen gave the instruction to the patients by moving his arms (80 trials left hand movement and 80 trials right hand movement).The BCI system was able to analyze the EEG in real-time and triggered a functional electrical stimulator of the corresponding left or right hand so that the hand really moved. Additionally the Avatar's hand were moving if the classification results was correctly available. The motor function improvements were measured with a 9-hole PEG test. In a chronic stroke patient (64 years, Feb 2014 stroke impaired left side, 18 month afterwards participation in the study) the 9-hole PEG test showed an improvement of the affected left hand movement from 1 min 30 seconds to 52 sec after 24 training sessions (healthy right hand: 26 sec). The BCI accuracy varied between 70% (session 2) to 98.5 % (session 13). The mean accuracy of the first 3 sessions was 81 % and of the last 3 sessions was 88 %. Before the training, the patient could not lift the arm to feed himself, but after the training the patient was able to reach his mouth. The BCI accuracy is a very objective marker if stroke patients are participating in the training task. 50 % would mean that patients don't follow (or are not able to follow) the task and the experimenter can coach them to improve. Interesting is that the patient achieved a very high maximum BCI accuracy and that he could also improve his BCI performance with training sessions, which shows motivation. Most important is that within only 25 training sessions the motor functions clearly improved. An important strategy is to activate first the motor cortex with the imagination. Then the arm is moving which activates the sensorimotor cortex and the patient sees also the movement which activates the mirror neuron system. The mirror neuron system and the sensorimotor cortex are tightly coupled and this leads to an effective setup. Very important is that the system worked also for a patient in a chronic state after the stroke (18 month later).

Title: Sensorimotor cortical plasticity induced by the brain-machine interface reduces phantom limb pain

Authors: *T. YANAGISAWA[1,4,2], R. FUKUMA[2,4], B. SEYMOUR[6], K. HOSOMI[2,7], H. KISHIMA[2], T. SHIMIZU[2], H. YOKOI[8], M. HIRATA[3,2], T. YOSHIMINE[3], Y. KAMITANI[9,5], Y. SAITOH[7,2];

Labs., [5]Computat. neuroscience laboratories, ATR, Kyoto, Japan; [6]Univ. of Cambridge, Cambridge, United Kingdom; [7]Dept. of Neuromodulation and Neurosurg., Osaka Univ. Grad. Sch. of Med., Osaka, Japan; [8]The Univ. of Electro-Communications, Tokyo, Japan; [9]Kyoto Univ., Kyoto, Japan

Abstract: Phantom limb pain is neuropathic pain after the amputation of a limb and partial or complete deafferentation. The underlying cause of this pain has been attributed to maladaptive plasticity of the sensorimotor cortex. However, how sensorimotor activities should be changed to reduce this pain has not been determined. Here, we used a brain-machine interface (BMI) to induce plastic changes in cortical activity. BMI training of a robotic hand using real-time magnetoencephalography (MEG) signals was applied in phantom limb pain patients to evaluate the association with changes in cortical information and symptomatic pain.
We included nine patients with brachial plexus root avulsion and one patient with amputation who had phantom limb pain. First, in open-loop conditions, they were instructed to perform grasping or opening movements with their unaffected hands during the MEG recording. The time-averaged MEG signals were used to train decoders to control the robotic arm in real time. The patients were instructed to control the BMI-controlled robotic hand by trying to move their phantom hands for 10 minutes while watching the movement of the robot. During this closed-loop session, the patients tried to improve their performance to control the robot. The phantom limb pain was evaluated by a visual analog scale (VAS) and SF-MPQ2. Moreover, the patients also performed grasping or opening movements with their phantom hands or unaffected hands during the MEG recording before and after the training to evaluate the cortical plasticity attributable to training.
The estimated cortical currents in the contralesion sensorimotor cortex significantly varied between the two types of movements (one-way ANOVA). The F-value of ANOVA of the sensorimotor cortex was decreased after the training. Also, classification accuracy using the cortical currents in the contralesion sensorimotor cortex was significantly decreased after the training. Interestingly, the phantom limb pain decreased as the movement classification accuracies decreased.
These results demonstrate a functionally relevant relationship between sensorimotor cortical

plasticity and phantom limb pain. BMI neurofeedback may become a novel treatment for phantom limb pain.

Inspired Life Support Res. Ctr., The Univ. of Electro-Communications, Chohu, Japan

Abstract: Brain-machine interface (BMI) or brain-computer interface (BCI) is an interface technology that utilizes neurophysiological signals from the brain to control external machines or computers. We have developed a P300-based BMI system to support daily activities of persons with disabilities, and found that green/blue chromatic and luminance flicker matrices improved the BMI performance for able-bodied subjects and spinal cord injury patients (Takano et al, 2009). We also created a region-based 2-step speller, which has a larger flashing area than the conventional visual array, and reported that the two-step procedure provided significantly increased accuracy compared with a conventional row/column speller for the amyotrophic lateral sclerosis patients (Ikegami et al., 2014). In this study, we applied the region-based 2-step P300 BMI speller to Duchenne muscular dystrophy (DMD) patients.
Eight DMD patients (23-38 years old, 8 men), who had not trained in BMI operation before,

were recruited in this study. The value of the modified Rankin Scale (mRS) was 5 in all patients, and tracheostomy were done in 4 out of 8 patients. They were required to input Japanese hiragana characters using the region-based two-step P300-based BMI system. We divided 6x9 matrix into six circled regions including nine characters each. First, each region was individually intensified, and the subject attended to the background circle that included the target character. When the region was selected, the speller matrix moved to the second step. In the second step, each character was intensified within the circled background region, and the subjects then selected the target character. The first step used 2x3 regions, and the second step used 3x3 regions. Eight channel EEG data were recorded, and a linear discriminant analysis distinguished the target region that a subject attended to from other non-target regions of the matrix. We evaluated their online classification accuracy.
The mean online accuracy for the 2-step procedure was 70.0% (the first step:91.3%,the second step:76.2%). The accuracy exceeded 70% in 4 out of 8 patients without significant training. These results suggest that the region-based 2-step speller for P300-based BMI may be beneficial for DMD patients.

Title: Decoding of multi-joint movements using high-density EMG signals and a 7-DoF exoskeleton

Authors: *A. SARASOLA-SANZ[1,2], N. IRASTORZA-LANDA[1,2], E. LOPEZ-LARRAZ[1], G. ROSSI[3], N. BIRBAUMER[1], A. RAMOS-MURGUIALDAY[1,4];
[1]Inst. of Med. Psychology and Behavioral Neurobio., Univ. of Tubingen, Tuebingen, Germany; [2]IMPRS for Cognitive and Systems Neuroscience, Max Planck Inst. Biol Cybenetics, Tuebingen, Germany; [3]Univ. of Padova, Italy, Padova, Italy; [4]Hlth. Technologies Dept., TECNALIA, San Sebastian, Spain

Abstract: Myoelectric decoders have been broadly proposed and used in combination with robotic exoskeletons as a tool for the rehabilitation of motor disabled patients. Most of them are limited to the classification of discrete movements and some others have shown a modest decoding performance of trajectories including very few degrees of freedom (DoFs) of the arm. Although it is still not clear to which extent the decoding performance could influence the rehabilitation effects of the therapy, it is natural to believe that a higher decoding accuracy may establish a more direct and robust link between the movement intention and the response stimuli (i.e. the feedback). In a previous study, we demonstrated the viability of a motor rehabilitation platform consisting of: i) a set of 10 surface bipolar electrodes placed over the abductor pollicis longus, extensor carpi ulnaris and digitorium, flexor carpi radialis, ulnaris and palmaris longus, pronator teres, biceps, triceps and anterior, lateral and posterior portions of the deltoid; ii) a myoelectric decoder that predicted multi-DoF kinematics based on the input EMG; iii) the IS-MORE 7-DoF robotic exoskeleton (Tecnalia, San Sebastian, Spain) that moved according to the predicted kinematics, providing the subject with visual and proprioceptive feedback. It was shown that the ridge regression was a potential algorithm for the EMG-decoding of trajectories. However, the non-optimized ergonomy of the exoskeleton and the small number of electrodes constituted a limitation to achieve a reliable and accurate EMG-control. In this study, we address those issues by optimizing the design of the fingers' interface of the exoskeleton and by recording forearm EMG with high-density electrodes. On the whole, this improved rehabilitation system offers the following advantages: i) It allows functional movements involving proximal and distal DoFs of the arm; ii) It can continuously map the EMG into multi-DoF kinematics; iii) It provides contingent feedback, which might lead to the activation of neuroplastic mechanisms restoring motor function; iv) Even severely paralyzed patients without residual movement can utilize this system. Here, we test the decoding ability of the system in 6 healthy subjects (age: 22-29, right-handed) in one session. Participants worn the exoskeleton on their dominant arm and were asked to reach different targets while supinating and opening their hand. EMG and kinematic data was recorded and the performance of the myoelectric decoder was evaluated offline. The performance values will be presented and the potential and applicability of the presented rehabilitation system will be discussed based on the results.

Title: Wireless earpiece to control robotic arm in functional tasks

Authors: *A. PROCHAZKA[1], M. J. GAUTHIER[1], M. BLOUIN[2];
[1]Neurosci. and Mental Hlth. Inst., Univ. of Alberta, Edmonton, AB, Canada; [2]Kinova Inc., Boisbriand, QC, Canada

Abstract: We have developed a wireless earpiece, similar in size to a hearing aid, that allows a person with paralyzed upper limbs to control a robotic arm to perform simple functional tasks. For example, with a robotic arm attached to their wheelchair, a person living with tetraplegia can perform a number of useful tasks such as feeding themselves, opening doors, moving objects from one place to another and pouring fluids. This can significantly improve their level of functional independence. Although robotic arms that have the appropriate motor capabilities have recently become available commercially, a major barrier is for a paralyzed user to transmit his/her voluntary intention to the robot's control system.

One approach that has caught the imagination of the public and that has become a major research focus around the world is to use neural signals recorded from the brain that are correlated with intentional movement (brain machine interfaces). Non-invasive EEG signals recorded from the scalp have been studied, but they tend to be too noisy and variable for this purpose. Multi-electrode recording arrays have been implanted in the cerebral cortex of a number of people with tetraplegia. The recorded neuronal activity has enabled remarkably good control of a robot arm in some cases, but these systems require invasive surgery, with a significant risk of infection. They are also very expensive and so far they have stopped working reliably after a year or two.

We have pursued an alternative, non-invasive and affordable approach by modifying a wireless earpiece that is currently used to control a wristlet that delivers electrical stimulation to the muscles that open and close the hand (Prochazka (2005, 2016)). The new earpiece detects head movements, humming and tooth-clicks to generate signals that control the position of a robot arm's hand, pronation-supination, flexion-extension and opening and closing of the hand's gripper. The control scheme has been verified on a Kinova Jaco robot arm. Human testing is scheduled for mid-2016.

Abstract: Recently, the ability of non-invasive Brain-Computer Interface (BCI) to control an exoskeleton was used for motor rehabilitation in stroke patients (Ramos-Murguialday et al., 2013) or as an assistive device for the paralyzed (Turner et al., 2013). However, there is still a

need to create a more reliable non-invasive BCI that could be used to control several degrees of Freedom (DoFs) to improve rehabilitation results (Ueki et al., 2012). Decoding different movements from the same limb, high accuracy and reliability are some of the main difficulties (non-psychological like user acceptability) when using conventional EEG-based BCIs.
We acquired EEG data in 9 healthy participants during three-dimensional (3D) center-out arm reaching tasks in 4 non-consecutive sessions and decoded 6 different functional movements performed with the same limb. Six functional movements consisted of reaching to each of four targets, backward movement, and rest. Furthermore, we investigated the influence of recalibrating the generated classifier with data from the same and previous sessions to improve stability and reliability of the decoding. Therefore, we used a multiclass extension of the Filter Bank Common Spatial Patterns (FBCSP) to define the features for three frequency windows (7–15 Hz, 15–25 Hz, and 25–30 Hz) and a linear discriminant analysis (LDA) as classifier. Artefacts were removed from the EEG data to avoid muscle or eye movement bias during the decoding. We decoded 3, 4 and 6 behavioral movements separately to compare decoding results, assuming 60% as an acceptable performance for online use of the system.
We obtained average decoding accuracies above 66% for 3-classes, 62% for 4-classes, and 50% for 6-classes. Decoding accuracy was increased for 3-class and 4-class if data from previous sessions and some minutes from the beginning of each session were used to retrain the classifier.

Title: A new brain-robot interface system based on SVM-PSO classifier

Authors: ***V. AZIMIRAD**[1], M. HAJIBABZADEH[1], P. SHAHABI[2];
[1]Mechatronics, Univ. of Tabriz, Tabriz, Iran, Islamic Republic of; [2]Neurosci. Res. Ctr., Tabriz Univ. of Med. Sci., Tabriz, Iran, Islamic Republic of

Abstract: This paper presents a new noninvasive brain-robot interface system for control of two degrees of freedom robot through motor imagery EEG signals. Signal classification is based on optimized Support Vector Machine (SVM) by Particle Swarm Optimization (PSO) algorithm. EEG signals of FC3, C3, CP3, FC4, C4 and CP4 Channels that are related to hands movement as well as Cz and FCz channels that are related to feet movement are considered. Radial basis function (RBF) and penalty functions of SVM are optimized through PSO algorithm. For validation of SVM-PSO classifier, the EEG signals are collected from two databases: PhysioNet and BCI Competition III, then features including Power Spectral Density (PSD) and wavelet parameters are used as the input of the classifier. By comparing the results of the SVM and SVM-PSO classifiers, is concluded that performance of classifier in terms of accuracy is increased through PSO algorithm. SVM-PSO classification accuracy for wavelet and PSD features are obtained 81% and 92%, respectively. The best algorithm is used to control a two degrees of freedom (one for left and right hand movements and the other for left and right foot movements) robot experimentally. It shows the applicability and effectiveness of proposed method for high accuracy brain-robot interface systems.

Title: Chinmotion: preserved sensorimotor pathways rapidly enable 3d computer interaction after tetraplegia

Authors: *F. GALAN[1,2], S. N. BAKER[1], M. A. PEREZ[2];
[1]Newcastle Univ., Newcastle Upon Tyne, United Kingdom; [2]Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL

Abstract: Current hands-free machine interfaces lack effective kinaesthetic feedback, preventing fast and accurate multidimensional prosthetic control. We developed an open-source wearable interface (ChinMotion) which non-invasively transforms chin, lips and tongue motion of people with tetraplegia into intuitive and accurate 3-D control commands.
To test ChinMotion we examined point-and-click performance of eight individuals with severe tetraplegia and eight uninjured aged-matched controls participating in a centre-out-centre reach-and-click task. Performance was estimated using Fitt's law and standard measures of speed and accuracy (ISO9241-9) allowing for comparison with current mainstream input devices and state-of-the art hands-free body- and brain- machine interfaces. On the first session using ChinMotion, the throughput of uninjured controls (0.54±0.05 bits/s, bits per second) and individuals with tetraplegia (0.55±0.07 bits/s) were similar, suggesting comparable target selection times across the range of target difficulties tested ($p>0.05$, Wilcoxon rank – sum test). Notably, the error rates of uninjured controls (18.4±3.8%) and individuals with tetraplegia (22.0±5.6%) were also comparable ($p>0.05$, Wilcoxon rank – sum test), suggesting similar accuracy across groups.
Within the same session, we also tested 3-D prosthetic control in a centre-out-centre reach-and-hold task. Participants moved a virtual robotic arm from a starting location and held its endpoint within the volume of an instructed target for 1 second. They then moved back, holding at the starting location for another second. Here, we found that all participants autonomously controlled the arm with 100% success rates. Furthermore, uninjured controls and individuals with tetraplegia completed the task at comparable speeds, requiring average trial completion times of 17.5±2.6 and 22.5±3.5 seconds, respectively ($p>0.05$, Wilcoxon rank – sum test).
Our results demonstrate that preserved sensorimotor pathways in the face offer a reproducible avenue towards the restoration of rapid and precise 3D computer interaction after severe paralysis. Coupled with advances in wearable flexible electronics and rapid-prototyping

methods, we hope that this approach will pave the way for a new generation of mainstream wearable control interfaces which are likely to be the most plausible option to restore independent function for the majority of individuals with paralysis.

Title: Multi-model wearable biosensing system

Authors: *S. SIDDHARTH[1], T.-P. JUNG[2], T. SEJNOWSKI[2];
[1]Electrical and Computer Engin., UCSD, San Diego, CA; [2]Inst. for Neural Computation, Univ. of California San Diego, San Diego, CA

Abstract: In the path to take Brain-Computer Interfaces (BCIs) outside of the laboratory domain, their bulkiness and discomfort in wearing still poses a significant problem. Today, BCIs are being used in diverse applications ranging from emotion recognition and mental disorders to gaming. Yet, the spatial resolution we get in EEG is poor and hence there are no "into the wild" i.e. real-world applications of the same. Moreover, the experiments being done in these areas are restricted to well-controlled laboratory environment only. This combined with the discomfort in using BCIs poses a significant limitation in developing BCIs for real-world applications. We designed a multi-modal biosensing system that can reliably measure EEG, ECG, GSR and other bio-sensing markers along with eye-gaze layered over the world's view of the subject. The system is wireless, wearable, comfortable, scalable and cost-effective. In addition to this, it can be custom modified as per the bio-sensing needs of the study such as changing the BCI to utilize more modalities or include EOG, EMG sensing. The system employs a world camera and an eye camera mounted on a sunglasses frame. The world camera captures subject's view of the world whereas the eye camera is Infrared based and is used to detect the center of the pupil. In this manner, location of the pupil in the eye camera frame is mapped to gaze position in the world camera frame after proper and user-friendly calibration before starting the experiment. Each video frame from the camera has a unique ID associated with it that helps in synchronizing the eye-gaze overlaid video with the time-stamped data from other bio-sensors. Using the eye-gaze information overlaid on the world view allows us to pinpoint events in the world to which the subject responds leading to changes in the biosensing data. The system transmits videos and physiological data streams from all the sensors wirelessly in real-time and synchronizes them.

Synchronization is done by time-stamping every packet data stream for each sensor in a wearable computer (Raspberry Pi3) and then sent to a host computer over Wi-Fi for processing. The designed system is being tested on experiments that invoke different emotions (both positive and negative valence) in the subject outside of the laboratory setting. The system is expected to facilitate inter-disciplinary research in the neuroscience community.

Title: BCI-based sensorimotor rhythm training can affect individuated finger movements

Authors: *D. J. MCFARLAND[1], S. L. NORMAN[3], W. S. SARNACKI[2], E. T. WOLBRECHT[4], D. J. REINKENSMEYER[5], J. R. WOLPAW[2];

Abstract: Brain-computer interface (BCI) technology can restore communication and control to people who are severely paralyzed. BCI technology might also be able to enhance rehabilitation of motor function (Lancet Neurology 7:1032-43, 2008). Toward this end, we are exploring in adults without motor impairment the possibility that training pre-movement sensorimotor rhythm (SMR) activity in the EEG over contralateral sensorimotor cortex can affect the performance of individuated finger movements.
In Phase 1, the subject performs a go-nogo task in which flexion of the index and/or middle fingers is cued during a warning phase by the colors of two circles on a video screen and then triggered by change in circle color. EEG activity for the period between the two cues is analyzed to identify SMR features (i.e., amplitude in specific mu (8-12 Hz) or beta (18-30 Hz) frequency bands at specific locations over contralateral sensorimotor cortex) that best predict movement performance, defined as the imperative stimulus condition. In Phase 2, the subject is trained to increase or decrease this feature. In Phase 3, the subject is instructed to increase or decrease this SMR feature prior to finger movement, and the impact of pre-movement SMR amplitude on movement performance is assessed.
In five subjects studied to date, appropriate SMR features have been identified in Phase 1. Four

subjects have learned to increase its amplitude in Phase 2. Two subjects have completed Phase 3. In both, pre-movement SMR amplitude affected finger movement performance.
These initial results are consistent with our previous work (Clinical Neurophysiology, 122:1820-1826, 2011; Journal of Neural Engineering, 12:066021, 2015) indicating that decreasing SMR amplitude during movement preparation can improve performance. They suggest that this finding also applies to individuated finger movements. Incorporation of pre-movement SMR training into rehabilitation protocols may be able to enhance functional recovery after stroke or other disorders that cause paralysis.

Title: Comparison of four control methods for a five-choice assistive technology

Authors: *S. HALDER[1,2], K. TAKANO[2], K. KANSAKU[2,3];
[1]Univ. of Würzburg, Würzburg, Germany; [2]Dept. of Rehabil. for Brain Functions, Res. Inst. of Natl. Rehabil. Ctr. for Persons with Disabilities, Tokorozawa, Japan; [3]Brain Sci. Inspired Life Support Res. Ctr., The Univ. of Electro-Communications, Chofu, Japan

Abstract: Motor impairments may affect the ability to communicate, and assistive technologies can restore the ability to communicate. We investigated four technologies that can be used to control assistive devices: visual, tactile and auditory P300 brain-computer interfaces (BCIs) and an eye-tracker. Both visual P300 BCIs and eye-trackers offer high communication speeds whereas auditory and tactile BCIs can be used by end-users with visual impairments. In this study we investigated a scenario of selection from five choices with a sample of healthy controls. Eleven healthy controls were recruited (six female, mean age 32.2 years). We configured a

BCI2000 five choice task for control with visual, auditory or tactile P300 BCI or a Tobii Eye-X eye-tracker. The visual P300 BCI used face stimuli, the auditory P300 BCI used Japanese Hiragana syllables and the tactile P300
BCI used a stimulator on the small left finger, middle left finger, right thumb, middle right finger and small right finger. The eye-tracker required a dwell time of three seconds on the target for selection. Participants were asked to select the five possible choices (the vowels a, i, e, o, u) four times (total 20 selections). Ac- curacies for the P300 BCIs were recalculated offline to determine the maximum speed with shrinkage linear discriminant analysis (LDA). Information transfer rates (ITRs) for the eye-tracker were calculated on basis of the total time needed to select all letters because the selection time varied from letter to letter.
We calculated accuracies and ITRs for each control method, and accuracies of 96.3% were achieved with the visual P300 BCI, of 69.1% with the auditory BCI, of 76.9% with the tactile BCI and of 100% with the eye-tracker. Corresponding bitrates were 21.1 bits/min with the visual P300 BCI, 2.2 bits/min with the auditory BCI, 2.2 bits/min with the tactile BCI and 27.2 bits/min with the eye-tracker.
Both visual P300 BCI and eye-tracker can provide very high communication speeds in this task with a sample of healthy participants. Even though the accuracy of the tactile BCI was higher than that of the auditory BCI the ITRs were identical due to the shorter selection times of the auditory BCI. We will in- vestigate further with various end-users with motor impairments in which scenarios the use of eye-trackers and in which the use of BCIs offers the greatest advantage.

Title: Learning arm movements instructed by a robotic system during motor imagery

Authors: A. TAKAI[1], T. NODA[1], G. LISI[1], T. TERAMAE[1], *H. IMAMIZU[2,1], J. MORIMOTO[1];
[1]Advanced Telecommunications Res. Inst. International(ATR), Kyoto, Japan; [2]Dept. of Psychology, The Univ. of Tokyo, Tokyo, Japan

Abstract: Assuming that human motor learning performance depends on brain states, we can probably develop an efficient training system to enhance motor skills by monitoring brain activities. In this study, through proprioceptive inputs without visual feedback, we investigate how motor learning performance depends on a subject's brain states. 20 healthy, right-handed subjects learned an arm movement on the horizontal plane by the guidance of a two-degrees-of-freedom parallel link manipulandum. Brain activities were simultaneously measured using an electroencephalogram (EEG) while a subject's left hand was moved by the manipulandum. All the subjects were instructed to memorize the guided hand trajectory while their hands were moved. Then, they tried to reproduce the instructed arm movement by themselves to evaluate the learning performance. In this period, the manipulandum measured the position and the velocity of the subject's hand. During the learning and reproducing sessions, the subjects were unable to see their current hand position. We evaluated the motor learning performance based on the average distance error between the subject's hand trajectory and the instructed target hand trajectory. We found that the learning performance significantly improved when the subjects performed motor imagery of the arm movements compared to when they failed to do so in the learning session, indicating that preparing a brain condition enhances motor skill improvement.

Title: A bootstrapping method for improving the classifier performance in the P300 speller.

Authors: *J. H. CRISTANCHO, J. F. DELGADO SAA;
Eléctrica y Electrónica, Univ. Del Norte, Barranquilla, Colombia

Abstract: A P300-speller BCI system makes the assumption that the actual P300 signal is buried in noise, therefore the average over many repetitions of the experiment is used to increase the signal to noise ratio. Although different classification methods are used to learn the distribution of the data containing P300 and non-P300 potentials, traditionally the coefficients of the classifier are learned to use single trial samples but tested using averages of the single trials. This cause the performance of the classifier to be sub-optimal and retraining the classifier with the average of single trials is a difficult task, given that the number of samples to learn from is small and the number of features remains constant. In this work, we first show how the performance of the classification task (detecting P300 vs Non-P300) is sub-optimal in the traditional approach, and we propose a bootstrapping method to re-sample from the original training data to retrain effectively a linear kernel Support Vector Machine (SVM) classifier using subgroups of single trials. The results show that the classification performance of the proposed method in terms of Cohen's Kappa (needed because of the unbalance in the class labels) is superior to the results obtained using traditional methods.

Title: Brain-machine interface for functional recovery of elevation of the shoulder girdle in a stroke survivor : A single case A-B-A-B design

Authors: *K. TAKASAKI[1], F. LIU[2], M. HIRAMOTO[2], T. NODA[3], S. KASUGA[1], K. MIZUNO[2], M. LIU[2], J. USHIBA[1];
[1]Grad. Sch. of Sci. and Technology, Keio Univ., Yokohama-Shi, Japan; [2]Dept. of Rehabil. Medicine, Keio Univ. Sch. of Med., Tokyo, Japan; [3]Dept. of Brain Robot Interface, Advanced Telecommunications Res. Inst. Intl., Kyoto, Japan

Abstract: Recent studies suggest that brain-machine interface (BMI) therapy for chronic stroke patients with severe motor paralysis is effective to improve their hand motor function. In the current study, to evaluate the effect of BMI therapy on shoulder motor function, we developed a novel BMI system using motor imagery of elevation of the shoulder girdle. Physiologically, the corticospinal tract (CST) projecting for proximal arm muscles is known to innervate bilaterally

from the hemispheres (Rosenzweig et al., 2009). In addition, in stroke patients the excitability of the unaffected hemisphere increases with motor recovery of the ipsilateral (i.e., paralyzed) upper-limb (Luft, et al., 2004). Therefore, we developed a BMI system that the exoskeleton robot assisted elevation of the shoulder girdle when ipsilateral event-related desynchronization (iERD) of electroencephalogram (EEG) was detected in the unaffected primary sensorimotor cortex (M1). We investigated neurological effects of the developed BMI intervention, by employing an ABAB experimental design to a severe stroke patient (N = 1). The epoch A was a control condition, where the patient received robot assists on the paralyzed shoulder and an electrical stimulation (ES) to the anterior-deltoid during motor imagery in all trials. In contrast, the epoch B was a BMI condition, where the patient received robot assists and ES only when BMI detected iERD during motor imagery. Both epochs lasted for successive 5 days, consisting of 8 motor imagery sessions (100 trials / session), 1 clinical evaluation session and 1 session of occupational therapy. During the clinical evaluation session, we measured clinical assessment scores, the range of motion (ROM) during active and passive elevation of the shoulder girdle, electromyogram (EMG) in the anterior-deltoid of the paralyzed arm, motor-evoked potentials (MEPs) obtained by transcranial magnetic stimulation to the shoulder hotspot in the M1 during elevation of the shoulder girdle in the paralyzed arm. Amplitudes of EMG in anterior-deltoid and the ROM during motor execution improved significantly before and after all the interventions ($p < 0.05$). MEPs in the BMI epoch tended to be larger than in the control epoch. Fugl-Meyer Assessment scores increased before and after all the interventions. These results indicate that BMI therapy using iERD may enhance the excitability in the ipsilateral CST, and resulted in the improvement of clinical assessment scores, ROM, amplitudes of EMG and MEPs. Hence it is conceivable that the BMI therapy using iERD for the functional recovery of elevation of the shoulder girdle is effective for severe stroke patients.

Title: Characterization of motor imagery-related cortical activity: MEG and ECoG findings

Authors: *M. KOROSTENSKAJA[1,2,3], K. H. LEE[3], T. KLEINESCHAY[2,3], P.-C. CHEN[1,3], M. WESTERVELD[3], A. J. HOROWITZ[1], J. SEO[3], H. SKINNER[3], J. BAUMGARTNER[3], E. M. CASTILLO[2,3];
[1]Functional Brain Mapping and BCI Lab., [2]MEG Lab., [3]Florida Epilepsy Ctr., Florida Hosp. For Children, Orlando, FL

Abstract: *Introduction:* Motor imagery- based BCIs (MI-BCIs) allow detection of neural activity associated with motor imagery that can be used for rehabilitation purposes. The knowledge about the cortical correlates of MI contributing to the optimal MI-BCIs performance, therefore, is of high importance. Nevertheless, there is discrepancy in currently existing findings concerning neural substrates of MI. To alleviate this discrepancy, we aimed to use neurophysiological techniques, such as magnetoencephalography (MEG) electrocorticography (ECoG) during real movement (RM) and motor imagery (MI) tasks. Moreover, behavioral factors contributing to the observed MI-related cortical activity were explored.
Methods: The MEG part of the study was performed in 4 healthy subjects (3 males, average age 23 years, SD 3). The ECoG part of the study was performed in 5 patients with pharmacoresistant epilepsy (2 males, average age 25 years, SD 15), undergoing evaluation for epilepsy surgery with implanted ECoG electrodes. The recording of electric (ECoG) and magnetic (MEG) brain activity was performed during the RM task and MI task of opening and closing their hand. Vividness of visual imagery questionnaire (VVIQ) was used to evaluate behavioral correlates of motor imagery in healthy subjects.
Preliminary results: The MEG data from healthy volunteers, and the ECoG data from patients shared common patterns. For example, the detected task-associated changes in MEG/ECoG signals were less robust during MI when compared to RM. However, some differences were observed as well. ECoG findings demonstrated that the cortical MI-related activations differed from those related to RM. Moreover, MI-related cortical activations were more widespread compared to focal RM-related activations. Although hand motor activation during RM was clearly localized in the primary motor cortex (M1) in all 5 patients, the MI-associated cortical activation was not universal. Only 2 from 5 patients exhibited the same M1 activation during MI as observed during RM. Other than primary motor cortex activations included pre-frontal, frontal and parietal areas.
Conclusions: Combining information from invasive and non-invasive imaging modalities can provide important insight into the neural origins of MI: they are not universal and might vary on individual basis. The assessment of individual MI-related cortical activation patterns and utilizing them to improve MI-BCI performance are warranted. The utilization of signals from MI-related substrates different than M1 can be of high importance for MI-BCI-based rehabilitation of patients with damaged/affected M1.

Abstract: Brain machine/computer interfaces (BMI/BCI) are an exciting novel area of research pursuing the development of direct modes of communication between humans and computer devices supported directly by the neural activity in the brain. In recent years significant achievements had been demonstrated in this area including advanced control of a robotic manipulator by a fully paralyzed quadriplegic patient by using microelectrode arrays embedded into the patient's brain. Noninvasive electroencephalographic (EEG) BMI/BCI had also demonstrated significant progress for certain applied tasks including interactions with computer programs and control of robotic systems such as a motorized wheelchair. Here we describe our progress directed at an implementation of a slow motor cortical potentials-based EEG BMI/BCI and report an extensive survey of the characterizations of EEG signal's properties of interest for EEG BMI/BCI applications. These include the spatial and the temporal properties of the EEG signal, autocorrelation and cross-correlation properties of the EEG signal across EEG electrodes, characterization of the EEG signal's statistical distributions and auto-regressive properties. We also study the properties of the EEG signal in frequency domain up to very high frequency bands of 500 Hz, and describe the impact of factors such as time and voltage resolution on the machine interpretability of the EEG signal. Finally, we demonstrate our offline and online classification of EEG signals within the BMI/BCI framework consisting of classical hand, leg and tongue movements imagery as well as the imagery of single hand's fingers movements and spelling of vowel and consonant sounds. Our results offer a wealth of new quantitative information about the key properties of the electroencephalographic signal as well as help inform future EEG BMI/BCI designs.

Title: Development of an eyes-closed SSVEP-based BCI for people with impaired vision

Abstract: Brain-computer interfaces (BCIs) can restore communication and control to people with severe motor disorders such as amyotrophic lateral sclerosis (ALS) (e.g., Sellers et al., Amyotroph Lateral Scler. 11:449-55, 2010). However, visual impairments (e.g., ptosis, diplopia, nystagmus) prevent many such individuals from using a vision-based BCI (e.g., McCane et al., Amyotroph Lateral Scler Frontotemporal Degener. 15(0): 207-215, 2014). Prior work indicates that a closed-eye SSVEP might be a solution for these individuals (e.g., Lim et al., J Neural Eng. 10:026021, 2013). In initial work with four healthy subjects, we found that a binary control signal could be derived with 86%(13%SEM) accuracy from EEG steady-state visual evoked potentials (SSVEPs) recorded when different flash frequencies were presented to closed left and right eyes. This used 5 seconds of EEG signals recorded from 8 locations (PO7, PO3, POz, PO4, PO8, O1, Oz, O2). We now seek to confirm and extend these results to the target population (i.e., people with severe motor impairments and compromised vision). Our system delivers SSVEP stimuli and records EEG signals from 16 locations (F3, Fz, F4, T7, C3, Cz, C4, T8, P3, Pz, P4,

PO7, PO8, Oz) and can be used at the bedside. It uses custom eyeglasses with embedded LEDs for stimulus delivery and BCI2000 for EEG recording. In studies to date, five subjects (one with ALS) performed 10 trials each. Each trial required the subject to attend to the left eye for 10 sec and then the right eye for 10 sec while the two stimulation frequencies (between 23Hz (f1) and 31Hz (f2)) flashed simultaneously. We analyze the EEG data for each 10-sec period to determine which of the two eyes (i.e., which stimulation frequency) the subject was attending. EEG is band-pass filtered into 0.4 Hz wide bands centered on the stimulation frequencies and their linear and non-linear harmonics (i.e., f1, f2, 2*f1, 2*f2, f1+f2, |f1-f2|, etc.). We derive a linear classifier using a regularized least-square fit to determine the relationship between the spectral power in these bands and the attended eye. The results to date show that the spectral power of the EEG increases for the attended frequency band (and its linear and non-linear harmonics) and decreases for the unattended frequency band (and its linear and non-linear harmonics). The accumulated output of the linear classifier predicts the eye attended with 100% accuracy in under 6 sec.(average time 3.6(SE .93)sec). These initial results suggest that, with further development, an eyes-closed SSVEP-based BCI could prove useful for people with severe neuromuscular disorders and impaired vision.

Title: Altered modulation of sensorimotor rhythms with chronic tetraplegia

Authors: *S. T. FOLDES[1,2,4,5], D. ROYSTON[3,4], D. WEBER[3,4,2], J. L. COLLINGER[1,2,4,3]; [1]VA Pittsburgh Healthcare Syst., Pittsburgh, PA; [2]Physical Med. and Rehabil., [3]Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA; [4]Ctr. for the Neural Basis of Cognition, Carnegie Mellon

Univ., Pittsburgh, PA; [5]Neurosci. Res., Barrow Neurolog. Inst. at Phoenix Children's Hosp., Phoenix, AZ

Abstract: Introduction After paralysis, the reduction in sensory and motor engagement leads to alterations of the sensorimotor system. This plasticity has been characterized with neuroimaging in individuals with spinal cord injury (SCI). However, it is unclear how chronic paralysis alters sensorimotor rhythms (SMRs) associated with attempted movement of paralyzed limbs. A better understanding of how SMRs change with paralysis will benefit our understanding of the brain and help in the development of rehabilitation strategies, such as brain computer interfaces that use SMR to control devices.
Methods We compared the modulation of SMRs during attempted and imagined hand grasping by 12 participants with partial or complete hand paralysis due to SCI and 13 able-bodied controls. Participants with SCI were grouped by whether or not they had some intact volitional hand-muscle activity during attempted grasping (n = 7 had EMG activity). Cortical source imaging from magnetoencephalography was used to quantify SMR desynchronization in the mu band (8 - 13 Hz) within contralateral S1 and beta band (15 - 30 Hz) in contralateral M1.
Results Peak modulation and area of activity were significantly decreased in the mu and beta bands during attempted grasping for individuals without volitional muscle activity compared to those with some intact muscle activity and able-bodied controls. However, no differences were found between subject groups during mentally simulated motor tasks (i.e. imagery) where no sensory consequences were expected from the task.
Conclusions These findings suggest that individuals with severe deafferentation have less SMR modulation than people with some intact task-relevant somatosensory and motor capabilities when attempting tasks where sensorimotor consequences are expected. However, during imagined motor tasks when no somatosensory feedback is expected, there are no significant differences in the modulation of SMR between paralyzed and able-bodied groups. These results provide evidence that SMR activity is dependent on the level of intact function after deafferentation. A better understanding of how cortical activity changes after paralysis can help in the development and evaluation of new therapies, such as motor imagery and neurofeedback interventions.

Title: Eliminating BCI-illiteracy: individualized training protocols enhance control of mu-based BCI device

Authors: *A. BATTISON[1], A. GORESHNIK[1], T. FULLER[1], M. SCHLUSSEL[1], Y.-C. YU[2], L. A. GABEL[3];
[2]Electrical & Computer Engin., [3]Psychology & Neurosci., [1]Lafayette Col., Easton, PA

Abstract: Brain-Computer Interface (BCI) devices create an alternate means of control and communication for those with severe motor impairment. Non-invasive BCI methods use EEG detected neural activity as control signals of external devices or computers, bypassing manual motor control. Mu rhythm, a sensorimotor rhythm that is synchronized or desynchronized in response to imagined movement or rest, can be controlled by the participant through biofeedback training. Due to the wide range of imagined motor activities that can be detected across the sensorimotor cortex, mu rhythm (8-13 Hz) has been particularly useful for a variety of diverse BCI applications. While BCIs continue to develop, most of this research has focused on creating technologically sound systems with improved signal acquisition features, with little work investigating how to improve participant control of the neural signals. In addition, it is important that the participant be able to control mu, as opposed to producing a strong signal for a minimal period of time, in order to maximize the usefulness of the mu-based BCI device. In the current study we focused on participant-oriented research that aims at testing and improving BCI user training procedures, accuracy, and consistency. By creating a novel bilateral mu-based BCI system that is based on motor imagery versus relaxation, we have attained stronger signals and better control. In addition, we have created a BCI targeting game which serves as a motivating factor for participants, in addition to testing their range of control and consistency. We have found that a single training session is just as effective as individual training sessions over a period of three successive days, suggesting the possibility for rapid training on the mu-based BCI device. By examining different types of individualized instruction and continuous neural control in a gaming environment, we found that 91% of participants learned successful control of the device when provided with individualized instructions as opposed to 50% of control participants. The results of this study show that continued research towards improving participant success and accuracy are bringing the BCI community increasingly closer to creating a system that could be used outside of the laboratory.

Title: The role of intact cognition and ocular function on three P300-based brain-computer interface spellers

Authors: *A. GERONIMO[1], Z. SIMMONS[2];
[1]Dept. of Neurosurg., Pennsylvania State Univ. Dept. of Neurosurg., Hershey, PA; [2]Neurol. and Humanities, Pennsylvania State Univ., Hershey, PA

Abstract: Previous work has shown that individuals with amyotrophic lateral sclerosis (ALS) may experience cognitive impairment and ocular dysfunction that prohibit effective use of visual P300 spellers. Two paradigms have been proposed to combat each of these limitations. In this study, we test the quality of evoked potentials using a classic checkerboard speller, one modified with the use of flashing face stimuli, and one with items presented sequentially in a single location (Rapid Serial Visual Presentation (RSVP) speller). The hypothesis was that those with cognitive limitations, specifically in the realm of attention, would produce an enhanced response in reaction to face stimuli, while those with slow or impaired ocular control would fare better with the RSVP speller. These three spellers were tested in 13 patients with ALS and 10 age, gender, and education matched controls using an electroencephalogram(EEG)-based P300 speller paradigm implemented in the BCI2000 programming environment. EEG recordings were performed with g.tec's gUSBamp system and eye position measured with Tobii's EyeX tracker. Patients tended to have higher incidence of self-reported double and blurry vision (four patients vs. one control). They also tended to have longer reaction times to visual targets. Although no group-wide differences in the precision of eye tracking were evident, those for whom eye tracking performed poorly tended to be patients with poor eyelid control or head positioning. Of the three spellers, flashing faces produced the highest online accuracy. For this task, patients who had better fixation to the target produced a stronger evoked response 250-500 ms following target presentation ($R^2 = .63$, $p = 0.003$), supporting the case that these early potentials are reliant on vigilant fixation. Among patients, online accuracy for the two grid-based spellers was reduced with age. All of the spellers generated P300 evoked potentials of lower quality in individuals with cognitive and behavioral impairments. These effects were strongest in the classic speller

(R^2= .67, p = 0.007 and R^2= .70, p = 0.005, respectfully). These results indicate that face stimuli may better serve patients with cognitive limitations compared to either an RSVP speller or one with classic visual stimuli. Further work will strengthen these results with additional data, further analysis of group and individual trends, as well as identification of the role, if any, of ocular control in the utility of the three spellers.

Title: Intermuscular coherence to control neural prostheses.

Authors: *J. A. NORTON[1], K. WINGERT[2];
[1]Neurosurg., [2]Col. of Med., Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: As neural prostheses evolve and become more widespread new approaches are being developed to more naturally control the devices. Much research has focused on brain-computer interfaces. We are investigating the use of EMG as the control signal. When electrical stimulation is used there are large electrical artifacts in the EMG signal. We use inter-muscular coherence analysis to extract neural signals that are not related to the stimulation. Methods. All experiments were performed with the approval of the University of Saskatchewan Human Ethics Research Board and subjects gave written, informed consent prior to participation. 20 subjects took part in one of 2 studies (10 per group), one examining static contractions of the upper limb and one leg muscles during walking. EMG activity was recorded using surface electrodes. Stimulation was applied using a constant current stimulator at 0.9, 1.0 and 2.0 times sensory threshold and 1 and 2 times motor threshold. Stimulation was applied at the subject's peak frequency of coherence, and $1/10^{th}$ that frequency. EMG signals were amplified, filtered and digitized (Signal, Cambridge Electronic Design) before being processed in the Matlab environment (The Mathworks), using routines based on Neurospec 2.0 (www.neurospec.org). Results. Subjects showed coherence in the Beta band in the absence of stimulation. The peak in the coherence spectra showed little variation between days. Stimulation at low frequencies, 1/10 peak coherence frequency, had no effect on the beta band coherence spectra. When stimulation was applied at the higher frequency, but less than twice sensory threshold, there was an increase

in the size of the coherence peak. At higher stimulation amplitudes, a 2nd peak in the coherence spectra was present, at a frequency close to, but not at, the stimulation frequency. Discussions. The study indicates that EMG-EMG coherence may be a control source for neural prostheses, and demonstrates the short term plasticity of the nervous system.

Title: Muscle activity reconstruction of ankle flexors and extensors using non-invasive brain activity recording methods

Authors: *A. MEJIA TOBAR[1,2], R. HYOUDO[1], K. KITA[3,2], T. NAKAMURA[2], H. KAMBARA[1], T. HANAKAWA[2], Y. KOIKE[1,2], N. YOSHIMURA[1,2];
[1]Tokyo Inst. of Technol., Yokohama, Japan; [2]Natl. Ctr. of Neurol. and Psychyatry, Tokyo, Japan; [3]Chiba Univ., Chiba, Japan

Abstract: Exoskeletons and functional electrical stimulators have drawn attentions as alternatives to wheelchairs. While these devices are controlled by switches on crutches or trunk movements, we aim to develop a control strategy based on a brain-computer interface (BCI). Several BCI studies have demonstrated control for virtual avatars and motorized ankle-foot orthosis, for walking and idling tasks. Our approach in this research is the reconstruction of muscle activity from ankle flexors and extensors using non-invasive methods. For this purpose, first Electroencephalography (EEG) cortical current sources (CS) were estimated from fMRI and EEG applying a Variational Bayesian multimodal-encephalography method (VBMEG), and then muscle activity was reconstructed using a Sparse Regression method (SPR).
The experimental tasks in the fMRI/EMG and EEG/EMG experiments included ankle flexion and extension at low and high force levels. The fMRI experiment was performed in a 3T Siemens Verio MRI scanner at the National Center of Neurology and Psychiatry. The EMG data in this experiment was used to check if participants performed the tasks properly. EEG was recorded by a BIOSEMI Mark II system using 32 channels. The EMG data was used for the SPR

machine learning.
In the VBMEG method, first a leadfield matrix was computed from EEG sensor positions, equidistantly distributed vertex positions on the cortex, and border coordinates of scalp, skull, and cerebrospinal fluid. Then, the activation area information obtained from the fMRI data, using a general linear model analysis in SPM software, was applied as prior to compute an inverse matrix and the CS.
Muscle activities were reconstructed with SPR using 12 combinations, i.e., high-force right flexion vs high-force left flexion, etc. One of the results for 5 subjects is shown in the figure. For each subject, 71 CS (SD ±3) were estimated. The left flexor activity was best reconstructed from CS than from EEG (R2 mean: CS 0.54, EEG 0.40; $p < 0.05$). Results varied largely for the extensors probably due to the co-contraction level in extensors during the flexion tasks.

Title: Viewing lateralized mu-band power to help train motor imagery in EEG-based BCI

Authors: *M. MOUSAVI[1], V. R. DE SA[2];
[1]UC San Diego, LA Jolla, CA; [2]UC San Diego, La Jolla, CA

Abstract: Brain computer interfaces (BCI) are systems that directly interpret neural signals from the brain when peripheral input is not available. Motor imagery is one common paradigm in EEG-based BCI's where the subject is instructed to imagine moving his left or right hand to perform a task: e.g., move a cursor on the screen to the left or right. This results in endogenous desynchronization in the mu frequency band, 8-13 Hz, and beta frequency band, 14-30 Hz, that is somewhat lateralized over the contralateral motor cortex; however, the subject usually needs training to be able to reliably generate machine discriminable signals and effectively control a BCI.
Most motor-imagery training involves providing feedback of a classifier output which is usually computed from a difference between the signal for right hand and left hand motor imagery. Some innovative work has trained subjects using visualization of cortical activations [Hwang et al, Journal of Neuroscience Methods, 2009; Mercier-Ganady et al, IEEE Virtual Reality, 2014; Frey et al, 27th annual ACM symposium, 2014]. Motivated by the work of Jeunet et al [6th International BCI Conference, 2014], we propose a simple paradigm that provides access to the underlying lateralized desynchronizations in mu-band power rather than the processed difference computed by the classifier. (We are not currently using the beta frequency band as this range can be highly contaminated with muscle artifacts making it difficult to provide reliable feedback without major processing of the signal.) Our paradigm accomplishes this goal without requiring the computational and visual complexity of visualizing cortical activity. We instruct the subjects to maximize the power differences between the signals on electrodes over the right and left motor cortices. The output which is presented as two bars on the screen, shows the cortical power on each side after short trials of motor imagery. Our results show that providing the inputs to the classifier (i.e., the power of the signals from each side) as opposed to the classifier output decision, provides a more informative guide for subjects to improve their motor imagery discriminability. Importantly, the subjects are able to distinguish successful mu desynchronization that is not sufficiently lateralized to successfully operate a classifier, from failure to desynchronize at all.

Title: Querying letter candidates in parallel with common letter segments in an eye-movement independent speller.

Authors: *J. M. STIVERS, V. R. DE SA;
UCSD, LA Jolla, CA

Abstract: Amongst healthy individuals, a computer/machine system's ease of use determines how readily it is adopted. For sufferers of degenerative conditions like ALS - which can impede eye muscle activity and reduce visual acuity - both directing overt attention to a stimulus and discriminating covertly attended stimuli becomes difficult. To this end, we designed a P300 brain-computer interface (BCI) speller with spatial independence, such that eye-movements are neither required nor desirable for stimulus classification. To this end, we implemented a rapid stimulus visual presentation approach, using common letter subsets in lieu of full letters. This allows multiple letters to be queried in parallel, and increases the information gained from the presentation of non-target stimuli. At the beginning of each trial, subjects were presented with a 5-by-7 grid of circular nodes. A variant of the scoreboard font used on low-resolution displays allowed for all 26 letters of the English alphabet to be uniquely represented. A 10-segment library was extracted from these letters, wherein each segment consisted of 2-5 contiguous pixels. All pixels in a given segment were assigned a specific color, with a unique color for each segment. During the experiment, participants were assigned a target letter, followed by 50 stimulations consisting of either a single segment or a full letter. When a segment appearing in the target letter was presented, the subject was told to increment a mental count by one. Conversely subjects were tasked with ignoring non-target segments. In the event of a full letter as a stimulus, subjects were asked to treat it as though it were a target segment; otherwise, it should be ignored. After 50 stimulations, the trial ended, and the participant was given a break or immediately assigned a new target letter. For a given trial, one of three stimulus-onset asynchronies (SOAs: 375ms, 567ms, 750ms) was selected, wherein one-third of the SOA was inter-stimulus interval. We found that the 375ms SOA provides comparable responses relative to the longer SOAs, and the presentation of two subsequent targets evokes similar responses for both targets.

Title: Changes of brain activity in Brain-Computer interface learning

Authors: *Y. MIZUNO[1], N. KIM[2], T. HANAKAWA[1];
[1]Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan; [2]Dept. of Neurosurgery, Osaka Univ. Grad. Sch. of Med., Osaka, Japan

Abstract: Event-related desynchronization (ERD) occur over the sensorimotor area in the alpha band and beta band when a human tried to move limb or image the same movement (Pfurtscheller et al., 1999). EEG based brain-computer interface (BCI) is very often used ERD by the limb motor imagery. In addition, it has been reported that whole brain activities is associated with BCI manipulation by the limb motor imagery using simultaneous EEG and magnetic resonance imaging (fMRI) measurement (Zich et al., 2015). However, change of whole brain activity after long-term BCI learning is not well known. We evaluate the change of whole brain activity after BCI learning using simultaneous EEG-fMRI measurement. A total of fourteen right-handed healthy volunteers. Each volunteers performed continuous 5-days BCI learning task. fMRI and EEG were simultaneously measured during the BCI task on the first day and the last day. On the second day to forth day, BCI task was performed using only EEG. We recorded 12 channel EEG signals during BCI task. Participant controlled horizontally moving cursor in response to the laterality of ERD derived from the motor imagery of right hand movement and left hand movement. In the online EEG processing, we removed the gradient artifact and ballistocardiogram (BCG) artifact. Next, we applied bandpass filter (1Hz to 23Hz) and large laplacian. We computed alpha band ERD in C3 and C4 by using Autoregressive (AR) filter. We analysis fMRI data during the BCI task from the first day and last day using SPM12. We evaluated differences in brain activity during the BCI task between first day and last day. We confirmed that recognition rate averaged across subject is significant increased on forth day and last day in comparison with first day. We found tendency of increase in brain activity in several motor-related areas after BCI learning. The results suggest the possibility that BCI learning enhance brain activity in motor-related areas.

Title: Physical mechanisms of ultrasonic neurostimulation in the *In vitro* retina

Authors: *M. D. MENZ, P. YE, P. KHURI-YAKUB, S. BACCUS;
Stanford Univ., Stanford, CA

Abstract: Focused ultrasound has been shown to be effective at stimulating neurons in both in vivo and in vitro preparations. Ultrasonic neurostimulation is the only non-invasive method of stimulation that could reach deep in the brain with high spatial-temporal resolution, and thus has potential clinical applications in addition to basic science studies. Understanding the physical mechanism by which energy in a high acoustic frequency wave is delivered to stimulate neurons will be important to optimize this technology. Two current candidates for a physical mechanism are radiation force, the delivery of momentum by the acoustic wave, and cavitation. The isolated salamander retina was placed on a planar multielectrode array and ganglion cell spiking activity was recorded. We studied the effects of changing the acoustic carrier frequency across a broad range (0.5-43 MHz) because different physical mechanisms scale differently with frequency. We find that response thresholds increase as ultrasonic neurostimulation becomes less effective at lower frequencies, a result consistent with radiation force and inconsistent with cavitation. In addition, we found that neural activity was strongly modulated by the distance between the transducer and a reflector (the electrode array) with a period of one-half wavelength (at 1.9 and 2.9 MHz), indicating the influence of standing waves on the response. We then tilted the transducer at angles of 11°-27° to vertical, reducing standing waves while increasing acoustic streaming - the effect of radiation force on the bathing medium. With greater tilt angles neurons still respond, but were no longer modulated with distance, indicating the lack of standing wave effects under this condition. We conclude that in the in vitro retina, radiation force, acoustic streaming, and standing waves all could contribute to the physical mechanism of stimulation while cavitation does not.

Title: A practical neurogaming design based on the SSVEP-based brain computer interface

Authors: *L.-W. KO[1], B.-J. YANG[1], S. KALYAN[1], J.-T. KING[1], C.-T. LIN[1], T.-P. JUNG[2]; [1]Natl. Chiao Tung Univ., Hsinchu, Taiwan; [2]Univ. of California San Diego, San Diego, CA

Abstract: This study aims to utilize a real-life game scenario to investigate, longitudinally, how changes in user mental and cognitive states affect electroencephalogram (EEG) signals that have been traditionally employed in brain-computer interface (BCI) systems. Despite the recent advances in BCI development, currently no BCI system has been routinely used in real-life environments. This is in part because no BCI system has provided strong evidence for its robustness over a long period of use in real-world environments. In fact, most of BCI demonstrations were done with experimental sessions that are sufficiently short and far apart in order to minimize the effects of changes in user states on BCI performance.

This study proposed to embed a BCI system into a gem-matching game for encouraging subjects to use the BCIs over considerable lengths of time, during which the players are very likely to experience changes in their brain states. A standard BCI system design usually involves a subject's mental task such as motor imagery (MI), steady-state visual evoked potential (SSVEP), P300 visual stimuli, or rapid serial visual presentation (RSVP) etc. Among these different BCI systems, SSVEP, a natural response to visual stimulation at specific frequencies, is a common EEG signal that has been widely used in BCIs due to the following advantages: (1) a high signal-to-noise ratio (SNR), (2) a high information transfer rate (ITR), (3) a large number of classes and (4) little user training. Therefore, this study adopted an SSVEP-based video game that resembled a popular match-three game such as the jewel game, zoo, or candy crush. This study also systematically explored the effects of flicking frequencies (e.g. theta, alpha and beta bands) of visual stimuli, and presentation duration (3-5 seconds) on the SNRs of elicited SSVEPs and BCI performance.

This study conducted a series of experiments to optimize the variables (e.g. stimulus flickering frequencies and durations) of the SSVEP-based BCI system. Experimental results showed that the classification performance (accuracy) of using visual stimuli flickering at theta band (4-7 Hz) could exceed 90% at the presentation duration of 3, 4, or 5 seconds, which was better than that of using visual stimuli flickering at other frequency ranges (e.g. alpha band (8-11 Hz), beta (14-17

Hz), and gamma band (30-33 Hz)). The design and optimization of the SSVEP-based BCI embedded into the gameplay while recording neural and behavioral data will lead to an unprecedented tested for investigating the robustness of the BCI under different mental/cognitive states in real-world environments.

Title: A novel method for fast detection of ssvep from eeg recordings.

Authors: *C. Y. OLIVARES CARRILLO[1], J. DELGADO SAA[2];
[1]Eléctrica y Electrónica, Univ. Del Norte, Soledad, Colombia; [2]Eléctrica y Electrónica, Univ. Del Norte, Barranquilla, Colombia

Abstract: Traditionally, it is assumed that the visual cortex respond to this stimuli is an oscillatory activity at the fundamental frequency of the stimuli and its harmonics. We recorded EEG data from 10 subjects while an flickering signal is presented in a screen. The stimuli presented is a square signal with duty cycle of 50% alternating between black and white at one of two different frequencies (4 Hz or 9 Hz). We propose a method to detect the SSVEP based on a coherent average of short segments of the signal, autoregressive modeling for spectral representation and classification by means of support vector machines (SVM). Our results show that the proposed method allow faster detection of SSVEP compared to traditional methods based on Fast Fourier Transform. Furthermore, analysis of the results suggest that although the spectral features are highly discriminant of the class of stimulation, and although the spectrum representation provides are mathematical accurate representation of the brain signal, this spectral representation does not necessarily allow a meaningful physiological interpretation. We suggest that any interpretation based on the spectral components of the brain signals need to be carefully analyzed, given that the brain signals usually violate the basic assumptions of linearity and stationary required by most of the available spectral decomposition methods.

Title: Inter- and intra-session variability in brain machine interface control of an exoskeleton for upper extremity stroke rehabilitation

Authors: *N. A. BHAGAT[1,2], R. PARANJAPE[3], C. LOSEY[4], N. YOZBATIRAN[3], J. SULLIVAN[4], R. G. GROSSMAN[1,5], G. E. FRANCISCO[3], M. K. O'MALLEY[4,3], J. L. CONTRERAS-VIDAL[1,2,5];

Inst., Houston, TX

Abstract: Brain-machine interfaces (BMI) based on electroencephalography (EEG) have the potential to *increase patient engagement* during robot-assisted rehabilitation for inducing cortical plasticity and thereby, accelerate motor recovery. However, due to the inherent *trial-to-trial variability of EEG* signals, BMI performance varies greatly across and within sessions, which undermines the long-term reliability and efficacy of EEG-based BMIs. To overcome this drawback, we have developed a novel BMI design approach for detecting motor intent from chronic stroke participants over multiple sessions (Bhagat et al, Frontiers in Neuroscience, vol. 10. 2016; http://dx.doi.org/10.3389/fnins.2016.00122). Under this approach, motor intent is inferred from *movement related cortical potentials* measured over an optimized set of EEG electrodes. Successful intent detection by the BMI triggers the motion of an upper-limb exoskeleton (MAHI Exo-II), to guide movement and to encourage user participation by providing instantaneous sensory feedback. This patient-specific BMI calibration approach is currently being tested over 12 sessions (3 times/week) in a clinical study, with a cohort (N = 12) of stroke patients having diverse motor capabilities. Preliminary results from four stroke participants demonstrate consistent BMI performance across days, as seen in Figure 1. The inter-session BMI accuracy (Mean ± Std. Dev.) for individual subjects were S1 = 77 ± 20%, S2 = 65 ± 20%, S3 = 92 ± 6%, S4 = 80 ± 12%, while the false positives were kept low across subjects (overall, 25 ± 19%). Importantly, for all subjects, the intra-session variance in BMI performance was less than 10%. These findings provide evidence that closed-loop EEG-based BMI for stroke patients can perform reliably across multiple days, *without requiring system recalibration*. We

will discuss various neural correlates associated with the subject's changing physiological and psychological states, which could further explain individuality and variability of neural activity and therefore, the BMI's performance variation.

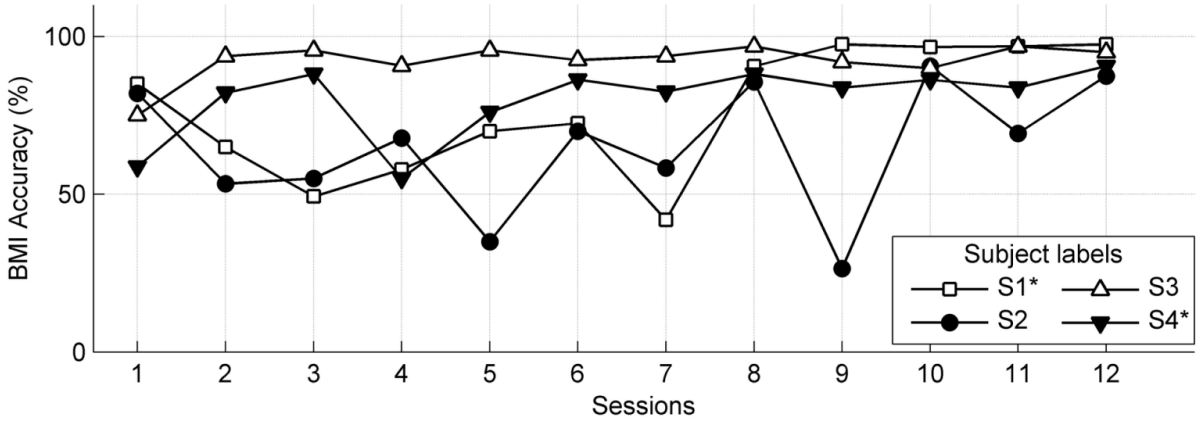

Figure 1. Closed-loop BMI performance for 4 stroke participants across multiple sessions of ongoing clinical study (ClinicalTrials.gov # NCT01948739). Subject labels marked by '*' indicate subjects that achieved significant improvement in inter-session BMI accuracy ($p < 0.05$)

Title: The effect of operant conditioning of the tibialis anterior motor evoked potential to transcranial magnetic stimulation on corticospinal excitation and inhibition

Authors: *R. COTE[1,2], A. THOMPSON[2];
[1]Col. of Hlth. Professions, Med. Univ. of South Carolina, Charleston, SC; [2]Dept. of Hlth. Sci. and Research, Med. Univ. of South Carolina, Charleston, SC

Abstract: The corticospinal tract (CST) is important in motor control, motor skill learning, and re-learning after CNS injury. Thus, a method that strengthens CST function might facilitate functional recovery in people with chronic CNS damage. We hypothesize that operant conditioning of the ankle dorsiflexor motor evoked potential (MEP) can strengthen CST connectivity and alleviate foot-drop in people after CNS damage. As the first step in testing this hypothesis, we investigated up-conditioning of the tibialis anterior (TA) MEP in neurologically normal subjects. Here we report changes in MEP, as well as the silent period (SP) after MEP, which reflects cortical and spinal inhibition.

Fifteen subjects (8 conditioning and 7 control) participated in the operant conditioning protocol that consisted of 6 baseline sessions and 24 up-conditioning (conditioning group) or control (control group) sessions over 10 weeks. In all subjects, TA MEPs were elicited by transcranial magnetic stimulation at 10% above threshold while the sitting subject provided ≈15% maximum voluntary contraction level of TA background EMG activity with ankle, knee, and hip joint angles fixed at ≈100°, ≈120°, and ≈110°, respectively. The background EMG was maintained constant throughout data collection. In control subjects, 225 MEPs were simply measured with no feedback on MEP size in each of 6 baseline and 24 control sessions. In conditioning subjects, MEPs were elicited without feedback during 225 control trials of each baseline session and 20 control trials of each conditioning session. During 225 conditioning trials of each conditioning session, the subject was encouraged to increase MEP, and was given immediate feedback indicating whether MEP size was above a criterion (i.e., whether the trial was a success). SP duration was measured from the time of stimulus to the return of prestimulus level of EMG activity.

Five of 8 conditioning subjects successfully increased MEP size over 24 conditioning sessions: their final MEP size (the average of the last 3 sessions) was 144±13(SEM)% of the baseline value. MEP did not change in
3 other subjects. In 7 control subjects, the final MEP size was 96±3% of the baseline. SP duration did not increase in the 5 successfully conditioned subjects (the final value was 81±9% of the baseline) or in the control subjects (91±6% of the baseline). There was no correlation between MEP size and SP duration elicited at a constant TMS intensity in any of the baseline or conditioning sessions. The results suggest that operant up-conditioning of the MEP produces a focused facilitation of corticospinal excitation, rather than a general facilitation of corticospinal excitation and inhibition.

Title: Soleus stretch reflex modulation during walking in people with chronic incomplete spinal cord injury

Authors: *A. K. THOMPSON[1], N. MRACHACZ-KERSTING[2], T. SINKJAER[3], J. ANDERSEN[2];
[1]Dept. of Hlth. Sci. and Research, Col. of Hlth. Professions, Med. Univ. of South Carolina, Charleston, SC; [2]Ctr. for Sensory-Motor Interaction, Aalborg Univ., Aalborg, Denmark; [3]Villum Fonden, Søborg, Denmark

Abstract: In people with spastic gait due to incomplete spinal cord injury (SCI), modulation of the soleus H-reflex, an electrical analogue of the stretch reflex, is often absent or greatly diminished during walking. Clonus is frequently observed in the early-mid stance phase of the step cycle. It has been presumed that the abnormal activity of the soleus stretch reflex pathways impairs gait in this population. However, to date, the soleus stretch reflexes have not been investigated systematically during walking in people with chronic SCI. To understand the contribution of stretch reflexes to spastic gait in people after SCI, across all phases of the gait cycle, we measured three components of the stretch reflex: spinal short-latency “M1” (mainly Ia afferent origin), spinal long-latency “M2” (presumably mainly II afferent mediated), and the long latency “M3” (suggested to be transcortical or subcortical).
Soleus stretch reflexes were quantified in 8 neurologically normal subjects and 9 subjects with hyperreflexia due to chronic incomplete SCI (AIS D, 2.5-11 yrs post injury), using a portable joint perturbation device capable of producing a precise amplitude and speed of ankle joint rotation. While the subject walked on the treadmill at his/her preferred speed, 10-15 unexpected ankle dorsiflexion perturbations (6°@250°/s) were imposed every 4-6 steps in 8 time segments (5, 17.5, 30, 42.5 55 67.5 80, and 92.5%) of the gait cycle. Before or after the stretch reflex measurement, the soleus H-reflex was also examined in 8 segments of the step cycle, comparable to the stretch reflex measurements.
In normal subjects, typical M1, M2, and M3 onset latencies were 49, 67, and 84 ms after the onset of stretch, respectively. All three responses were clearly modulated throughout the step

cycle; the responses were largest in the mid stance phase (i.e., segment 3) and almost completely suppressed during the stance-swing transition and swing phases (i.e., segments 5-7), similar to previous findings (Clin Neurophysiol 110:951-959, 1999). The H-reflex modulation was similar to the M1 and M2 modulation. In subjects with SCI, M1 and M2 (onset latencies similar to those in normal subjects) were large in the mid-late swing phase (i.e., segments 7-8) while the M3 modulation was similar to that in normal subjects. The H-reflex was also large in the mid-late swing phase. Absolute amplitudes of M1, M2, and H-reflex in the mid-late swing phase were 10-15x larger in SCI than in normal subjects, despite similar maximum M-wave amplitudes in both groups. The results suggest that abnormal modulation of these spinal stretch reflexes contributes to spastic gait disorders in people with chronic incomplete SCI.

Title: Operant down-conditioning of the soleus H-reflex during the swing phase of walking in ambulatory individuals with chronic incomplete spinal cord injury

Authors: *C. R. THOMPSON[1], S. PUDLIK[2], J. WOLPAW[3], A. THOMPSON[2];
[1]Dept. of Hlth. Sci. and Res., [2]Med. Univ. of South Carolina, Charleston, SC; [3]Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Ctr., Albany, NY

Abstract: People can change a spinal reflex through operant conditioning (J Neurosci 29: 5784-5792, 2009). Previously, we showed that down-conditioning the soleus H-reflex during standing can markedly improve walking in people with spastic hyperreflexia and impaired walking due to chronic incomplete spinal cord injury (SCI) (J Neurosci 2013;33:2365-2375). Based on this success, this study aimed to test the hypothesis that H-reflex down-conditioning during the swing phase of walking can improve reflex modulation and walking in people after SCI. We down-conditioned the soleus H-reflex in the late swing phase, when it is very small or absent in normal

subjects but very large in people with spastic hyperreflexia due to chronic SCI.
Twelve ambulatory individuals with spastic hyperreflexia due to chronic (1-14 yrs) incomplete SCI were studied with either the conditioning (N=7) or the control (N=5) protocol. The conditioning protocol comprised 6 baseline and 30 down-conditioning sessions over 12 weeks (3/week). In each baseline session, the subject completed 3 blocks of 75 control H-reflex trials, in which soleus H-reflex size was measured without feedback. The H-reflex was elicited in every other step by tibial nerve stimulation just above M-wave threshold in the late swing phase of walking. In each conditioning session, the subject completed 3 blocks of 75 conditioning trials, during which s/he was asked to reduce H-reflex size with the aid of visual feedback. The control protocol comprised 36 sessions in which the subject simply walked a comparable number of steps on the treadmill without H-reflex elicitation. Before and after the conditioning or control protocol, 10-m walking speed and swing-phase H-reflex were assessed.
In 6 of 7 conditioning subjects, H-reflex down-conditioning was successful: final swing-phase H-reflex size was 52±13(SEM)% of baseline value. Their 10-m walking speeds increased by 11±3% ($p=0.004$ by paired t-test). In control subjects, final swing-phase H-reflex size was 155±58% of baseline and final 10-m walking speed was 100±5%. The results suggest that operant conditioning of the swing phase H-reflex is possible and may improve walking in ambulatory people with SCI. Simply walking on the treadmill did not appear to improve walking. To better understand the impact of swing-phase H-reflex conditioning, analysis of locomotor kinematics and EMG is underway.

Title: Hopping high on two feet: Lower leg kinematics and EMG during maximal height hopping

Authors: *W. HAUG, A. THOMPSON;
Med. Univ. of South Carolina, Charleston, SC

Abstract: Hopping is a series of jumps in which landing from a jump seamlessly transitions to the subsequent jump. While it is a common form of jump, motor control and generation of two-foot hopping is not well understood. The aim of this study is to delineate joint kinematics and modulation of the lower leg EMG activity during the maximal height two-foot hopping, in comparison to those during landing after the last maximal height hopping.
Physically active adults with various athletic backgrounds participate in this study. Each subject performs 14-20 sets of maximal two-foot hops (4 maximal hops preceded by a 2 hop build up) that ends with a landing, with a 90 s interval. Surface EMG from the soleus (SOL), medial (MG) and lateral gastrocnemius (LG), and tibialis anterior, vertical ground reaction force (GRF), and knee and ankle joint motion are measured. SOL, MG, and LG H-reflexes are also measured across different phases of hopping cycle.
In 14 subjects studied to date (7 men and 7 women), the hopping cycle (728±71(SD)ms) consists of 247±21 ms of ground phase and 481±63 ms of flight phase. In hopping, ground contact occurs with the knee slightly flexed (26±11°) and the ankle plantarflexed (-27±18°). From there, both joints immediately undergo a rapid flexion towards the peak GRF timing (94±16 ms after ground contact): 51±8° for peak knee angle and 20±10° for peak ankle angle. After the GRF peak, both joints rapidly extend towards toe off and remain extended throughout the flight phase. In landing, ground contact occurs with the knee (11±6°) and ankle (-39±9°) more extended than for hopping ($p<0.05$), and is followed by faster knee and ankle flexion (landing vs. hoping: 320±71°/s vs 226±84°/s for knee and 574±144°/s vs 483±89°/s for ankle), potentially leading to earlier peak GRF ($p=0.06$) and abrupt cessation of force production.
During the flight phase, little or no EMG activity is present until about 100 ms prior to ground contact (in both hopping and landing). Then, in hopping, SOL, MG, and LG EMG activity sharply increases upon ground contact and sharply decreases just before or around the toe off. During the first 100 ms after ground contact, SOL, MG, and LG EMG activity is significantly larger in hopping than in landing ($p<0.01$), indicating clear contribution of these muscles' activity to hopping. Furthermore, during hopping, MG and LG H-reflexes are phase-dependently modulated ($p<0.05$, ANOVA); the H-reflex is largest during the first 100 ms of ground contact and smallest 300-200 ms (for MG) and 200-100 ms (for LG) before ground contact.
These findings suggest that maximal height two-foot hopping involves dynamic neural control of knee and ankle joint motion within the constraints of rapid motion.

Title: Lower limb electrical stimulation alters trunk stability in individuals with spinal cord injury

Authors: *K. MOMENI, S. CANTON, A. RAMANUJAM, E. GARBARINI, G. F. FORREST; Human Performance and Engin. Res., Kessler Fndn., West Orange, NJ

Abstract: Loss of movement ability below the level of injury is often a consequence of spinal cord injury (SCI). Subsequently, the associated rapid muscle atrophy after the injury may negatively affect overall functional recovery. Previously, our data have shown that a novel form of multi-muscle electrical stimulation (ES) combined with dynamic stand retraining task (SRT) can increase the amplitude of muscle activation in the lower limbs during continuous step training. Our early preliminary data also demonstrated that this dynamic clinical intervention could also potentially improve trunk stability during stepping and standing. The purpose of the present study was to further examine trunk stability in persons with motor-complete SCI during the first minute of a 10-minute stepping bout on a treadmill, using an overhead body-weight support system, before and after the SRT+ES clinical intervention. Sixty sessions of electrical stimulation was applied 4-5 times per week, for 60 minutes each. Symmetrical, biphasic pulses of 300 μs at 35 Hz were delivered to four lower limb muscles over a duty cycle of 11 seconds on and 60 seconds off. During treadmill stepping, trunk stability was measured by examining 2-dimensional spatial and temporal profiles of Center of Mass (CoM), as well as the underlying neuromuscular changes that precipitate the alterations in postural mechanics.Our results demonstrated that the training, which combines the SRT and ES, improves trunk stability by showing a decrease in the anterior-posterior excursions of the CoM. Greater anterior-posterior excursions before the training might be due to a deliberate activation of the trunk muscles during treadmill stepping in order to maintain stability and postural form. However, after the training, it could be argued that the major contribution to the movement is not from the trunk, but the pelvis during treadmill stepping. Furthermore, overall consistency of the CoM excursions across multiple gait cycles improved after the SRT+ES training.

Abstract: Acute spinal cord injury often leads to rapid muscle atrophy in the paralyzed limbs. Recently, we have shown that an intense novel form of standardized multi-muscle neuromuscular electrical stimulation (NMES) combined with dynamic standing retraining tasks may potentially restore muscle structure and function after a sub acute to chronic, motor-complete spinal cord injury. Specifically, we have presented data for a large number of standardized repetitive task specific training sessions of multi muscle NMES of the lower limbs combined with mechanical loading to demonstrate an increase in bilateral muscle volume in conjunction with a significant increase in flexor and extensor muscle activation amplitude during continuous stepping. However, reported data has been for a small sample. We will present data for a much larger cohort to show the effect of NMES (35 Hz, 300usec) training on muscle cross sectional area/muscle volume of the left and right lower limb. Data for longitudinal training effect of NMES training combined with loading compared to the “no loading” or the “no NMES” group shows a significant increase in average muscle volume for each of anterior, posterior and total lower limb muscle groups. Furthermore, for the multi-muscle "NMES loaded" group there was an increase in cross sectional area throughout slices within the limb. The "NMES alone" group (unloaded) compared to "no NMES" group shows a significant increase in average muscle volume in the lower limbs particularly in the posterior lower limb.

Title: Understanding the contralateral effects of neuromuscular electrical stimulation through surface electromyograms

Authors: *R. PILKAR, A. RAMANUJAM, S. CANTON, G. FORREST;
Human Performance and Engin. Res., Kessler Fndn., West Orange, NJ

Abstract: Functional electrical stimulation (FES) has been used to assist or restore neuromuscular function to paralyzed muscle after spinal cord injury (SCI). During FES, electrical current is applied to a nerve to elicit action potentials in denervated peripheral muscles. Chronic application of FES have been shown to have therapeutic effect on tissue health or voluntary function to some extent. Surface electromyography (EMG), otherwise an effective tool to analyze underlying muscle activity, limits the assessment of the direct effect of FES on a muscle or nerve due to the presence of overpowering stimulus artifact. Recent advances in biomedical signal analysis have yielded algorithms that show significant success in removing electrical stimulation (ES) artifacts from EMG recorded from the stimulated muscle. In this study, we used the empirical mode decomposition (EMD) with Notch filtering based approach to remove ES artifact from EMG of the stimulated (35 Hz, 300μs) rectus femoris (RF) muscle. With this, we clearly showed distinguishable, artifact-free, muscle activations during 'only ES' and 'ES combined with volitional effort' conditions in individuals with a SCI (n=2) and able bodied (n=5) participants. However, it is also observed that the application of a single channel unilateral FES also has an effect on, not only ipsilateral neighboring muscles (tibialis anterior, vastus lateralis), but also the contralateral RF muscle. Furthermore, the amplitude and shape of the ES train travelling to the contralateral muscles are altered relative to that of the ipsilateral (stimulated) side. This could be due to the inherent physiological properties of motor-neuronal pathways, connectivity, muscle properties, and travel delay. Post EMD-Notch filtering, the contralateral muscle activation profiles directly suggest the effect of 'leaked' ES on the non-stimulated side.

Abstract: Background: Children with cervical and high thoracic spinal cord injury (SCI) are particularly at high risk for developing respiratory complications. Evaluation of respiratory function is critical to both acute and chronic stage of the injury. Currently, pulmonary function testing and airway pressures are used as important tools to diagnose, assess and manage respiratory diseases, both in adults and children. However, assessments using these tools fail to provide information about underlying neural drive to the respiratory motor system. **Aim/Hypothesis**: The aim of this study is to compare respiratory functional measures in children with SCI to children who are neurologically intact (NI) by using a respirator multi-muscle surface electromyography (sEMG) assessed during standard spirometry and maximal airway pressure efforts. We hypothesized that pulmonary function measures are significantly reduced in children with SCI and associated sEMG activation patterns are significantly different when compared to children who are neurologically intact. **Methods**: Seven children with cervical or high thoracic SCI (4 ± 3 years) have been recruited in the SCI group (3 males & 4 females) with age of 6 ± 3 (mean ± SD) years and 12 children in the NI group (7 females & 5 males) with age of 7 ± 2 (mean ± SD) years from Frazier Rehabilitation Institute - Pediatric NeuroRecovery program and community, respectively. Informed consent and assent were obtained as approved by Institutional Review Board for Human Studies at University of Louisville. **Results:** The analysis indicates no significant difference between two groups for Forced Vital Capacity (FVC), Forced Expiratory Volume in one second ($FEV_{1)}$, Maximum Expiratory (PE_{max}) and Maximum Inspiratory Pressure (PI_{max}) values. Significant reduction in sEMG magnitude of rectus abdominus (p=.003), intercostal (p=.014) and external oblique (EO) (p=.008) muscles during PE_{max} and significant reduction in activity of pectoralis major (p=.007) and thoracic paraspinal (p=.028) muscles during PI_{max} efforts was found in SCI group. **Conclusions**: In children, injury at cervical or high thoracic spinal cord levels resulted in weakness or paralysis of muscles involved in forced expiration and coughing. These results indicate decreased activity of

respiratory muscles below neurological level of injury associated with compensatory over activity in trunk muscles above such level.

Title: Task-dependent recruitment of spinal motor pools after pediatric spinal cord injury

Authors: ***A. L. BEHRMAN**[1], S. A. TRIMBLE[3], L. ALVARADO[2], D. ATKINSON[2]; [2]Anatom. Sci. and Neurobio., [1]Univ. of Louisville, Louisville, KY; [3]Spinal Cord Med. Outpatient - Pediatric NeuroRecovery, Frazier Rehabil. Inst., Louisville, KY

Abstract: Spinal cord injury (SCI) in the cervical and thoracic segments disrupts descending communication between supraspinal centers and the intact lumbosacral spinal cord resulting in paralysis of the lower limbs. However, motor pools below the lesion may still be activated in a task-dependent manner by peripheral afferents (i.e., body-weight supported, assisted stepping) in adults with SCI (Maegele et al., 2002). We studied activation of lumbosacral motor pools during voluntary single- and multi-joint movement attempts, passive cycling, standing, and body-weight supported, assisted stepping on a treadmill in children with motor complete (4) and motor incomplete (3) SCI between the ages of 2 and 15 years old (8.2 ± 4.3 years). Five males and two females were studied and age at injury ranged from birth to 4.9 years (2.5 ± 1.8 years). Time since injury ranged from 4 months to 11 years (5.8 ± 4.1 years). Data also was collected from two typically developing children, aged 7 and 9 years. Children with clinically complete SCI were unable to generate volitional movement, while those with incomplete SCI typically demonstrated multi-joint muscle activation rather than isolated single-joint movements. Bilateral

alternating leg muscle activity was evoked during body-weight supported, assisted treadmill stepping in all children. These results provide evidence that the spinal cord can interpret afferent input and produce task-specific motor activity in children with complete SCI. Assessment of motor activity during standing and stepping supports the use of activity-based therapies to promote recovery of motor function after pediatric SCI (Behrman et al., 2008; Fox et al., 2010).

Title: Unexpected stepping gains in a young child with a functionally isolated lumbosacral spinal cord

Authors: ***S. A. TRIMBLE**[1], D. A. ATKINSON[2], A. L. BEHRMAN[2];
[1]Frazier Rehab Inst., Louisville, KY; [2]Univ. of Louisville, Louisville, KY

Abstract: Following adult spinal cord injury (SCI), intact spinal networks below the level of lesion can initiate, alter, and sustain motor activity absent of descending motor control from the brain. There is little evidence as to whether these same networks exist following SCI to the developing spinal cord prior to birth and preceding the typical development of postural control, volitional motor control, weight-bearing, or mobility (rolling, crawling, walking, etc.). We

previously demonstrated the effect of appropriate afferent input via task-associated repetition and practice on recovery of stepping below the lesion in a child injured at 3.5 years of age and non-ambulatory for 16 months (Behrman et al., 2008). Here we investigated whether and how the cord responds to afferent input applied through activity-based therapies in a child injured prior to birth. At birth, the child presented with a T4-T9 neuroblastoma and complete paralysis below the lesion. At age 1, the child had flaccid paralysis and drag crawled for mobility. At age 2, hyperreflexia and clonus emerged. At ages 2, 3, and 4, the child underwent 60, 24, and 20 sessions, respectively, of intense stand and step training on a treadmill (1 hr/day) and off (30 mins) 5x/week. At age 2, the child responded to manual/afferent cues generating a step; age 3, initiated repetitive steps without manual cues; and at age 4, within specific contexts, stood 30 minutes and independently took 10 steps using a walker. Outside these contexts, the child drag crawled with no observable voluntary movements of the lower extremities (LEs). Electromyographic (EMG) signals were recorded from bilateral lower extremity muscles during volitional movement attempts and passive movement in supine, as well as while standing and stepping on a treadmill with body-weight support. LE EMG activity demonstrated the dependence of the child's lumbosacral spinal cord on context-associated afferent input to generate reciprocal leg muscle activity during upright load-bearing stepping responses and alternating, reciprocal flexion and extension in standing. Without specific afferent input, no motor activity was observed below the lesion. These data provide evidence that spinal networks required to generate bilateral, multi-joint motor activity exist even absent typical development of upright posture or mobility. More importantly, these networks, below the lesion, may be activated and trained through the delivery of appropriate proprioceptive and tactile input to produce stepping responses. Two functionally independent nervous systems appear at work, one above the lesion under brain and spinal control and one below the lesion under spinal control.

Title: Improvements in bladder, bowel and sexual outcomes following task specific training in human spinal cord injury

Authors: *A. N. HERRITY[1], C. HUBSCHER[2], L. MONTGOMERY[2], A. WILLHITE[1], C. ANGELI[1], S. HARKEMA[1];
[1]Univ. of Louisville, Frazier Rehab Neurosci. Collaborative Ctr., Louisville, KY; [2]Anatom. Sci. & Neurobiol., Univ. of Louisville, Louisville, KY

Abstract: The loss of urogenital and bowel functions are some of the most important sequalae as a result of spinal cord injury (SCI). In an upper motor neuron (UMN) injury, a neurogenic bladder may manifest as a failure to store, characterized by uninhibited bladder contractions and an areflexic outlet or as a failure to empty with an areflexic bladder and a sphincter that is unable to relax. An UMN injury also results in increased colonic and anal tone and as a result, constipation and fecal retention are prevalent. Depending on the degree of preserved neurologic function, in men with SCI, reflexogenic erections may be achieved but not necessarily maintained and most often ejaculation is impaired. In females with SCI, impairments in genital responses and sexual arousal are common, while the impact of injury on fertility is not as severe as it is in men. While standard pharmacological therapy aims to manage the prevalent urogenital and bowel issues, therapies addressing recovery of function are still needed. Locomotor training (LT) is one such tool which has been shown to be effective for improving post-SCI motor outcomes, but has also been shown to have a beneficial impact on responses from autonomic systems, such as with cardiovascular and respiratory. Given the overlap of neural networks controlling the pelvic viscera and locomotor function in the lumbosacral cord, we hypothesized that a viscerosomatic relationship is influenced by LT resulting in improved bladder, bowel and sexual function. In this study, eight subjects who sustained a SCI received 80 daily 1-hr sessions of LT on a treadmill, using body-weight support, or 1-hr of LT and stand training (on alternate days). Urodynamic assessments were performed at pre-and post-training time points, revealing significant increases in bladder capacity, voiding efficiency and detrusor contraction time as well as a significant decrease in voiding pressure post-training. Questionnaires were used to assess bowel and sexual function management and it was found that post-training there was a significant decrease in the time required for defecation as well as a significant increase in sexual desire. These results suggest there is an appropriate level of sensory information provided to the spinal cord, generated through task-specific stepping and/or loading, which appears to influence the neural circuitry involved urogenital and bowel control.

Title: Structural and functional changes in lower limb skeletal muscle after chronic complete spinal cord injury

Authors: *L. HE[1,2], A. WILLHITE[1], S. HARKEMA[1,2,3], E. REJC[1,2];
[1]Kentucky Spinal Cord Injury Res. Ctr., Louisville, KY; [2]Dept. of Neurolog. Surgery, Univ. of Louisville, Louisville, KY; [3]Frazier Rehab Inst., Louisville, KY

Abstract: Motor complete spinal cord injury (SCI) leads to severe lower limb skeletal muscle atrophy, which is accompanied by reduction of force output and a shift toward a fast-fatigable muscle fiber phenotype. With the advent of novel neuro-rehabilitative approaches, the recovery of functional lower limb motor control in chronic complete paraplegics is potentially on the horizon. Hence, it is important to understand whether the main lower limb flexors and extensors are affected similarly or differently by chronic complete paralysis in order to optimize their reconditioning by neuromuscular electrical stimulation or other interventions and achieve extensors-flexors relationships similar to those of able-bodied (AB).
In this study, we investigated the effects of chronic motor complete SCI on muscle mass, strength and quality in different lower limb muscle groups. Eight individuals with chronic clinically motor complete SCI (time since injury = 3.4 ± 1.4 years) and 7 AB individuals with similar age, body mass and height underwent the following assessments: *i)* diffusor tensor imaging MRI, in order to analyze the cross-sectional area (CSA) of quadriceps femoris, hamstrings, triceps surae and tibialis anterior; and *ii)* maximal isometric knee extension, knee flexion, plantar-flexion and dorsi-flexion (induced by neuromuscular electrical stimulation in SCI; voluntary efforts with twitch superimposition in AB) in order to analyze the maximal torque exertion of each muscle group. The relative differences between the extensor and flexor muscles of the knee and ankle joint were determined by intra-compartment ratios (quadriceps femoris : hamstrings and triceps surae : tibialis anterior). In addition, muscle quality was defined as the ratio between maximal torque and CSA.
CSA of all four muscle groups was significantly smaller in SCI (between -37%, tibialis anterior, and -51%, quadriceps femoris) compared with AB ($p < 0.05$). Interestingly, the intra-compartment CSA ratios were similar between SCI and AB ($P > 0.05$). The difference in maximal torque between SCI and AB ranged from -65% (triceps surae) to -82% (tibialis anterior) ($p < 0.05$); also the intra-compartment maximal torque ratios were similar between SCI and AB

($P > 0.05$). Muscle quality was on average 58% lower in SCI compared to AB.
This study showed that the deleterious effects of chronic SCI did not alter the structural and functional relationships between extensor and flexor muscle groups at knee and ankle joints. This main finding suggests that muscular reconditioning after chronic clinically motor complete SCI should be equally distributed across the lower limb muscle groups.

Title: Selective late I-wave stimulation enhances voluntary motor output after spinal cord injury

Authors: J. LONG, P. FEDERICO, *S. LEHMANN, M. A. PEREZ;
Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL

Abstract: Targeted stimulation of the corticospinal tract has been shown to improve voluntary motor output in humans with spinal cord injury (SCI; Bunday and Perez, 2012). Here, we used a novel protocol that targeted late synaptic inputs into corticospinal neurons in humans with and without incomplete cervical chronic SCI. We used 180 paired transcranial magnetic stimulation (TMS) pulses over the hand representation of the primary motor cortex at interstimulus intervals of 4.3 ms (targeting I3-wave circuits; iTMS protocol) and 3.5 ms (targeting no I-wave interval; control protocol) at 0.1 Hz for a total of 30 min. Motor evoked potentials (MEPs) in an intrinsic finger muscle where measured at rest before, immediately after, and up to 30 min after the stimulation with the coil oriented to induce currents in the brain in the posterior-anterior (PA) and anterior-posterior (AP) direction to preferentially activate early and late synaptic inputs to

corticospinal neurons, respectively. We found that MEPs size increased in the AP but not in the PA direction after the iTMS protocol for up to 30 min after the stimulation in control (by ~175%) and SCI (by ~142%) participants. No changes in MEP size were observed after the control protocol when tested with the coil either in the PA or AP direction in both groups. Notably, EMG and force outcomes during index finger abduction increased after the iTMS protocol in control (EMG by ~135%; force by ~129%) and SCI (EMG by ~130%; force by ~127%) participants. No changes were observed after the control protocol. SCI subjects needed ~15% less time to complete the nine-hold-peg-test after the iTMS protocol compared to baseline. Thus, we propose that targeting late synaptic inputs into corticospinal neurons might represent a novel strategy for enhancing corticospinal drive and voluntary motor output after human SCI.

Title: Absent grip-dependent modulation of motor cortical maps after spinal cord injury

Authors: *T. TAZOE, M. A. PEREZ;
Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL

Abstract: We previously demonstrated that motor cortical maps of intrinsic hand muscles are topographically reorganized at rest and during tonic voluntary activity in humans with spinal cord injury (SCI; Tazoe and Perez, 2014). Whether this reorganization is also present during a functionally relevant motor task remains unknown. Using neuro-navigated transcranial magnetic stimulation (TMS) we constructed motor cortical maps in the first dorsal interosseous muscle

during a precision grip and a power grip with the TMS coil oriented to induce currents in the brain in the posterior-anterior (PA) and anterior-posterior (AP) direction to preferentially activate early and late synaptic inputs to corticospinal neurons, respectively, in humans with and without chronic incomplete cervical SCI. We reasoned that these different coil orientations will allow us to examine different sets of synaptic inputs into corticospinal volleys, which are differentially affected after SCI (Cirillo et al., 2015). We found in control subjects that the area and peak amplitude of motor cortical maps decreased during power grip compared with precision grip, regardless of the coil orientation tested. In contrast, in SCI subjects, the area of motor cortical maps remained unchanged during precision and power grip with the TMS coil in the PA and AP direction. Notably, we found linear correlations between motor maps area and behavioral outcomes in SCI subjects. The area of maps in the AP direction correlated with the variability of electromyographic activity while the area of maps in the AP direction correlated with reaction times across grip configurations. Our findings suggest that reorganization in motor cortical maps is affected in a task-dependent manner following SCI in humans.

Title: Evidence for a contribution of the reticulospinal tract to hand control after human spinal cord injury

Authors: B. N. STUART[1], *M. A. PEREZ[2];
[1]Inst. of Neurosci., Newcastle Univ., Newcastle upon Tyne, United Kingdom; [2]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami Dept. of Neurolog. Surgery, Miami, FL

Abstract: Multiple descending motor pathways likely contribute to the recovery of hand motor function following spinal cord injury (SCI). Reticulospinal neurons project to spinal motoneurons controlling hand muscles; therefore, it has been proposed that reticulospinal connections might be one of the descending motor pathways involved in hand function after SCI. To test this hypothesis, we examined the effect of a Start-React paradigm, a test that engages reticulospinal inputs, on reaction times measured by electromyographic activity in intrinsic finger muscles in individuals with and without anatomically incomplete chronic cervical SCI. A red light-emitting diode (LED) was presented alone or in combination with a startle (>115 db; 50 ms) or a quiet (<90 db; 50 ms) acoustic stimulus while performing index finger abduction, a precision grip, and a power grip. Reaction times in response to a LED were shorter in controls compared with SCI subjects but in each group reaction times were similar across tasks. Notably, we found that individuals with SCI had shorter reaction times during a startle compared with a quite acoustic stimulus while performing a power grip but not during index finger abduction and a precision grip. Whereas control subjects shortened their reaction times during a startle compared with a quite acoustic stimulus to a similar extent across tasks. These results provide the first evidence that in humans with SCI reticulospinal inputs likely contribute to the control of finger muscles during gross compared with more dexterous finger manipulations.

Title: H-reflex up-conditioning may improve motorneuron axon initial segment recovery after sciatic nerve regeneration in rats

Authors: *Y. WANG[1,2], Y. CHEN[3,2], L. CHEN[3,2], J. R. WOLPAW[1,4,5], X. Y. CHEN[1,2]; [1]Wadsworth Ctr. NYS Dept Hlth. & SUNY, Albany, NY; [2]Natl. Ctr. for Adaptive Neurotechnologies, Albany, NY; [3]Wadsworth Ctr. NYS Dept Hlth., Albany, NY; [4]Natl. Ctr. for Adaptive Neurotechnologis, Albany, NY; [5]Stratton VA Med. Ctr., Albany, NY

Abstract: Up-conditioning of soleus (SOL) H-reflex (HR) after sciatic nerve transection and repair in rats produces faster recovery of SOL background EMG activity, a larger final SOL HR, and stronger primary afferent reinnervation of SOL motoneurons (J Neurosci 30: 16128-16136, 2011). The present study is assessing the impact of SOL HR up-conditioning on the motoneuron axon initial segment (AIS) after sciatic nerve transection and repair. Adult Sprague-Dawley rats are implanted with EMG electrodes in right SOL and tibialis anterior (TA) muscles and a stimulating cuff on the right posterior tibial nerve. After control data collection, the sciatic nerve is transected and repaired (J Neurophysiol 97:1127-1134, 2007), and the rat is exposed for 120 days to continued control data collection (TC rats), SOL H-reflex up-conditioning (TU rats), or SOL H-reflex down-conditioning (TD rats). At the end of data collection, each rat is injected in SOL with CTB-Fluor488 and in TA with CTB-Fluor594, and perfused 3 days later. Untransected naive control (NC) rats of comparable weight are similarly injected and perfused. Serial 16-μm lumbar spinal cord coronal sections are processed immunohistochemically for the SOL and TA labels and anti-ankyrin G (which labels the AIS). The number and morphology of AISs on SOL and TA motoneurons are assessed in a blinded manner. All values are expressed in % of average values for NC rats. To date, we have studied 8 TU, 5 TC, and 5 NC rats. The proportion of SOL motoneurons with an AIS (expressed in % of the proportion in NC rats) averaged 102(±14SE)% in TU rats ($p>0.4$ vs. NC by ANOVA followed by Tukey test) and 58(±10)% in TC rats ($p<0.02$ vs. NC; $p<0.01$ vs. TU). The proportion of TA motoneurons with an AIS averaged 93(±15)% in TU rats ($p>0.9$ vs. NC) and 62(±19)% in TC rats ($p>0.3$ vs. NC or TU). SOL AIS length averaged 97(±6)% of the NC average in TU rats ($p>0.6$ vs. NC) and 123(±10)% in TC rats ($p=0.03$ vs NC; $p=0.01$ vs TU). TA AIS length averaged 111(±5)% in TU rats ($p>0.1$ vs. NC) and 124(±7)% in TC rats ($p<0.01$ vs. NC; $p<0.05$ vs. TU). These initial results suggest that SOL H-reflex up-conditioning improves motoneuron AIS recovery after sciatic nerve transection and repair in rats.

Title: Impact of soleus H-reflex up-conditioning on recovery of the soleus H-reflex and locomotion after sciatic nerve regeneration has occurred in rats

Authors: ***Y. CHEN**[1,2], L. CHEN[1,2], X. YANG[1], Y. WANG[1,2], J. R. WOLPAW[3,2,4], X. Y. CHEN[3,2];
[1]Lab. Neural Injury and Repair, Wadsworth Ctr, NYS Dept Hlth., Albany, NY; [2]Natl. Ctr. for Adaptive Neurotechnologies, Albany, NY; [3]Lab. Neural Injury and Repair, Wadsworth Ctr, NYS Dept Hlth. & SUNY, Albany, NY; [4]Stratton VA Med. Ctr., Albany, NY

Abstract: Operant conditioning of the spinal cord stretch reflex or its electrical analog, the H-reflex (HR), can produce plasticity at multiple spinal cord sites (Encyclop of Neurosci 7:225-233, 2009 for review). Studies in both rats and humans indicated that an appropriate reflex conditioning protocol can restore more normal locomotion after partial spinal cord injury (J Neurosci 26: 12537-12543, 2006; J Neurosci 33: 2365-2375, 2013; J Neurophysiol 111: 1249-1258, 2014; J Neurophysiol 112:2374-81, 2014). Furthermore, reflex conditioning can help to restore spinal reflexes after peripheral nerve injury and regeneration (J Neurosci 30:16128-16136, 2010). We are now exploring the impact of soleus HR conditioning after sciatic regeneration has occurred on the recovery of locomotion. Sprague-Dawley rats are implanted with EMG electrodes in the right soleus muscle and a stimulating cuff on the right posterior tibial nerve. After control HR data collection, the right sciatic nerve is transected and repaired. After 120 more days of control data collection, the rat is exposed for 100 days to: continued control data collection (TCd rats); soleus HR up-conditioning (TUd rats); or soleus HR down-conditioning (TDd rats). Locomotor EMG and kinematics are assessed before transection, 120 days after transection, and 220 days after transection (i.e., the end of data collection). We have studied 6 TUd rats to date. In these rats, the soleus protocol HR (i.e., HR during the conditioning protocol) averaged 23.8(±5.9 SEM)% of its pre-transection value 120 days after nerve transection and 47.4(±10.6)% 100 days later at the end of HR up-conditioning ($p=0.012$ by paired t-test). The locomotor HR (i.e., HR during the stance phase of treadmill locomotion) averaged 12.5(±4.9)% of its pre-tarnsection value 120 days after nerve transection and 30.0(±5.1)% 100 days later at the end of up-conditioning ($p=0.046$). The soleus locomotor burst averaged 27.2(±9.0)% of its pre-transection value 120 days after nerve transection and 49.9(±13.7)% 100 days later at the end of up-conditioning ($p=0.033$). These initial results

suggest that HR up-conditioning may be able to increase the HR and improve locomotion after nerve regeneration has already occurred. Study of TCd and TDd rats, detailed analysis of locomotor kinematics, and assessment of associated anatomical effects is underway.

Title: Operant conditioning of spinal reflexes: Development of a user-friendly clinical system

Authors: A. EFTEKHAR[1], *L. M. MCCANE[1], S. M. HECKMAN[1], G. SCHALK[1], A. K. THOMPSON[2], J. WOLPAW[1];
[1]Natl. Ctr. for Adaptive Neurotechnologies, Wadsworth Center, NYS Dep. Hlth., Albany, NY;
[2]Med. Univ. of South Carolina, Charleston, SC

Abstract: Operant conditioning protocols that change spinal reflex pathways can improve locomotion in animals and people with partial spinal cord injuries (J Neurosci 26:12537-12543, 2006 & 33:2365-2375, 2013). At present, reflex conditioning in human subjects is a complicated laboratory-based process that entails subject-specific configuration requiring detailed knowledge of spinal cord physiology and specialized technical expertise. Thus, its wider dissemination in clinical research settings is not currently practical. Our goal is to develop an automated, easy-to-use, and robust system that will enable research therapists to effectively execute the current reflex operant conditioning protocol in clinical research studies. This is a necessary step toward the eventual development of a therapeutic operant conditioning system for clinical practice. To achieve this goal, we need to: (1) configure the essential reflex conditioning hardware into a compact and robust system; (2) develop a robust software package that largely automates the current complicated laboratory procedures; (3) optimize and validate the resulting hardware/software system through comprehensive user testing; (4) create a concise training program and documentation that ensures the effective use of the system by research therapists. We are now designing algorithms that automate key elements of the reflex conditioning protocol, including: selection of stimulation and recording sites; derivation of M-wave and H-reflex recruitment curves; and selection and ongoing adjustment of stimulus parameters and operant

conditioning criteria. They are intended to interact smoothly with the operator (i.e., the therapist) so that the individual steps in the protocol occur in a seamless straightforward fashion. We expect that this work will create a robust system that enables evaluation of reflex conditioning protocols in wider clinical research settings, and will thereby facilitate eventual dissemination of spinal reflex operant conditioning as an important new therapy that can complement current rehabilitation methods and enhance recovery of function for people with spinal cord injuries or other chronic neuromuscular disorders. Title: Activation of extracellular signal-regulated kinases (ERKs) may be involved in sensorimotor cortex stimulation-induced spinal cord motoneuron GABAergic terminal plasticity in rats

Authors: *X. Y. CHEN[1,2], Y. WANG[3,2], Y. CHEN[3,2], J. R. WOLPAW[1,2,4];
[1]Lab. Neural Injury and Repair, Wadsworth Ctr, NYS Dept Hlth. & SUNY, Albany, NY; [2]Natl. Ctr. for Adaptive Neurotechnologies, Albany, NY; [3]Lab. Neural Injury and Repair, Wadsworth Ctr, NYS Dept Hlth., Albany, NY; [4]Stratton VA Med. Ctr., Albany, NY

Abstract: Electrical stimulation of rat sensorimotor cortex (SMC) produces soleus motoneuron GABAergic terminal and receptor changes (J Neurophysiol 108:2668-2678, 2012). These

changes are likely to alter the neural activity underlying many important behaviors. To further explore the mechanisms of the spinal GABAergic plasticity induced by SMC stimulation, we are examining the effects of this stimulation on phosphorylated ERK1 and ERK2 (pERKs) in spinal motoneurons; pERKs are thought to play important roles in learning and memory (Neuron 61:160-167, 2009). To date, 9 male Sprague-Dawley rats have been implanted with stimulating electrodes over left SMC, soleus EMG recording electrodes and a tibial nerve stimulating cuff in the right leg, and posterior epidural spinal cord volley recording electrodes at T12. Each was exposed to weak SMC stimulation (1-s train of 25 1-ms ~30-μA biphasic pulses (25-Hz pulse rate)) every 10 s for 30-40 days as previously described (J Neurophysiol 108:2668-2678, 2012). Immediately after SMC stimulation ended (Early (E) SMC rats, n=6), or 60-109 days later (Late (L) SMC rats, n=3), each rat was injected in right SOL with CTB-Fluor dye and perfused 3 days later. Five naive control (NC) rats of comparable weight were similarly injected and perfused. Alternating 16-μm lumber spinal cord sections were processed for either pERKs or GAD67 immunoreactivity (pERKs-IR or GAD67-IR); pERKs-IR in soleus motoneuron nucleus and soma and GAD67-IR terminal coverage of the motoneuron membrane were assessed with the NIH image J program in a blinded manner. In the 6 E-SMC rats, soleus motoneuron nuclear pERKs-IR averaged 134(±13SEM)% of that in NC rats (p=0.12 vs. NC) and GAD67-IR terminal coverage averaged 123(±7)% (p=0.04). In the 3 L-SMC rats, pERK-IR averaged 93(±18)% (p=0.77) and GAD67-IR terminal coverage averaged 105(±9)% (p=0.67). Linear regression analysis showed that nuclear pERKs-IR correlated significantly with GAD67-IR in the E-SMC rats (r=0.85, p=0.02) but not in the NC rats (r=0.27, p=0.66). These initial results suggest that the ERK/MAPK signal pathway may play a role in the spinal motoneuron GABAergic terminal plasticity produced by SMC stimulation

Title: Impact of soleus H-reflex up-conditioning on recovery of the soleus H-reflex and locomotion during sciatic nerve regeneration in rats

Authors: *L. CHEN[1,2], Y. CHEN[3,2], X. YANG[3,2], Y. WANG[3,2], J. R. WOLPAW[3,4], X. Y. CHEN[3,2];
[1]Lab. Neural Injury and Repair, Wadsworth Ctr, NYS Dept Hlth. & SUNY, Albany, NY; [2]Natl. Ctr. for Adaptive Neurotechnologies, Albany, NY; [3]Lab. Neural Injury and Repair, Wadsworth Ctr, NYS Dept Hlth., Albany, NY; [4]Natl. Ctr. for Adaptive Neurotechnologiues, Albany, NY

Abstract: Operant conditioning of the spinal cord stretch reflex or its electrical analog, the H-reflex (HR), can produce plasticity at multiple spinal cord sites (Encyclop of Neurosci 7:225-233, 2009 for review). Studies in both rats and humans indicated that an appropriate reflex conditioning protocol can restore more normal locomotion after partial spinal cord injury (J Neurosci 26: 12537-12543, 2006 & 33: 2365-2375, 2013; J Neurophysiol 111: 1249-1258, 2014 & 112:2374-81, 2014). Furthermore, reflex conditioning can help to restore spinal reflexes after peripheral nerve injury and regeneration (J Neurosci 30:16128-16136, 2010). We are now exploring the impact of soleus H-reflex conditioning during the period of sciatic regeneration on the recovery of locomotion. Sprague-Dawley rats are implanted with EMG electrodes in the right soleus muscle and a stimulating cuff on the right posterior tibial nerve. After control H-reflex data collection, the right sciatic nerve is transected and repaired. After 20 more days of control data collection, the rat is exposed for 100 days to: continued control data collection (TC rats); soleus HR up-conditioning (TU rats); or soleus HR down-conditioning (TD rats). Locomotor EMG and kinematics are assessed before transection and at the end of data collection. To date we have completed data collection from 6 TU rats and 7 TC rats. In TU and TC rats, the soleus protocol HR (i.e., HR during the conditioning protocol) averaged 47(±10 SEM)% and 14(±5)%, respectively, of its pre-transection value ($p=0.03$ by t-test); the locomotor HR (i.e., HR during the stance phase of treadmill locomotion) averaged 41(±8)% and 12(±5)%, respectively, of its pre-transection value ($p=0.01$); and the soleus locomotor burst averaged 63(±12)% and 36(±13)%, respectively, of its pre-transection value ($p=0.16$). In addition to confirming previous work indicating that HR up-conditioning during the period of sciatic nerve regeneration increases the HR, these initial results suggest that it also improves locomotor recovery. Study of additional animals, detailed analysis of locomotor kinematics, and assessment of associated anatomical effects is underway.

Title: Noradrenergic pathways and epidural electrical stimulation synergistically modulate proprioceptive feedback circuits in order to restore locomotion after spinal cord injury

Authors: *K. BARTHOLDI[1], Q. BARRAUD[1], E. FORMENTO[1], A. ROWALD[1], P. MUSIENKO[2], M. CAPOGROSSO[1], G. COURTINE[1];

Abstract: Several interventions exploiting chemical and electrical neuromodulation therapies have been designed to engage spinal sensorimotor circuits to facilitate the recovery of standing and walking after spinal cord injury. However, the mechanisms through which electrical and chemical stimulation modulate spinal circuits remain poorly understood. To study these mechanisms, we investigated the circuit-level interactions between noradrenergic receptor modulation and epidural electrical stimulation during standing and walking after a complete spinal cord injury. Previous work suggested that epidural electrical stimulation facilitates motor control through the modulation of proprioceptive feedback circuits. Using genetic deletion experiments and calcium imaging, we confirmed that epidural electrical stimulation promotes locomotion through the activation of proprioceptive feedback circuits. Anatomical experiments in genetically modified mice revealed that noradrenergic receptors are prominently expressed on these circuits. In turn, pharmacological testing in rats and genetic deletion in mice showed that the manipulation of noradrenergic pathways strongly modulated the gain in proprioceptive feedback circuits, which abolished or augmented the effects of epidural electrical stimulation. This electrochemical stimulation strategy restored robust locomotion in paralyzed animals. Our findings provide new insights into the mechanisms through which electrochemical neuromodulation therapies facilitate motor control after injury, and provide a framework to refine these interventions for clinical applications.

Title: Rerouting cortical drive through residual spinal tissue mediates motor function recovery after severe spinal cord injuries

Authors: *L. ASBOTH, Q. BARRAUD, L. FRIEDLI, J. BEAUPARLANT, C. MARTINEZ-GONZALEZ, S. ANIL, G. PIDPRUZHNYKOVA, E. REY, L. BAUD, J. KREIDER, M. ANDERSON, J. VON ZITZEWITZ, G. COURTINE;

Abstract: A severe contusion of thoracic segments disrupts the motor-circuit communication matrix linking the brain and the spinal cord. Electrochemical stimulation applied over lumbar segments restored this communication, which enabled volitional control of leg movements in rodents and humans with motor complete paralysis. However, the circuit-level mechanisms through which the cortical drive regains functional access to the spinal circuits controlling leg movements during electrochemical stimulation remain poorly understood. Using mice expressing light-sensitive channels in cortical projection neurons, we first showed that electrochemical stimulation enabled the hindlimb motor cortex to regain a graded control over hindlimb locomotor movements in otherwise paralyzed animals. Using virus-mediated tract tracing and circuit-specific inactivation techniques, we found that after injury the cortical drive is rerouted through glutamatergic reticular neurons with residual projections below the injury. Robot-assisted gait training enabled by electrochemical stimulation promoted an extensive reorganization of these pathways. We found a robust growth of motor cortex projections into the reticular formation, and a substantial sprouting of residual reticulospinal axons into specific regions of the spinal cord below the injury. We established causal relationships between this anatomical reorganization and the recovery of voluntary leg motor control in response to gait rehabilitation. These results illustrate the remarkable capability of neural pathways to reorganize in order to mediate motor recovery, even after the most severe types of spinal cord injury.

Abstract: Various studies in animal models showed that robot-assisted gait rehabilitation enabled by epidural electrical stimulation of the lumbar spinal cord improves the recovery of leg motor control after spinal cord injury. Recent studies showed that this stimulation is also capable of activating lumbar spinal circuits in paraplegic people. Here, we conducted a preliminary study to evaluate the therapeutic impact of a gait rehabilitation program enabled by an overground robotic bodyweight support and continuous epidural electrical stimulation in a non-ambulatory person with a chronic incomplete spinal cord injury. The participant suffered a herniated disc collapse at the cervical level, which led to severe deficits on the left leg and moderate impairments on the right leg (AIS-C). After following a conventional rehabilitation program for more than one year after injury, she was not able to walk overground, even with assistive devices. She had previously been implanted with an epidural electrode array over lumbar spinal cord segments to alleviate neuropathic pain in the legs. We searched the electrode configurations in this array that targeted the muscles that the participant could not access voluntarily. Continuous stimulation through these electrode configurations improved a number of relevant gait parameters during locomotion. The participant then underwent a gait rehabilitation program that was conducted overground using a multidirectional robotic support system, and facilitated with the personalized stimulation protocols. After completion of the gait rehabilitation program, the participant was able to use a walker to progress overground without robotic assistance and

without stimulation. Her WISCI-II score had thus increased from zero to thirteen, while her AIS score converted from C to D. Urodynamic examination revealed the disappearance of uninhibited bladder contractions and detrusor sphincter dyssynergia. This study provides preliminary evidence that robot-assisted gait rehabilitation enabled by epidural electrical stimulation may promote clinically relevant neurological improvements that persist without stimulation.

Title: Robotic platform maximizing gravity-dependent gait interactions to train standing and walking after neurological disorders

Authors: *J.-B. MIGNARDOT[1,2], C. G. LE GOFF[1,2], R. VAN DEN BRAND[1,2], N. FUMEAUX[1], S. CARDA[4,2], J. VON ZITZEWITZ[1], J. BLOCH[2,3], G. COURTINE[1,2]; [1]EPFL, Lausanne, Switzerland; [2]Clin. Neurosciences, [3]Neurosurg., Univ. Hosp. of Vaud, Lausanne, Switzerland; [4]Neurorehabilitation, Univ. Hosp. of Vaud, Lausanne, Switzerland

Abstract: Gait recovery after neurological disorders requires re-mastering the interplay between body mechanics and gravitational forces. Despite the importance of gravity-dependent gait interactions for promoting this learning, this essential aspect of gait rehabilitation have received little attention. Here, we introduce a robotic interface that assists trunk movements in order to maximize gravity-dependent gait interactions during highly participative locomotion within a large and safe environment. We elaborated an algorithm that automatically configures multidirectional forces applied to the trunk based on patient-specific needs. This robotic assistance enabled walking in non-ambulatory individuals with spinal cord injury and stroke, and allowed less impaired individuals to execute skilled locomotion that they could not perform

without robotic assistance. The robotic interface improved locomotor performance after a single gait training session, whereas the same amount of training restricted to vertical support on a treadmill did not ameliorate gait. These results establish a new rehabilitation framework to augment motor recovery after neurological disorders.

Amsterdam, Ctr. for Neurogenomics and Cognition research, Amsterdan, Netherlands; [6]Lab. for Neuroregeneration, Netherlands Inst. for Neurosci., Amsterdam, Netherlands

Abstract: Introduction. Non-human primates can be trained to ambulate on a treadmill. Cervical contusions lead to both upper and lower extremity functional deficits. These can be analyzed in a coupled manner using kinematic tracking of forelimb and hindlimb joint cycles. We tested the following hypotheses. **1)** Kinematic analysis has sufficient sensitivity to detect differences in injury severity after C3/4 hemi-contusion. **2)** The impact of locally delivered experimental therapeutics including autologous Schwann cells (aSC) and lentivirus expressing chondroitinase ABC (LV-ChABC) on gait is evident on limb-coupled kinematic analysis. **3)** This analysis adds relevant data not evident in hand dexterity testing. **Methods.** Five monkeys (M. fascicularis) were pre-trained. Following a right sided hemi-contusion the animals were

randomized into A) No treatment controls (n= 1); B) LV-ChABC injected perilesionally 2 hours post spinal cord injury (n=2); C) LV-ChABC injection and transplant of aSC 14 days post-injury (n=2). Treadmill activity occurred weekly. Quadrupedal locomotion analysis was performed pre-injury, 3 and 6 months post-injury. Joints in the left and right sides were marked with ultraviolet ink and data was captured using black lights and a Vicon Motus tracking system. The variables assessed were joint track consistency and distance, stride length, and height. **Results.** All animals, except those receiving LV-ChABC, had notable deficits in quadrupedal locomotion at 3 months post-injury (step height, length). The wrist and ankle joint cycles were inconsistent possibly due to impaired strength, proprioception, and balance. By six months post-injury the joint cycles of groups A and B were more consistent and approached baseline. Animals in group C (aSC) showed persistent gait impairments. Analysis of contusion parameters including force delivered and ultrasound quantitative assessment of injury volume do not account for the behavioral differences. **Conclusion.** Kinematic quadrupedal locomotor assessment is useful to quantify recovery, adding to assessments of hand dexterity. The animals continue to survive. Final MRI, histology, and CST tracing will be correlated to the quadrupedal kinematic analysis.

Netherlands; [6]Ctr. for Neurogenomics and Cognition research, Vrije Univ. Amsterdam, Amsterdam, Netherlands

Abstract: Introduction: Chondroitinase ABC and Schwann cells have been shown independently to promote functional recovery in rodents after contusive injury. Autologous human Schwann cells ahSC are being tested in Phase 1 clinical trials for sub-acute and chronic SCI. Recognizing the necessity of combination strategies, we are exploring the acute injection of a lentiviral transfer vector carrying a mammalian compatible engineered chABC gene (LV-chABC), with or without sub-acute aSC transplantation, in primates following unilateral C3/4 SCI. Here, we present the preliminary evaluation of the hand and arm recovery up to six months post-injury and treatment. Methods: Seven young adult male primates (*Macaca fascicularis*) received a right-sided hemi-contusion using the Miami Large Animal Impactor. They were randomized into: Injury only controls (n=2), Injury + 2 hours post-injury perilesional injection of LV-chABC (n=3), and Injury + LV-chABC injection + aSC transplant 14 days post-SCI (n=2). Animals were acclimatized to be comfortable within a primate chair and also provided with cage objects to promote grasp practice. They were trained to retrieve food pellets from a modified Brinkman board consisting of 20 cross-shaped slots suited to the monkeys' fingers. The board was presented in the horizontal and vertical planes (relative to the floor) to test arm and shoulder strength, wrist rotation and thenar opposition. Both hands were exposed to the tasks equally during the pre and post injury phases. Results: Significant differences in retrieval time and retrieval quality were found between the left (control) and right (injured) hand in each animal and between the 3 groups as of 6 months post-injury. LV-chABC injected animals showed the most rapid recovery. Additionally observed differences include the rate to reach hand function plateau and the variety of strategies developed to perform the task. Conclusions: Animals continue to survive. The tests discriminate recovery of fine dexterity of finger movements from adaptation strategies. Deficits and recovery of combined upper and lower extremity gait coupling are assessed with treadmill kinematics.

Title: Robot-driven epidural stimulation prevents collapse in function found after brain-derived neurotrophic factor (BDNF) treatment of adult spinal cord injury.

Authors: *J. LEE[1], S. F. GISZTER[2];
[1]Neurobio. & Anat., Drexel Univ., Philadelphia, PA; [2]Neurobio. & Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: The use of robotic technology in various interventions of SCI is an effective means of rehabilitation in the rats transected as adults (ATX). In our lab, we use robotic assistance at the pelvis in our trunk-based rehabilitation paradigm to significantly improve locomotor function. In addition, we have shown that our robot can be used to drive epidural stimulation (ES) in the ATX model to increase body weight support and promote stepping patterns.
In our previous work studying viral delivery of BDNF to induce stepping in the ATX model, we showed that approximately 46% of ATX animals treated with AAV5-BDNF eventually develop a partial, but highly significant collapse in function. Previously stepping animals developed hyperreflexia in the hindlimbs that prevented robust locomotion. The use of our robot intervention increased their peak performance on treadmill, but did not prevent collapse in some rats. To investigate further this interaction, we prepared four groups of rats with various combinations of robot-driven epidural stimulation (rd-ES), robot-assisted treadmill training, and AAV5-BDNF. One group (n=9) received all three therapies, while a control (n=8) received a sham virus. Another group (n=10) received only BDNF and robot assistance, while a fourth (n=8) received BDNF and conventional ES. After recovery, animals were trained for six weeks, and assessed for locomotor function. We discovered that the BDNF-treated rats on robot and rd-ES had significant improvement in AOB ($p = 0.0005$), body weight support ($p = 0.0002$), and percent weight-supported stepping ($p = 0.006$), though they were not significantly different from each other. However, we discovered that BDNF-treated animals in groups that received any ES during training had no incidents of functional collapse, which is a highly significant effect ($p << 0.01$).
To conclude, the combination of robot driven epidural stimulation with the AAV5-BDNF gene therapy created a condition in which the deleterious effects of AAV5-BDNF otherwise seen in some rats were completely avoided. This highly synergistic interaction could not have been anticipated a priori.

Title: Ankle-based robotics, BDNF and epidural stimulation for locomotion rehabilitation after complete SCI

Authors: *D. LOGAN[1], J. K. LEE[1,2], A. R. HIMES[1], T. KIEMEL[3], S. F. GISZTER[1,2];
[1]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Biomed. Engin., Drexel Univ., Philadelphia, PA; [3]Univ. of Maryland, College Park, MD

Abstract: Our lab has previously found that functional scores in animals rehabilitating from a complete adult spinal cord injury (SCI) show promising locomotion gains when using a combined approach of Adeno-associated viral delivery of Brain-derived neurotrophic factor (AAV5-BDNF) and robotic-assistance at the pelvis. Addition of feedback-based epidural stimulation has led to these rehabilitation gains being more consistent. In this study we investigated if addition of epidural stimulation to the combined BDNF and robotic therapy would also lead to more consistent rehabilitation gains in an ankle-based, air stepping rehabilitation setting. SD rats (n=6) were implanted with hindlimb intramuscular EMGs prior to complete transection (T10) and implantation of bipolar stimulating electrodes on spinal cord dura at L2 and S1. All rats received AAV5-BDNF microinjections caudal to injury. After recovery, all animals were trained 5x weekly (20 min/session) with an ankle-based robotics system consisting of two robots (OMNI) with each robot's arm attached to an ankle, which are programmed to dictate ankle kinematics of hindlimbs to create air stepping. One group (a-robot/BDNF/Epi, n=3) of these animals received constant 40 Hz stimulation at both epidural sites while the other group (a-robot/BDNF, n=3) did not. Animals were functionally scored (AOB) after injury prior to training and then after every five training sessions in a 5 minute robotic-assisted (at pelvis) treadmill context. After 15 days of training, the a-robot/BDNF group improved little with AOB scores increasing from .33 ± .58 (S.D.) pre-training to 2.3 ±1.5 post-training, on average across animals. The a-robot/BDNF/Epi group, however, showed increases from 1.7 ± .58 pre-training to 11.33 ± 1.5 post-training, on average across animals. The inability of the a-robot /BDNF group to transfer the ankle-based training to the treadmill context suggests that the trunk control engaged by robot assistance at the pelvis during training is critical, reflecting a context dependence of the ankle-based training. The larger increases in functional scoring in the a-

robot/BDNF/Epi group suggest that epidural stimulation enhanced the ankle-robotic therapy for functional stepping, allowing some treadmill-context functioning. The results emphasize the need to further investigate training context and emphasis (limb trajectory vs. trunk control) in multifaceted approaches to locomotion rehabilitation after SCI.

Title: Buspirone effect on h-reflex in acute spinal decerebrated mice.

Authors: *Y. DEVELLE[1], H. LEBLOND[2];
[1]UQTR, Trois-Rivières, QC, Canada; [2]anatomy, Univ. du Quebec à Trois-Rivieres, Trois-Rivières, QC, Canada

Abstract: It was shown in mice that buspirone, a partial 5HT1A agonist, promotes locomotor recovery after a complete spinal cord transection (Tx). Since H-reflex is commonly used to evaluate spinal networks excitability, we propose to study herein the effect of buspirone on the H-reflex after an acute Tx in adult mice. To avoid possible impacts of the anesthetics on depression of the reflex, experiments were performed in unanaesthetized mice (N=8) after a decerebration. The H-reflex was recorded in plantar muscles of the hindpaw after stimulation of the tibial nerve with a bipolar hook electrode two hours after a complete Tx at the 8th thoracic vertebrae level. The averaged H/M ratio (30 stimulations at 0.2 Hz) was compared before and every 10 minutes following buspirone administration (8 mg/Kg, i.p.) for 60 minutes. Frequency-dependent depression (FDD) of the H-reflex was also evaluated before and 50 minutes after treatment by comparing the H-reflex amplitude at 0.2, 5 and 10Hz. Before buspirone, H-reflex could be elicited in acute spinal mice with H/M ratios averaging between 10 to 30%. A FDD of the H-reflex was observed at 5Hz (68%) and at 10Hz (70%) compared with 0.2Hz. After buspirone, a decrease in the H/M ratio was initially observed with values around 69% of pretreatment. Then, a significant increase was measured later from 30 to 60 minutes after buspirone administration reaching a high of 170% of pretreatment 60 minutes after injection. A FDD was also measured 50 minutes after buspirone at 5Hz (81.2%) and at 10 Hz (84.9%). There

was no significant incidence of the treatment on inhibition at 5Hz and 10HZ (respectively p=0.163 and p=0.224 two way ANOVA). These results suggest that the enhancing effect of buspirone on H-reflex may be due to a postsynaptic action. Thus, burspirone may promote locomotor activity by acting on motoneuronal sensitivity. Further work should be done to investigate the effect of buspirone later after the lesion in chronic spinal animals at a time where an absence of FDD was shown in order to see if the later can be preserved.

Title: Electroacupuncture reduces the alterations provoked on the H reflex & gait locomotion by a spinal compression injury in the rat.

Authors: *S. QUIROZ-GONZÁLEZ[1], S. TORRES-CASTILLO[1], R. LÓPEZ-GÓMEZ[1], Y. GARCÍA-PICENO[1], B. SEGURA-ALEGRÍA[2], I. JIMÉNEZ-ESTRADA[3];

Abstract: This study was aimed to explore the action of electroacupuncture (EA) stimulation on the alterations provoked by a spinal compression in the Hoffman Reflex (HR) evoked in plantar muscles by tibial nerve (TN) stimulation (at 0.2, 5 y 10HZ). Locomotor behavior and gait kinematic analysis of rats were also evaluated. The spinal lesion was made by insuflating one Fogarty balloon placed into the epidural space of the T9 spinal segment in adult Wistar male rats (200-250gr; n=45). EA stimulation was applied at 2, 50 and 100Hz at the acupoints *Zhiyang* (GV9), *Jizhong* (GV6), *Yaosh*u (GV2) and *Changqian* (GV1). After 5 weeks, BBB scores of the lesioned group of rats treated with 50 Hz-EA showed a noticeable recovery (77 ± 5.5%, n=8) as compared to untreated (34 ± 2.7% n=5) and 2 (44 ± 3.1% n=7) or 100Hz groups (39 ± 2.7% %, n=5). Unrestrained gait kinematic analysis of spinal lesioned rats treated with 50Hz-EA showed a significant recovery in duration, length and speed of strides, as compared to those rats treated with 2 and 100Hz and untreated (60 ± 4.8% $p < 0.05$). In lesioned rats, TN stimulation applied at 0.02 Hz provokes a facilitation of the RH response (152 ± 4.8%) which is partially reverted by EA stimulation (78 ± 3.2 %). By the contrary, TN stimulation applied in sham operated animals showed a notorious reduction in HR amplitude which is dependent of the stimulus frequency

(0.2Hz: 100%; 5HZ: 24 ± 4.6%, 10HZ: 2 ± 0.12%, n=7). However, lesioned animals showed a lesser depression of the HR amplitude (0.2: 100%; 5HZ: 72 ± 4.6%, 10HZ: 55 ± 3.2%, n=8). In such animals, 50Hz-EA stimulation induced a partial recovery of the HR depression (0.2: 100%; 5 Hz: 57 ± 4.1% and 10 Hz: 36 ± 2.5%). Our results indicate that EA stimulation applied at 50Hz reduced the excitability of the spinal pool of motoneurons participating in the generation of the plantar muscle-RH response in rats suffering a T9 spinal cord compression and partially reverted the HR depression evoked in a frecuency dependent manner in the lesioned rat.

Title: A selective non-competitive AMPA receptor antagonist as a potential drug for sporadic amyotrophic lateral sclerosis (ALS) -rescue of motor dysfunctions and loss of motor neurons with TDP-43 pathology in ALS model mice.

Authors: *M. AKAMATSU[1], T. YAMASHITA[1], T. HOSAKA[1], N. HIROSE[1], S. TERAMOTO[1], S. KWAK[1,2];
[1]Grad. Sch. of Med., The Univ. of Tokyo, Tokyo, Japan; [2]Clin. Res. Cent. Med., Intl. Univ. of Hearth and Welfare, Tokyo, Japan

Abstract: TAR DNA-binding protein 43 (TDP-43) pathology is the pathological hallmark of amyotrophic lateral sclerosis (ALS), the fatal and most common adult-onset motor neuron disease. In addition, the vast majority of sporadic ALS patients exhibit progressive reduction in the expression of an RNA editing enzyme called adenosine deaminase acting on RNA 2 (ADAR2) in the motor neurons. This molecular change results in the expression of abnormal glutamine/arginine (Q/R) site-unedited GluA2, an α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptor subunit, thereby increasing the Ca^{2+} permeability of the AMPA receptors containing unedited GluA2. The expression of the abnormal AMPA receptors lead to

death of motor neurons with exhibiting TDP-43 pathology in the motor neurons of ALS patients and TDP-43 pathology-like mislocalization was observed in the motor neurons expressing unedited GluA2 in the conditional ADAR2 knockout AR2 mice. In this study we evaluated the effects of a selective non-competitive AMPA receptor antagonist perampanel on the progression of behavioral and pathological ALS phenotype in the AR2 mice. After testing the effective dose of perampanel by 14-day-administration, we administered the maximum tolerable dose (20 mg/kg/day) of perampanel orally to the AR2 mice at 26 weeks of age every day for 90 days. Methylcellulose solution used for dissolving perampanel was used as vehicle. The vehicle-treated AR2 mice exhibited progressive decline in the rotarod performance, whereas the perampanel-treated AR2 mice exhibited constant rotarod performance during the 90 days of experiment. The number of anterior horn cells (AHCs) in the spinal cord that was counted after the end of perampanel administration was significantly higher in the perampanel-treated AR2 mice than in the vehicle-treated ones. Furthermore, TDP-43 immunohistochemical study revealed that the number of AHCs exhibiting nuclear TDP-43 immunoreactivity was significantly higher in the perampanel-treated AR2 mice than in the vehicle-treated AR2 mice in which the majority of AHCs lost nuclear TDP-43. Because exaggerated Ca^{2+} influx through the AMPA receptor causes subcellular mislocalization of TDP-43, the present results indicate that perampanel effectively inhibited the progression of ALS phenotype in the AR2 mice by blocking exaggerated Ca^{2+} influx through the Ca^{2+}-permeable AMPA receptors. As excitotoxicity is a long-held hypothesis of ALS and perampanel has already been approved as an anti-epileptic drug, the present robust results would provide rational for clinical trial of perampanel for ALS.

Title: Investigation of mitophagy and related stress pathways in ALS and motor neuron dysfunction

Authors: *E. CLARK, J. R. BOSTROM, B. A. LINK;
Cell Biology, Neurobiology, Anat., Froedtert and Med. Col. of Wisconsin, Milwaukee, WI

Abstract: ALS is a neurodegenerative disease that leads to motor neuron loss, muscle atrophy, and eventually paralysis of voluntary muscles. While it is known that mutations in mitophagy related genes such as *OPTINEURIN* leads to ALS, how defects in mitophagy cause ALS is unknown. Furthermore, the relationship between mitophagy, mitochondrial health, and other stress pathways requires further understanding. In the present study we sought to determine the role of mutations affecting mitophagy and mitochondrial dynamics in motor neuron dysfunction and ALS. Towards this goal, we have generated zebrafish mutations targeting *optineurin, dync1h1* (more commonly cytoplasmic dynein-heavy chain), *calcoco2* (more commonly ndp52), and *sqstm1* (more commonly p62) to disrupt mitophagy and mitochondrial homeostasis. RNA-Seq comparing 18-month old *optineurin* mutant and wildtype zebrafish spinal cords revealed gene expression changes related to mitophagy and the unfolded protein response stress pathways. Furthermore, previous work from the lab has suggested defects in vesicle trafficking in *optineurin* mutants (Paulus and Link, 2014). Optineurin can bind the motor protein Huntingtin (Faber et al., 1998) which in turn binds Dynein (Caviston et al., 2006), suggesting an important role for these interactions in motor neuron trafficking of autophagosomes (Wong and Holzbaur, 2014) and potentially mitophagy. Abnormal trafficking could sensitize motor neurons to metabolic and other cellular stress. Respiration defects were not observed in *optineurin* mutant embryos at 48hpf, indicating development is normal in these animals. To further investigate stress pathways in zebrafish embryos, as well as in adult fish, characterization of fluorescent protein based reporters for oxidative stress (mito-roGFP), mitophagy (mito-mKeima), unfolded protein response (multimerized atf6 binding sites: GFP), mitochondrial structure and dynamics (coxVIII fusion protein), as well as motor neuron morphology (mnx1 promoter: GFP) is underway. To visualize fluorescent reporters within neurons from aged animals, we are adopting tissue clearing techniques as well as in vitro culture strategies. In conclusion, these results highlight the role of Optineurin and interacting proteins in controlling mitochondrial homeostasis, and when mutated, their contribution to motor neuron dysfunction. Establishment and validation of stress pathway assays for embryonic and adult zebrafish will serve as a platform for ongoing studies of ALS and other neurodegenerative diseases.

Title: TACE promotes TNF-α secretion and massive gliosis in a mouse model of amyotrophic lateral sclerosis

Authors: *J.-K. LEE[1,2], B. KIM[2], J. SHIN[3];
[1]Korea Univ., Seoul-City, Korea, Republic of; [2]Neuracle Sciecne, Seoul, Korea, Republic of;
[3]P&K Skin Res. Ctr., SEOUL, Korea, Republic of

Abstract: Previously, we have addressed that iron is selectively accumulated in ventral motor neurons from SOD1(G93A) mice even at 4 weeks of ages, which directly induces oxidative stress triggered by SOD1(G93A). Chelating irons with deferoxamine mesylate (DFO) delays not only disease onset and but extends survival in SOD1(G93A) mice (Lee et al., 2015). Here, we further show that SOD1(G93A)-induced iron accumulation mediates the increase in the enzymatic activity of TNF-a converting enzyme (TACE, ADAM17) as well as cleavage (activation) of the enzyme in glial cells of SOD1(G93A) mice. These events lead to secretion of TNF-a and activation of astrocytes and microglia at least in part through iron-dependent oxidative stress. Our results suggest that iron functions as a key determinant of early demises of motoneurons as well as neuroinflammation at symptomatic stage in ALS model mice.

Title: Locomotor compensation in severe motor neuron loss during als disease progression

Authors: L. M. LANDONI, *T. AKAY;
Dept. of Med. Neurosci., Dalhousie Univ., Halifax, NS, Canada

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease characterized by progressive motor neuron (MN) death, leading to paralysis and eventually death. Manifestation of symptoms and progression of the disease is highly variable. As a result, it is very difficult to diagnose and treat ALS. When symptoms become clinically evident, patients and ALS model animals (mSOD1^{G93A} mice), have already lost a large portion of motor units. This suggests that the spinal circuity has a compensatory mechanism in place that allows for reactively normal movement in the presence of neuromuscular pathology. The overall aim of our study is to develop an understanding of ALS disease progression in mSOD1^{G93A} mice and the mechanisms underlying spinal compensation. An understanding of how compensation is occurring, will inform the development of exercise training programs that specifically target the compensatory mechanism, thereby improving mobility and quality of life in ALS patients. To characterize ALS disease progression in the mSOD1^{G93A} mouse, we chronically implanted stimulation electrodes to tibial nerve and electromyogram (EMG) recording electrodes to multiple muscles. By performing tibial nerve stimulation experiments, we tracked the compound muscle action potential (CMAP) of the gastrocnemius (Gs) throughout the disease course in mSOD1^{G93A} mice and correlated the results with histological neuromuscular junction (NMJ) data. At ~P90, mSOD1^{G93A} mice have a large drop in the Gs CMAP (indirect measure of muscle innervation) followed by a slow decline, both absent in wild-type (WT) mice. Changes in Gs CMAP occurred in conjunction with increasing denervation at the NMJ level in mSOD1^{G93A} mice. Analysis of kinematic and electromyogram (EMG) recordings during walking and swimming revealed that despite extensive muscle denervation there is only a subtle change in behaviour of mSOD1^{G93A} mice. This manifests as a “bursty” activation pattern of the tibialis anterior (TA) muscle that is paralleled by an observable stutter movement of the leg during swing phase at ~P85. A large drop in the ratio of peak Gs swimming:walking EMG amplitudes is observed at ~P90 in mSOD1^{G93A} mice. This suggests that during later stages of the disease mSOD1^{G93A} mice lose the ability to modulate motor neuron excitability. Previously published data shows that C-boutons are involved in the upregulation of Gs activity during swimming versus walking, suggesting that C-boutons may be involved in ALS disease progression. We are presently investigating cholinergic modulation of motor neurons during ALS disease progression as a potential compensatory mechanism for motor unit loss.

Title: Parkin ablation modulates mitophagy and attenuates mutant SOD1 toxicity *In vivo*

Authors: G. M. PALOMO[1], A. ARREGUIN[1], D. ZHAO[1], C. KONRAD[1], J. MAGRANE[1], H. KAWAMATA[1], *G. MANFREDI[2,1];
[1]The Feil Family Brain and Mind Res. Institute, Weill Cornell Med., New York, NY; [2]Weill Med. Col. Cornell Univ., New York, NY

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease caused by the demise of upper and lower motor neurons. Familial ALS account for 10% of all cases, and of those, a 20% is associated with mutations in Cu-Zn superoxide dismutase 1 (SOD1). Several mechanisms have been proposed for the toxic effects of mutant SOD1, including mitochondria damage and dysfunction. Damaged mitochondria are eliminated by mitochondria quality control (MQC) mechanisms and Parkin plays an essential role in tagging damaged mitochondria for selective autophagy (mitophagy). To study the potential involvement of Parkin and mitophagy in ALS, we used motor neuron-like NSC34 cells stably transfected with either G93A mutant SOD1 or wild type SOD1. These cells naturally lack Parkin, but expression of Parkin-YFP in differentiated NSC34 motor neurons resulted in increased number of parkin-tagged mitochondria in G93A-SOD1 cells as compared to non-transgenic cells. In addition, p62, a protein involved in the clustering of mitochondria and a substrate of autophagy, showed increased localization on G93A-SOD1 mitochondria. Taken together, these results suggest that in NSC34 neurons mitophagy is impaired by G93A-SOD1, because p62-tagged mitochondria are increased, and that Parkin-YFP is involved in tagging damaged mitochondria for mitophagy. To assess the role of Parkin in SOD1 ALS in vivo, G93A-SOD1 mice were crossed with Parkin knockout mice (both in the C57BL6 background). Littermates with the following genotypes were compared: Parkin KO/G93A-SOD1, Parkin WT/G93A-SOD1, non-transgenic controls, and Parkin KO. Interestingly, Parkin KO/G93A-SOD1 mice had a slower disease progression than Parkin WT/G93A-SOD1. They performed better on grip strength tests, showed slower rate of body weight loss and had extended survival (20%), compared to Parkin WT/G93A-SOD1. Furthermore, Parkin KO/G93-ASOD1 spinal cord had increased mitochondrial proteins, as determined by western blot, and function, as shown by cytochrome c oxidase and citrate synthase activity measurements. Altogether, these results show that Parkin plays an important role in

mitophagy in the CNS of G93A-SOD1 mice. Also, they suggest that Parkin ablation could exert a protective role in these mice by preventing excessive mitophagy and subsequent mitochondrial depletion, which could result from protracted activation of MQC caused by mutant SOD1-induced mitochondrial damage.

Title: Exacerbation of ALS phenotype in SOD1 rats following repeat traumatic brain injury

Authors: *A. MA, A. KO, M. HARADA, P. AVALOS, N. DHILLON, P. HARO, O. SHELEST, C. N. SVENDSEN, E. J. LEY, G. M. THOMSEN;
Cedars-Sinai Med. Ctr., West Hollywood, CA

Abstract: Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disease that affects the brain and spinal cord, leading to muscle weakness and atrophy. There is an elevated risk of ALS and other neurodegenerative disease among individuals that have previously suffered from head injury. While acute stab-wound injury to the spinal cord and a one-time severe traumatic brain injury (TBI) have been shown to not exacerbate ALS in the SOD1 rat model of ALS, the brain has recently been shown to play an important role in initiating ALS disease onset. In an attempt to better understand the effect of recurrent concussive injury in a population that may be genetically predisposed to neurodegenerative disease, we established a novel rodent head injury model that leads to long-term functional deficits after repetition. Previous rodent models of TBI that use one-time, or repeat unilateral injury demonstrate only transient motor function deficit. Our work suggests the necessity of a cumulative, bilateral injury model to reveal sustained effects of multiple TBI events. We implemented this novel repetitive concussion injury model by delivering a once-weekly, mild/moderate, bilateral, closed-skull, controlled cortical impact (CCI) injury to SOD1 rats over five weeks, to determine whether this repetitive injury induced an exacerbated ALS phenotype.
We found that, when administered starting at 60 days of age, recurrent, mild/moderate TBI demonstrates unique long-term deficits in WT rats and an earlier development of the ALS

phenotype in SOD1 rats. SOD1 TBI rats that exhibited sustained functional rotarod deficits as a result of injury reached disease onset significantly earlier than uninjured SOD1 sham rats. SOD1 TBI rats reached their peak body weight earlier and presented with earlier onset of forelimb paralysis relative to SOD1 shams. This earlier disease onset also translated into a shortened lifespan, as SOD1 TBI rats reached disease endpoint significantly sooner than SOD1 shams. Assessment of brain pathology also suggests a significantly greater rate of brain atrophy in SOD1 rats, whereby cortical and corpus callosum shrinkage is exacerbated in SOD1 TBI rats relative to WT TBI rats euthanized at similar time points.
This research may provide an improved clinical understanding of how repeat head injury presents in professional athletes and military personnel, and how it might relate to those genetically predisposed to neurodegenerative diseases.

Title: Stathmin 1/2-triggered microtubule loss mediates Golgi fragmentation in mutant SOD1 motor neurons

Authors: *S. BELLOUZE[1], G. BAILLAT[1], D. BUTTIGIEG[1], P. DE LA GRANGE[2], C. RABOUILLE[3], G. HAASE[1];
[1]Inst. Des Neurosciences De La Timone CNRS & Aix-Marseille Univ., Marseille, France; [2]Genosplice, Paris, France; [3]Hubrecht Inst., Utrecht, Netherlands

Abstract: Pathological Golgi fragmentation represents a constant pre-clinical feature of many neurodegenerative diseases including amyotrophic lateral sclerosis (ALS) but its molecular mechanisms remain hitherto unclear.
Here, we show that the severe Golgi fragmentation in transgenic mutant SOD1^{G85R} and

$SOD1^{G93A}$ mouse motor neurons is associated with defective polymerization of Golgi-derived microtubules, loss of the COPI coat subunit β-COP, cytoplasmic dispersion of the Golgi tether GM130, strong accumulation of the ER-Golgi v-SNAREs GS15 and GS28 as well as tubular/vesicular Golgi fragmentation. Data mining, transcriptomic and protein analyses demonstrate that both SOD1 mutants cause early presymptomatic and rapidly progressive up-regulation of the microtubule-destabilizing proteins Stathmins 1 and 2. Remarkably, mutant SOD1-triggered Golgi fragmentation and Golgi SNARE accumulation are recapitulated by Stathmin 1/2 overexpression but completely rescued by Stathmin 1/2 knockdown.
We conclude that Stathmin-triggered microtubule destabilization mediates Golgi fragmentation in mutant SOD1-linked ALS and potentially also in related motor neuron diseases.

Title: An examination of noninflammatory astrocyte secretions of glutamate in the SOD1 G93A ALS mouse model

Authors: *K. JORDAN, J. MURPHY, A. SINGH, G. COAN, C. S. MITCHELL;
Biomed. Engin., Georgia Inst. of Technol., Atlanta, GA

Abstract: Astrocytes can be found between the vascular and neuronal elements of the CNS, where they take up and release molecules in order to maintain a homeostatic microenvironment for optimal neuron growth. Dysregulation of these astrocyte functions can lead to neuronal depolarization, hyperexcitability, excitotoxicity and subsequent neuronal death. Changes in astrocyte characteristics and function have previously been identified in Amyotrophic Lateral Sclerosis (ALS) transgenic mouse models. We hypothesize that changes in the levels and relationships between glutamate and glutamate transporters in astrocytes contribute to ALS disease progression and, and specifically, motor neuron death. Application of inclusion and exclusion criteria to a database comprising findings from over 3,000 ALS transgenic mouse

model papers resulted in data from over 60 papers. Experimental data measuring glutamate concentrations and glutamate transmitter levels from SOD1 G93A (superoxide dismutase-1 glycine 93 to alanine) transgenic ALS mouse models were normalized to wild-type mice and graphed over time. We perform correlation analysis and survival analysis to determine the role of astrocytic glutamate regulation in ALS disease progression. We demonstrate that GTL-1, GluR-1, and GluR-2 levels from astrocytes decrease over time. We propose that this trend may be associated with early increases in extracellular glutamate concentrations and compensatory efforts to maintain homeostasis. The findings of this analysis give insight into the non-inflammatory role of astrocytes in the pathophysiology of ALS.

Title: A dynamic meta-analysis of apoptosis, bioenergetics, and oxidative stress molecular mechanisms in the G93A SOD1 transgenic ALS mouse model

Authors: D. VITHARANA, T.-N. BACH, *K. Y.-K. ZHANG, G. COAN, C. S. MITCHELL; Biomed. Engin., Georgia Inst. of Technol., Atlanta, GA

Abstract: Apoptosis, bioenergetics, and oxidative stress have been identified as some of the major molecular mechanisms contributing to Amyotrophic Lateral Sclerosis (ALS) disease progression. However, it is unclear as to how the interactions within this highly inter-related triad of categories influences the time course of the disease or, moreover, how effective therapeutic modulation could be accomplished. In this study, we aim to map the timing of the interactions between these molecular mechanisms in order to determine which parameters and relationships have the most significant impact on ALS in each stage of the pathology. In addition, we examine the possibility of homeostatic instabilities within the triad prior to, during, and after ALS symptom onset. We conduct a dynamic meta-analysis of experimental data collected from over 160 peer-reviewed articles in order to identify and characterize relationships between parameters

(such as caspase, ATP, and reactive oxygen species levels) falling under each of the three broader categories of apoptosis, bioenergetics, and oxidative stress. We construct an interactive model to forecast the relative magnitude and the rate of change of each parameter over time in high-copy SOD1 G93A (superoxide dismutase-1, glycine 93 to alanine) transgenic mice and age-matched wild type mice. We identify regulatory differences within the apoptosis-bioenergetics-oxidative stress triad between ALS and wild type mice that could contribute to homeostatic instability leading to ALS symptom onset and disease progression.

Title: Zinc and 4-hydroxy-2-nonenal(HNE) released from G93A SOD-1 expressing astrocytes contribute to selective motoneuronal death

Authors: *T.-Y. KIM[1], J. KIM[1], J.-Y. KOH[1,2];
[1]Univ. Ulsan Col., Seoul, Korea, Republic of; [2]Neurol., Asan Med. Ctr., Seoul, Korea, Republic of

Abstract: Several studies have demonstrated that overexpression of ALS-linked human SOD1 mutant genes induces selective motoneuronal death in a non-cell-autonomous manner. For instance, astrocyte-specific expression of SOD1 seems sufficient in producing ALS phenotype in mice. Moreover, Nagai and colleagues showed that astrocytes expressing human G93A SOD1 release unidentified small size toxic factor(s) to kill motor neurons. In the present study, we tried to identify motoneuron-selective toxic factor(s) released from astrocytes. As reported, conditioned medium taken from astrocyte cultures of G93A SOD1 Tg mice (TgACM) selectively injured motoneurons in spinal cord slice cultures in a BAX- dependent manner, but showed no toxic effects on cultured cortical neurons. Consistent with the finding that zinc dyshomeostasis may contribute, TgACM increased free zinc levels in motoneurons. Moreover, addition of 500 uM CaEDTA, a zinc chelator, significantly reduced motoneuronal loss by

TgACM, whereas ZnEDTA that cannot chelate zinc, showed no protective effect. Next, we examined whether TgACM contained higher levels of Zn than control ACM from wild type astrocyte cultures (NTgACM). Free zinc concentrations assessed with a pZn meter were about 450 nM in NTgACM and 490 nM in TgACM. In addition, we found that levels of HNE adducts were also increased in Tg astrocytes and TgACM. Of interest, whereas increasing either free zinc or HNE in NTgACM to levels in TgACM, had little toxic effect on motoneurons, increasing levels of both zinc and HNE to the levels measured in TgACM, produced BAX-dependent selective motoneuronal death in an identical manner as TgACM, suggesting toxic synergism. One possible mechanism of the synergism is via zinc influx through TRPM channels, which are modulated by oxidative stress such as HNE exposure. Consistently, non-specific TRPM channel inhibitors 2-APB and AP18 substantially attenuated the motoneuronal zinc dyshomeostasis and death induced by TgACM or Zn/HNE-added NTgACM. Present results showed that G93A SOD-1 expressing astrocytes may release higher levels of zinc and HNE, which may synergistically act to produce selective death of nearby motoneurons in a BAX-dependent manner.

Title: Non-cell-autonomous effect of membralin-deficiency triggered motor neuron death

Authors: ***L.-L. JIANG**, B. ZHU, D. ZHANG;
Sanford Burnham Prebys Med. Discovery Inst., LA Jolla, CA

Abstract: Membralin, a novel protein with little function being known, was found to be critical for motor neuron survival previously. Here, we show that membralin in astrocytes plays a predominant role in motor neuron survival by using Cre-loxp conditional knockout system. Specific depletion of membralin in astrocytes causes the death in mice around postnatal 22 days as compared to the conventional membralin knockout mice that exhibit motor neuron death symptoms and die around postnatal 5-6 days. Meanwhile, using the co-culture system of mouse motor neurons derived from embryonic stem cells and mouse primary astrocytes, we find the degeneration of motor neurons when culturing with the membralin knockout astrocytes. The conditional medium collected from membralin knockout astrocytes is also toxic to the motor

neurons. Thus, our study reveals that membralin-deficient astrocytes play a predominant role in triggering the death of motor neurons. These findings also demonstrate that membralin-deficient astrocytes can be a good model system to study the non-cell-autonomous effect in triggering motor neuron death.

Title: Two superoxide dismutase prion strains transmitting amyotrophic lateral sclerosis.

Authors: *T. BRANNSTROM[1], E. EKHTIARI BIDHENDI[2], J. BERGH[2], P. ZETTERSTRÖM[2], P. M. ANDERSEN[3], S. L. MARKLUND[2];

Abstract: Amyotrophic lateral sclerosis (ALS) patients and transgenic mice carrying mutant human superoxide dismutase-1 (hSOD1) develop aggregates of unknown significance. Using a novel assay for structural characterization - binary epitope mapping – we have found that two different strains of hSOD1 aggregates, denoted A and B, can arise in mice. Minute amounts of strain A and B hSOD1 aggregate seeds, prepared by centrifugation through a density cushion, were inoculated into lumbar spinal cord of 100-day-old mice carrying a hSOD1 transgene. The mice developed premature signs of ALS and became terminally ill after around 100 days — 200

days earlier than mice which had not been inoculated or were inoculated with a control preparation. Concomitantly, exponentially growing strain A and B hSOD1 aggregations, respectively, propagated rostrally throughout the spinal cord and brain stem. The structures of the A and B strains are widely different, and the disease phenotypes they caused differed regarding aggregation and symptom progression rates, aggregate distributions along the neuraxis, and histopathological pictures. Thus, the hSOD1 aggregate strains are prions and spreading templated aggregation is the core disease mechanism in SOD1-provoked ALS.

Title: A comprehensive approach for efficient monitoring of motor function in als.

Authors: *M. DANCY[1], M. MILLER[2], T. GARRETT[1], S. ELBASIOUNY[1];
[1]Neuroscience, Cell Biol. and Physiol., [2]Wright State Univ., Dayton, OH

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a devastating degenerative disease that affects upper and lower motor neurons causing weakness, paralysis, and eventual death. Survival time for an individual diagnosed with ALS is 3-5 years and currently there is no cure. Research has been conducted in our lab to establish a behavioral data baseline for SOD1-G93A mice and their wild type littermates. Behavioral data has shown significant decreases in motor function and neurological score in SOD1 mice. A significant decline in motor function occurs at Postnatal Day 95 (P95) and progressed to severe motor deficits leading to eventual paralysis and death at P129 on average. Comparatively, their wild type littermates showed no motor deficits or changes in their neurological scores. In addition to establishing a baseline for motor function, motor nerve recordings were completed by measuring Compound Muscle Action Potential (CMAP) amplitude and calculating Motor Unit Number (MUNE). Significant declines in CMAP Amplitude and MUNE score occurred around P70 for SOD1 mice. Similar to previous literature these changes occur at a much earlier age than the functional motor deficits. Interestingly, when comparing the rate of decline for CMAP amplitude, MUNE score and motor function, no significant differences were found. This suggests that motor nerve recordings and behavioral

testing have a similar rate of degradation and could be used interchangeably. Using CMAP or MUNE scores could allow an earlier determination in improvement of motor function among treated animals. Using these techniques improves our understanding of disease progression and how to best measure new therapeutic treatments.

Title: ALS-linked mutant PFN1 affects cellular protein trafficking in motor neurons

Authors: *C. FALLINI, A. W. GIAMPETRUZZI, E. W. DANIELSON, J. E. LANDERS; Neurol., Univ. of Massachusetts Med. Sch. Dept. of Neurol., Worcester, MA

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease specifically affecting cortical and spinal motor neurons. ALS is the most common neuromuscular disease worldwide, with an average age of onset of 55 years and a mean survival of about 3-5 years from the beginning of symptoms. Death due to progressive motor neuron loss and muscle paralysis occurs within 3-5 years from the first symptoms. Although several pathways have been proposed to play a major role in the development of ALS, no consensus has yet emerged on a pathogenic mechanism common to different forms of ALS. Mutations in two cytoskeletal genes, the actin binding protein *profilin 1* (*PFN1*) and the microtubule subunit *α-tubulin 4A* (*TUBA4A*), are associated with familial ALS, which suggests that alterations in the cytoskeleton architecture and dynamics may play an important role in the pathogenesis of ALS. In particular, we hypothesize that disruption to the actin and microtubule cytoskeleton affects multiple pathways, including protein trafficking and mRNA post-transcriptional processing. To explore this hypothesis, we investigated the effects of PFN1 mutations on the localization of ALS-relevant RNA-binding proteins TDP-43 and FUS. Aggregation and nuclear depletion of TDP-43 and other mRNA binding proteins such as FUS is a hallmark of ALS pathology. Our results show that mutant PFN1 leads to increased aggregation of TDP-43 but not FUS. Using quantitative immunofluorescence, we show that mutant PFN1 causes specific defects in the

nucleocytoplasmic distribution of TDP-43 and FUS. Further evidence supports the possibly that these defects may be dependent on the disruption of nuclear transport factors such as Ran and RanGAP1. Together, our results support the hypothesis that alterations to protein trafficking and mRNA post-transcriptional processing represent a common pathogenic mechanism in different forms of ALS.

Title: Cacophony, the type II voltage gated calcium channel, rescues motor defects in a *Drosophila* TDP-43 loss of function ALS model.

Authors: *K. M. LEMBKE[1], C. SCUDDER[2], D. B. MORTON[2];

Abstract: TDP-43 is a nuclear RNA binding protein whose loss of nuclear function is associated with motor neuron disease. In Drosophila, the loss of nuclear function can be modeled by creating Drosophila TDP-43 null animals. The Drosophila ortholog of TDP-43 is called TBPH. Loss of TBPH causes adult lethality and third instar larvae to crawl shorter distances. Mechanically, the TBPH null animals show a 65% decrease in the number of peristaltic waves, a 20% increase in wave failure, and a 200% increase in peristaltic wave time-to-completion. At the neuromuscular junction, TBPH null animals show a loss of patterned motor neuron bursts. Previously published data showed that TBPH null animals have a 50% reduction in protein expression of a type-II voltage gated calcium channel called *cacophony* and restoring the levels of *cacophony* in discreet sets of cells within the central nervous systems could rescue the peripheral and central effects of loss of TBPH. Genetically restoring *cacophony* with the OK6-Gal4 motor neuron driver rescues the crawling behavior, the change in mEPP frequency, and the motor unit burst pattern. It does not, however, rescue the change in mEPP amplitude, suggesting the change in NMJ physiology is not sufficient to cause the crawling defect. Genetically restoring *cacophony* with the R75C05-Gal4 driver also rescues the crawling behavior and motor unit firing, but not the NMJ physiology. The R75C05-Gal4 driver shows restricted expression to

a pair of neurons called AVM001B/2B, which are located centrally in the brain hemispheres and whose activation with TrpA1 drives increased crawling distance and peristaltic wave frequency.

Title: The role of octopamine in syllable-period selective phonotaxis in female cricket Acheta domesticus

Authors: *D. MAGNO, B. A. NAVIA, 49104;
Dept. of Biol., Andrews Univ., Berrien Springs, MI

Abstract: Female crickets respond phonotactically to the calls of conspecific males. This phonotactic response has been reported to be variable and ranges from unselective to rather selective in response to calls with varying syllable periods (30 - 90 ms). Few neurotransmitters have been reported to be influential in modulating behavioral responses. For instance, octopamine, a neurotransmitter common in invertebrates, has been reported to increase aggressive behavior in crickets (Stevenson *et al.* 2005). However, the effects of octopamine on behaviors such as phonotaxis have not been investigated. It has been suggested that the underlying neural network involved in the selective phonotaxis of female crickets is partly based in the prothoracic ganglion. Whether octopamine plays a modulatory role in this network remains undetermined. Preliminary data, however, shows apparent changes in phonotactic behavior as a result of prothoracic nanoinjection of octopamine in female *A. domesticus*. The goal of this study is to determine the effects of octopamine on the phonotactic response of female crickets when exposed to calling songs with varying syllable periods. It is hypothesized that octopamine increases the phonotactic selectiveness of the females to these model calls.

Title: Chelerythrine chloride and its effects on behavioral and physiological responses in female cricket Acheta domesticus

Authors: *B. A. NAVIA, H. SHIN, A. LYNCH, J. STOUT;
Dept. of Biol., Andrews Univ., Berrien Springs, MI

Abstract: Selective phonotaxis by female crickets has been shown to be variable. Mechanisms which underlie such behavioral variability and neuronal plasticity are being studied. Juvenile Hormone III is a neuromodulator that has been shown to increase selectivity in phonotactic behavior of female crickets, narrowing phonotactic choices for syllable periods of the calling songs that most closely resemble the natural call of the male. Similarly, Juvenile Hormone III also increases the decrement of the L3 auditory interneuron in response to calls with syllable periods that fall within the range of those produced by the male. A signaling pathway which activates protein kinase C has been suggested for the action of Juvenile Hormone III. In an attempt to further explore the neuromodulatory pathway of Juvenile Hormone III and its effects on the behavioral and physiological responses of our model, experiments with chelerythrine chloride, a protein kinase C inhibitor have been performed. Results show that chelerythrine chloride reverses the effect of Juvenile Hormone III in the decrementing response of L3. This poster reports on the effect of chelerythrine chloride on both, selective phonotaxis and the decrementing response of the L3 auditory interneuron. Key words: Phonotaxis, Selective processing, L3 auditory neuron, Neuromodulation

Title: Diversity of GABAergic inhibitory impacts on dendritic integration for directional tuning in insect mechanosensory projection neurons.

Authors: *H. OGAWA[1], R. MITANI[2];
[1]Dept. of Biol. Sciences, Fac. of Sci., [2]Biosystems Sci. Course, Grad. Sch. of Life Sci., Hokkaido Univ., Sapporo, Japan

Abstract: Inhibitory inputs have a great effect on sensory tuning in dendritic processing in neurons. In general, soma-targeting inhibitory neuron modulates response gain, and dendrite-targeting inhibitory neuron shifts response level. However, it is still unknown what impact the dendritic location of the inhibitory inputs has upon their contribution to computation underlying the sensory tuning like directional selectivity. To address this question, we used wind-sensitive projection neurons identified as giant interneurons (GIs) in the cricket, because each type of GIs has unique dendritic morphology and distinct response characteristics, which are identical among the individual crickets. The GIs directly receive excitatory synaptic inputs from the sensory afferents of mechanoreceptor neurons having various directional sensitivities. And, some types of GIs also receive pre- and post- synaptic inhibitory inputs from local interneurons. The GIs displays distinct directional selectivity, but neither dendritic distribution of inhibitory input sites nor inhibitory effects on the directional selectivity have been clarified. To illuminate the spatial organization of inhibitory inputs on dendrites and their effects on the directional tuning, we examined effects of pictotoxin (PTX), GABA-A receptor antagonist, on dendritic Ca^{2+} responses to air current from various directions. The PTX application enhanced the Ca^{2+} responses more largely at distal dendritic regions, but the magnitude, distribution, and directional profile of inhibitory effects depended on the type of GIs. The inhibitory inputs have two different impacts on the directional tuning of the Ca^{2+} responses. In GIs 9-2, 10-2, and10-3, the PTX application reduced directional selectivity, while in GI 9-3, the preferred angle of the Ca^{2+} responses was altered by PTX. Furthermore, the decrement of the directional selectivity by PTX was larger in the response at proximal dendrite close to the axon than that at distal regions of dendrites in GI 10-3. On the other hand, the difference of directional preference was prominent in the response at distal region of specific dendritic branch in GI 9-3. These results suggest that inhibitory impacts sharpening the directional selectivity will be received at proximal dendritic regions, and

that inhibitory inputs received on distal regions of specific dendrite effectively alter the preference of directional selectivity.

Title: Acoustic stimulus impacts on directional variability of wind-elicited walking behavior in the cricket

Authors: *M. FUKUTOMI[1], H. OGAWA[2];
[1]Grad. Sch. of Life Sci., [2]Dept. of Biol. Sciences, Fac. of Sci., Hokkaido Univ., Sapporo, Japan

Abstract: Animals exhibit various escape behaviors even in response to the identical triggering stimuli. Direction of the escape response is fluctuated and this directional variability depends on surrounding environment or behavioral state of animals. In goldfish, acute cooling of water surrounding the fish facilitates escape responses towards the aversive stimuli, which results in extend the directional variability of the escape response (Preuss and Faber, 2003). In herrings, schooling fish show less directional variability in their escapes than solitary do (Domenici and Batty, 1997). This contextual modulations of escape response arise from cross-modal interaction between triggering stimulus and contextual stimulus. On the other hand, the directional variability also depends on stimulus angle relative to body axis of the animal. The variance of escape trajectories of the cockroach decreases in response to wind stimuli applied from the posterior directions (Domenici et al., 2008). However, it is unknown what impact the additional context has upon the stimulus-angle-dependency of directional variability. To address this question, we used the crickets *Gryllus bimaculatus* which exhibit escape response to wind stimulus. We have reported that preceding auditory stimulus (10 kHz pure tone) biased walking direction backward in the wind-elicited escape response (Fukutomi et al., 2015). It suggests that cross-modal interaction between the auditory and wind-sensitive systems alters the directional control of the escape response. In this study, we developed an air current stimulator with 8 nozzles arranged at different angles, which allows us to measure the stimulus-angle dependency of the directional variability. To analyze the directionality of the escape response, we calculated walking direction and turn angle measured with the spherical treadmill system (Oe and Ogawa,

2013). The variance of the walking direction in response to the air current from front was larger than that in response to the stimulus from behind. The auditory stimulus reduced this directional variability in response to the frontal stimulus but not affected on the response to the stimulus from behind. In contrast, the auditory stimulus enhanced the variance of the turn angle in response to air current from front. These results demonstrated that the preceding auditory stimulus modulated the directional variability in the wind-elicited escape behavior, and that the cross-modal interaction had different impacts on the walking direction and turn angle. It implies a trade-off between variances of walking direction and turn angle in the escape behavior.

Title: Identification of neural activity in the silkworm moth brain contribute to the odor source search behavior

Authors: *S. SHIGAKI[1], D. KURABAYASHI[2];
[2]Dept. of Systems and Control Engin., [1]Tokyo Inst. of Technol., Tokyo, Japan

Abstract: In this study, we aim to solve odor source search problem, which is known as the engineering challenge, by focusing on insect odor source search ability. Insects are possible to practically solve the problem in a momentarily changing environment. This is equivalent to that they solve the "Exploration vs. Exploitation Dilemma." The online decision-making consists of two fundamental choice: One is "Exploration" and other is "Exploitation." Exploitation is that make the best decision given current information, and exploration is the choice to gather more information. The balance of this weight is very important because exploration and exploitation cannot be run at the same time. Similarly, in the odor source search of insects, it is important to select the exploration and exploitation behavior adaptively according to the situation in order to locate the odor source in an environment that continues to change. We determine the presence or absence of the state depending behavior selection process by the simultaneous measurement of the brain activity and the behavior output.

In this study, we employ a male silkworm moth, *Bombyx mori*, as the model insect. A silkworm moth does not exhibit any voluntary movements including eating and drinking except mating behavior driven by the sexual pheromone. Thereby, a silkworm moth is an insect that is suitable for system identification because input and output relationship is very clear. To identify the brain neural activity that is directly related to the behavior selection, we carried out neural activity in the brain and odor source search behavior simultaneous measurement experiment using the tethered system. We gave the 0.5Hz (duration: 0.2s, interval: 1.8s) pulse odor stimulation to a silkworm moth, and measured behavioral change and brain activity change. In the brain activity measurement, we used 20μm microwire electrode and focused on lateral accessory lobe (LAL) area. Area of LAL plays a very important role in determining the walking direction. From the result of the simultaneous measurement, we observed the LAL neural activity unit corresponding to the forward movement (exploitation) and the turning movement (exploration) that make up odor source search behavior of silkworm moth. Accordingly, behavior switching index based on brain information was acquired and became possible to elucidate the state-depending odor source search behavior based on brain information.

Title: Spatiotemporal calcium waves generated in the excitatory dendrite of an identified visual interneuron in response to looming stimuli

Authors: *Y. ZHU, F. GABBIANI;
Dept. of Neurosci., Baylor Col. of Med., Houston, TX

Abstract: The lobula giant movement detector (LGMD) in the locust is an identified visual interneuron that responds preferentially to objects approaching on a collision course and their two-dimensional simulations on a projection screen, called looming stimuli. It receives retinotopic excitatory synaptic inputs from an entire visual hemifield. How the LGMD neuron integrates these excitatory synaptic inputs spatiotemporally on its extended excitatory dendrite in response to looming stimuli remains largely unknown. To address this question, we performed two-photon calcium imaging of the excitatory dendrite of the LGMD while simultaneously presenting black expanding looming stimuli to the locust eye. Our preliminary data show that as the black edge of the stimulus moves across the receptive field of photoreceptors, it triggers calcium responses in the dendritic regions on the excitatory dendrite of the LGMD to which those photoreceptors project, in agreement with the known retinotopic mapping from the visual field to the LGMD's excitatory dendrite. As the looming stimulus expands on the retina, it triggers a calcium wave on the excitatory dendrite of the LGMD that spreads from a central location towards the surrounding dendritic regions. When the presentation angle of looming stimulus relative to the eye is changed, the central location of the calcium wave also changes accordingly. The observed calcium waves allow to infer the relative timing of activation of various dendritic compartments in response to looming stimuli and to indirectly monitor the membrane potential in these regions.

Title: Parallel encoding of spatial memory and self-motion during navigational decision-making in *Drosophila*

Authors: *H. M. SHIOZAKI, H. KAZAMA;
RIKEN Brain Sci. Inst. - Wako, Wako, Japan

Abstract: Animals navigate the environment by using multiple types of information such as current and past landmark locations and self-motion. In *Drosophila melanogaster*, studies have implicated the existence of neural codes for these navigational cues, but where and how these cues are represented remains unknown partly because recording neural activity in behaving flies is technically challenging and hard to combine with existing navigation tasks requiring memory. Here we developed a memory-guided spatial orientation task that is compatible with neural recording, and show that spatial memory and self-motion are distinctively encoded in complementary regions in the bulb (BU), which is upstream of the central complex (CX), the insect navigation center. Behavioral analyses revealed that head-fixed flies navigate a virtual space based on short-term memory of landmark location. Two-photon calcium imaging during flight revealed that the dorsal part of the BU, a region in the central brain, encodes spatial memory as persistent activity, whereas the ventral part of the BU tracks the self-motion reflecting steering maneuvers. Photolabeling-based circuit tracing demonstrated that these functional compartments of the BU constitute adjacent yet distinct anatomical pathways that co-enter the CX. Thus, the fly's navigation system organizes multiple types of information in parallel channels, which may compactly transmit signals without interference for decision-making during flight.

Title: Increased adult size due to larval royal jelly exposure does not affect climbing or circadian locomotor activity in adult D. melanogaster

Authors: *J. A. SEGGIO, J. A. HICKS, N. F. NASCIMENTO, A. HATZIDIS, N. L. ARRUDA, R. R. GELINEAU, I. DE PINA MONTEIRO;
Biol. Sci., Bridgewater State Univ., Bridgewater, MA

Abstract: Royal jelly (RJ) is the substance that leads to queen differentiation in the honey bee *Apis mellifera*. Queen bees are markedly larger, develop more rapidly, and have significantly longer lifespans than sterile worker bees. The effects of RJ were previously characterized to be conserved in *Drosophila melanogaster*, as rearing *D. melanogaster* in the presence of RJ also increased body size and lifespan of female progeny. This study aims to determine if the increased size due to RJ exposure leads to altered climbing or circadian locomotor activity in D. melanogaster. In both flies and bees, there is some evidence that increased body size can lead to impairments to locomotor activity. Additionally, RJ also seems to improve motor function in mice. *Canton-S Drosophila melanogaster* were raised on 4 mL of instant fly food combined with 10 mL of either 0% (i.e., water) or 20% pure honeybee royal jelly (w/v) through thorough manual mixing. The flies were allowed to mate, and upon confirmation of larvae within the vial, parents were removed. Body length was subsequently measured from eclosed female offspring (approximately two days old). Additionally, multiple vials of virgin flies were made to assess lifespan of these eclosed flies. To assess climbing or vertical locomotor behavior, 10 flies were placed into an empty fly vial with a marked line 6.5 cm from the bottom and allowed to habituate; flies were gently tapped to the bottom of the vial and the percentage of flies above the line was calculated after 30 seconds. Circadian locomotor activity parameters, including overall activity and a bout analysis in both LD and DD was observed by placing adult flies raised on RJ or control media into *Drosophila* Activity Monitors. We were able to replicate the findings of increased body size and increased longevity, which was previously found for *D. melanogaster* raised on royal jelly in other studies. Flies exposed to RJ were able to exhibit entrainment and stable free-running rhythms as well as climbing behavior. In addition, flies raised on 20% RJ showed no differences in climbing behavior or any of the circadian locomotor activity parameters tested in both LD and DD. While adult flies with increased size may show awkward locomotion, the increased size due to RJ exposure has no bearing on locomotor activity patterns both horizontally (circadian activity) and vertically (climbing); thus, RJ may lead to anti-fatigue properties or improved muscle function in *D. melanogaster*, as sometimes seen in some rodent studies.

Title: The dynamics and control of body saccades during object fixation in *Drosophila*

Authors: *J.-M. MONGEAU[1], F. KHAN[2], A. SALOMON[2], M. A. FRYE[2];
[1]Integrative Biol. and Physiol., [2]UCLA, Los Angeles, CA

Abstract: During free flight in flies, body saccades account for the vast majority of the total net change in heading yet little is known about their control. Here, we studied visual fixation of objects in magnetically-tethered *Drosophila* free to rotate about the yaw axis. We hypothesized that flies rely on smooth and saccadic tracking of visual objects. When an object was rotated against a stationary visual landscape, tracking was dominated by sustained bouts of saccades, with little smooth pursuit between saccades. Object-tracking saccades were significantly smaller and slower than spontaneous saccades. The duration, angular amplitude, and peak angular velocity of saccades were tuned to object velocity, which rejects the hypothesis that saccades are reflexive, all-or-none motor actions; instead, saccades are precisely pre-programmed. Saccade dynamics are regulated such that the initial torque generated by the wings is tuned to object velocity while the counter-torque scales with initial torque amplitude. Saccades are triggered when the spatio-temporal integrated error between the object and the fly's heading reaches a fixed threshold. A reduced-order, switched, integrate-and-fire model predicts measured tuning and triggering dynamics. Object tracking saccade dynamics on a moving ground depend upon the ground speed whereas the initial trigger for a saccade depends only on the integrated object error. Collectively, our findings provide evidence that visual fixation in *Drosophila* is enabled by precise control of targeted body saccades. To characterize neural circuits that control saccades, we used 2-photon excitation calcium imaging to determine the response of candidate neural circuits known to implement temporal integration. We recorded the response of Lobula Plate Tangential Cells (Horizontal System) cells to moving objects and found that they do not integrate object error, suggesting instead that more specialized object-sensitive neural circuits integrate error signals.

Title: Multi-timescale analysis of sequential behavior decisions in fly grooming

Authors: P. RAVBAR[1], K. BRANSON[2], *J. H. SIMPSON[1];
[1]Mol. Cell Developmental Biology/ Neurosci. Res. Inst., Univ. of California Santa Barbara, Santa Barbara, CA; [2]HHMI Janelia Res. Campus, Ashburn, VA

Abstract: Common logic and circuit design principles may govern the pattering and production of action sequences. We are exploring fruit fly grooming behavior, which is surprisingly complex and variable. It is an innate sequence composed of individual grooming movements (IGMs), such as head cleaning and leg rubbing, that are grouped into anterior and posterior "motifs". The sequence of motifs is probabilistic while alternations between IGMs within motifs are more determined. Thus there are two distinct time-scales: 1) rapid transition between IGMs and 2) slower alternation between the anterior and posterior motifs. When stimulated by dust, flies groom in an anterior to posterior progression, cleaning high priority body parts e.g. head before lower priority parts e.g. wings. The complex structure of fly grooming behavior presents an opportunity to address some fundamental questions in neuroscience: to what extent are individual decisions about IGMs or motifs driven by external sensory stimuli vs. internal triggering? To what degree does the structure of a motif (e.g. frequency of transitions between IGMs in the motif) predict the structure of the next motif? How is behavior organized with respect to both time scales? To model the grooming sequence with suitable statistical power, we needed to collect and annotate very large amounts of video data. To this end, we developed an automated behavioral recognition system which can quickly and reliably classify IGMs from video with minimal human effort. Our video data was challenging for existing behavior classification systems that require alignment and body part identification because our flies have changing distributions of dust and are freely moving. To circumvent these problems we developed a method based on spatial-temporal features, invariant to animal's position and orientation. We use these features to carry out two steps of unsupervised classification, based on the two time-scales at which the behavior occurs. First we identify the general behavioral context, and then we determine the specific IGMs. We achieve robust and reliable recognition of fly grooming behavior. This strategy of combining of alignment-invariant features and multi-timescale analysis is an algorithm that may be generally useful for movement-based

classification of behavior from video. Here we present: 1) the analysis of hundreds of hours of video of fly grooming behavior to offer a detailed description of moment-to-moment dynamics and an improved descriptive model of this complex and variable behavior. 2) the automated behavior recognition system and how its results compare to manually annotated behavior.

Title: Do flies in groups make individual choices?

Authors: *E. A. GOROSTIZA, I. STEYMANS, B. BREMBS;
Inst. of Zoology - AG Brembs, Univ. Regensburg, Regensburg, Germany

Abstract: In every behavioral population paradigm where groups of animals are being exposed to forced-choice situations, there is the question whether or not the individual animals can be assumed to make their own choices. We approach this hypothesis by testing *Drosophila* fruit flies for their photopreference in a light/dark T-maze. Approximately 75% of a randomly chosen group of wild type flies decide to approach the bright arm of the T-Maze, while the remaining 25% walk into the dark tube. Taking these subgroups of flies and re-testing them revealed a similar 75-25 distribution in each subgroup.
In order to increase the number of choices each subgroup makes without losing too many flies in the process, we used the classic phototaxis experiment developed by Seymour Benzer in the 1960s. In this experiment, flies are exposed to a light source while they are confined in transparent tubes aligned with the direction of light. Each round of the experiment consists of 5 consecutive choices were the animal can either stay or walk towards the light (positive phototaxis). At the end of a round the original group is split into 6 subgroups according to their sequence of choices.
We discovered that while the test/re-test distributions were similar, there was a tendency of the extremely phototactic animals (positive and negative) to skew their distributions towards their respective end.
These results are consistent with observations in single-animals where individual choice probability was discovered to be itself distributed over a population of flies (Kain et al., 2012). To test for potentially confounding effects of general activity and walking speed, we tested individual flies after their phototaxis experiments in Buridan's Paradigm, where flies walk

between two opposing black stripes. We detected small walking speed and general activity differences, suggesting a quantitative interaction between general and light-specific processes contributing to the performance scores in Benzer's phototaxis experiment.

Title: A comparison of speed, grooming and seeking behavior in north and south american cockroaches

Authors: B. D. ORTIZ[1], G. F. TRUJILLO[1], J. F. GOMEZ-MOLINA[2], M. CORREDOR[3], *U. M. RICOY[1];

Abstract: Invertebrates are powerful tools for teaching and research. Conditioned place preference (CPP) continues to be one of the most popular models to study the motivational effects of drugs and non-drug treatments in experimental animals. With the underlying mechanisms strongly conserved in evolution, invertebrates have recently emerged as a powerful new model in addiction research. The purpose of our research is to identify the differences in speed, grooming, drug seeking behavior and CPP of Periplaneta Americana, a North American cockroach (PANC) and Blaptica Discoidalis, a South American cockroach (BDSC) using vanilla and peppermint.
METHODS Adult PANC and BDSC were taken from the lab-maintained colonies. Male last-instar nymphs were taken from the stock colony to the cage and were reared under 12:12 LD regime at 28 ± 1 °C. Cockroaches were transferred into the experimental setup where they were kept for at least two weeks prior to tests. The experiments started in the first half of a dark phase. Water and food were provided ad libitum.10 of each species were placed one at a time in a single

lane of a Plexiglas apparatus with vanilla and peppermint placed at different ends of the apparatus. Each experiment had five conditions in which the contents of the substances as well as the delivery method of the substances were manipulated. Each session was recorded from a top and side view for approximately two minutes; one minute ten second video sessions were analyzed at a later time for the amount of time spent on each side of the apparatus (Drop-Point, Vanilla, and Peppermint). Data obtained was entered into Microsoft Excel for statistical analysis. Behavior was recorded by video camera in two 30 min intervals only in the clean Plexiglas test chamber. In some experiments cockroaches were supplied with octopamine solution 10 min before the start of recording; water was used as a control. Video files were processed frame by frame. Obtained data were transferred to Excel and Matlab for statistical evaluations.

CONCLUSIONS

1. PANC is faster than DBSC. 2. PAN and DBSC prefer vanilla over peppermint. Restricted food and water enhances vanilla preference and peppermint aversion. 3. Octopamine and vanilla modify (increase) grooming behavior in PANC. 4. Grooming behavior when exceeds certain frequency, might follow a different sequence of actions in relation to normal grooming. In the first case, an internal drive for reward balance can compensate disturbances of reward homeostasis due to stressors. Concern about stress reduction is important in order to reduce artifacts and unnecessary suffering in these small animals. A control-engineering approach can be sketched.

Title: Active dendritic conductances generate dynamic neural computation underlying locust predator avoidance

Authors: *R. B. DEWELL[1], F. GABBIANI[1,2];
[1]Dept of Neurosci., Baylor Col. of Med., Houston, TX; [2]Computat. and Applied Mathematics, Rice Univ., Houston, TX

Abstract: Approaching objects produce a characteristic pattern on an observer's retina, expanding outwards from a single point at an increasing rate. Detection of approaching predators relies on discriminating this particular spatio-temporal pattern of retinal activation. In locusts, visual discrimination of approaching predators can be accomplished by a single neuron within each optic lobe. This lobula giant movement detector neuron (LGMD) integrates inputs from every photoreceptor of the ipsilateral eye, following two intermediate processing stages within the lamina and medulla. We used a combination of physiology, behavior, and computational modeling to investigate the role of active conductances within the LGMD of *Schistocerca americana* to better understand the complex, nonlinear computations implemented within this looming sensitive neuron. We found that an h-current selectively increases responses to spatially coherent looming stimuli, while a 4-AP dependent, slowly inactivating K^+ current (IKD) within the LGMD selectively decreases responses to spatially incoherent looming stimuli. How these currents produce this selectivity was investigated with a morphologically accurate, multi-compartmental model of the LGMD within the NEURON simulation environment. With this model we show that this coherence preference depends on the retinotopic arrangement of excitatory synaptic inputs, the temporal patterning of excitatory synaptic inputs, and dynamic interactions between the active conductances. Briefly, prolonged depolarization due to a combination of Ih and appropriately patterned synaptic excitation can initiate a positive feedback loop resulting in K^+ channel inactivation - as IK decreases, greater depolarization occurs, which causes more inactivation. Without Ih or properly patterned excitation, however, the activation of IK produces a negative feedback loop, whereby IK prevents depolarization which prevents K^+ channel inactivation. These competing feedback loops are further influenced by low threshold Ca^{2+} channels and Ca^{2+}-dependent K^+ channels near the spike initiation zone. Physiological data reveals that the LGMD uses these active conductances to discriminate the spatial coherence of approaching objects, and behavioral experiments show that this discrimination is key to initiating escape behavior. The LGMD is an attractive model to investigate the influence of active conductances on the spatio-temporal filtering of synaptic inputs, allowing us to not only investigate the role of active conductances for dendritic integration, but also to ground these data in the context of an ecologically important neural computation.

Title: Investigating a circuit connecting visceral sensory neurons to hormone-producing output neurons in *Drosophila* larvae

Authors: *C. QIAN[1], M. KAPLOW[1,2], J. LEE[1,2], W. B. GRUEBER[1];
[1]Columbia Univ., New York, NY; [2]New York Univ., New York, NY

Abstract: Sensing and adjusting the internal state of the body is critical for tissue and organ homeostasis. We are investigating the neural control of internal state in fruit fly larvae. We have identified a group of internal sensory neurons associated with the airway and present evidence that they express Gustatory Receptor genes that mediate detection of aversive stimuli. We find that these sensory neurons project axons into the central nervous system to target two distinct neuropils. First, axons make en passant connections with peptidergic neurons situated in the ventral nerve cord, and second they terminate in a gustatory center in the brain, the subesophageal zone (SEZ). In the SEZ, we show that the axons terminate in close proximity with primary gustatory neurons that detect aversive/bitter stimuli. Thus, these internal sensory neurons may be functionally similar to aversive/bitter gustatory neurons. We also show that proper targeting of axons in the SEZ requires POU homeodomain transcription factor function. Within the ventral nerve cord, we identified specific neuropeptidergic populations as downstream synaptic targets. Notably, these peptidergic neurons project axons back out to the periphery and likely release peptide hormones into the hemolymph. This system may therefore provide a sensory neuron-peptidergic neuron monosynaptic arc to release a hormonal signal into the body. We will present our progress on testing the physiological function of this circuit in maintaining body homeostasis.

Title: Investigating the influence and regulation of catecholamines on circadian rhythmicity of anti-predator behavior in the orb-weaving spiders.

Authors: *R. J. WILSON, J. B. PRICE, T. C. JONES;
Biol. Sci., East Tennessee State Univ., Johnson City, TN

Abstract: While it is widely assumed that circadian rhythms benefit organisms by allowing them to anticipate changing conditions, only a few studies have directly tested this. Being both predator and prey, orb-weaving spiders offer a novel, tractable model system to test whether circadian rhythms are adaptive due to their variety of temporal foraging strategies across species. Previous work suggests that spiders modulate their aggression/wariness over the 24-cycle and that aggression and wariness are modulated by biogenic amines (neurohormones). In this study, we analyzed temporal changes in catecholamine levels and transcriptional regulation in the orb-weaving spider *Larinioides cornutus*. *L.cornutus* individuals were collected from sites in northeast TN. After a 7-day entrainment period, spider cephalothoraxes were dissected and haemolymph was collected at 4 different time points over a 24-hour cycle. We measured gene transcription levels and neurohormone levels in haemolymph and cephalothoraxes using RNA-sequencing and HPLC-ED, respectively. Levels of catecholamine neurohormones did change over the 24-hour period however, the patterns found were not uniform. Like brain-reward pathways in many other taxa, dopamine levels did rise during foraging periods (nighttime) of *L.cornutus*. In addition, patterns in gene expression further supported the fluctuating patterns of catecholamines.

Title: Movement feedback signal processing in a curve walking stick insect is task and segment specific

Authors: *J. SCHMITZ, M. GRUHN, A. BÜSCHGES;
Univ. of Cologne, Koeln, Germany

Abstract: Walking animals constantly have to adjust their leg movements to a given motor task. Changes during curve walking are generated by specific modifications in the kinematics of each leg on both sides of the animal: a middle outside leg generates large amplitude, longitudinally directed stance movements, whereas the inside leg generates small amplitude stance movements with marked tibial flexion (Gruhn et al., 2009). In a previous study, Hellekes et al. (2012) showed that such task-specificity in leg stepping kinematics is accompanied by differences in the processing of movement-related feedback on both sides of the curve walking animal. Flexion signals from the Femur-Tibia (FTi-) joint, reported by the femoral chordotonal organ (fCO), induce reinforcement of the *Flexor tibiae* activity more often on the inside than on the outside. In the present study, we asked, if 1) different parameters of tibial movement are processed differently between inside or outside steps, and if 2) the same parameters of tibial movement are processed differently during directional stepping.To answer this, we stimulated the middle leg fCO with a large range of stimulus velocities (150-750deg/s), varying amplitudes of FTi-joint movement (40-100deg), and at varying starting angles (70-150deg) while recording tibial motoneuron and muscle activity in curve walking animals.
The frequency of occurrence of reinforcement of tibial motoneuron activity increased with increasing starting angles and decreasing stimulus velocities (cf. Bässler,1988) for both, the inside and outside leg, while it was unaffected by the amplitude of the FTi-joint excursion. The likelihood for the generation of reinforcement of movement for all three modalities was significantly higher during inside compared to outside steps. The highest probability was found to be 70% for the inside leg condition with an FTi-joint movement amplitude of 100deg, a movement velocity of 150deg/s and a starting angle of 150deg (N=11, n=132).
Our results show that the occurrence of movement reinforcement during inside and outside steps caused by fCO flexion signals is in both cases mostly dependent on starting angle and the velocity of the angular movement. However, the thresholds for eliciting the response are drastically lower for the inside leg. It is quite conceivable that during curve stepping such differences in processing of tibial movement signals can support leg kinematics generated on each side. To explore the mechanism behind this difference, we currently perform intracellular recordings from tibial motoneurons and premotor interneurons (cf. Driesang and Büschges, 1996).

Title: Analysis of perceptual mechanisms related to control of travel direction in navigating ants

Authors: *D. D. LENT;
Biol., CSU Fresno, Fresno, CA

Abstract: How do animals successfully navigate and interact with their environment? An insect foraging for food may travel tens of meters. It will encounter local and global visual cues (e.g. trees, horizon) as well as other sensory cues. Yet, as the insect sets out, it cannot know which information is relevant to its return home or return to an as-yet-unfound site. The insect needs neural mechanisms to identify and store relevant information. These mechanisms must be robust against environmental instability or noise (e.g. obscured visual landmarks or changes in lighting). The goal in real world navigation is to maximize stability by combining information about multiple sensory stimuli, contextual cues, motor actions and past experiences. The behavioral output of ants foraging in laboratory settings has revealed a number of visual features used to guide familiar routes. These behaviors have been used to develop image analysis algorithms to extract known visual features that wood ants use for guidance in naturalistic panoramic scenes. In order to investigate how visual cues are extracted and prioritized, a model was created to simulate ant navigation in procedurally generated environments where the visual cues could be precisely characterized. In these computer-simulated environments, the visual perception algorithms were used to examine how different cues were viewed and learned during a single random foraging walk. Following this single bout of foraging and learning, the success of the simulated ant in finding the goal location using the information stored was examined. In addition to the simulated environment, a series of panoramic images from a wooded area, that is similar to the foraging terrain of wood ants and carpenter ants used in the lab, revealed a number of potential guiding features. There were local features such as edges, peaks, and troughs available to guide routes, as well as global features such as scene center of mass and segmented centroids. Progressing over even a short distance produced considerable instability in nearby local features. However, there were several stable features that could be used to provide reliable landmarks to facilitate route learning. These image analysis algorithms can rapidly extract visual information from any scene and provide testable predictions about the reliability and stability of specific visual features within complex, and cluttered panoramic scenes. The results of this data have provided insight into the mechanisms involved in prioritization and perception of visual information. Additionally, it has provided the framework to investigate how memory can be optimized in simple networks and nervous systems.

Title: Behavioral state modulates the inputs to the directionally selective neurons in *Drosophila*

Authors: *S.-T. WU, J. STROTHER, A. NERN, A. WONG, E. ROGERS, M. B. REISER; Hhmi/Janelia Res. Campus, Ashburn, VA

Abstract: Motion detection is critical for animal navigation. Well known computational models predict the structure of circuits required to extract directional selectivity from non-selective signals. These models have motivated the experimental search for the neural basis of directionally selective (DS) circuits, most recently focused on genetic model organisms, such as flies and mice. The components of DS computation (time delays, receptive-field properties, and nonlinearities) are often treated as static properties, and yet several studies in *Drosophila* have shown that active locomotion modulates the response gain of motion-sensitive neurons post-synaptic to the DS cells. Furthermore it has been shown that the neuromodulator octopamine, the invertebrate analog of norepinephrine, plays a crucial role in this behavioral-state-dependent modulation. It is not known whether this modulation acts broadly in the visual system, and whether it affects the DS neurons or their inputs. Here we show that behavioral state modulates the activity of the directionally selective circuit inputs (DSCIs) in the *Drosophila* visual system, and suggest that this modulation is mediated by several octopaminergic feedback neurons (OFNs), that connect a pre-motor center in the central brain, the posterior slope, to the optic lobes. Intriguingly, by using optogenetics and 2-photon calcium imaging, we found that distinct subsets of OFNs produce either an increasing or a decreasing calcium response in a GABAergic DSCI, Mi4. Mi4 neurons play an important role in the detection of ON DS motion, and interconnect with the other excitatory and inhibitory DSCIs in the ON pathway. This result demonstrates that behavioral-state modulation acts upstream of the DS neurons. We also perform behavioral genetic experiments on tethered walking flies to test the role of the OFNs and octopamine receptors expressed in the DSCIs in the contrast and speed sensitivity of fly motion vision.

Title: The behavioral effects of taurine of male crayfish, procambarus clarkii

Authors: *B. N. THOMAS[1], C. M. MECCA[2], R. F. WALDECK[2];
[1]Neurosci., [2]The Univ. of Scranton, Scranton, PA

Abstract: Male crayfish serve as a model for experimentation in behavioral studies. Crayfish have a naturally occurring tendency to engage in aggressive behavior after confrontation with one another. This aggression is shown in a duel, where crayfish actively fight. Fights between males end with a dominant and a submissive male. Afterwards, a submissive male may experience both neural and behavioral changes. Submissive males tend to fight less aggressively after losing. In a number of studies, these behavioral changes leave lasting effects.
In this experiment, six male crayfish, *Procambarus clarkii,* were immersed in a 25 mg/L solution of taurine to determine if fighting behavior was chemically altered with taurine. Taurine is a naturally occurring amino acid that plays a role in neural development. It is also one of the active ingredients found in most energy drinks today. Preliminary data has shown that crayfish under the influence of taurine had increased aggression when fighting. It was hypothesized that taurine would reverse the effects of submissive behavior. In a series of control trials a dominant and submissive crayfish were identified. Afterwards, submissive crayfish were immersed in taurine solution. Though a small sample size was used, results show that those under the influence of taurine had grown more submissive than before. This suggests that taurine either had no effect on the crayfish or increased the submissive behavior in losing crayfish.

Title: Influence of hormonal state on primary chemosensory neurons mediating pheromone reception

Authors: *M. R. MEISELMAN[1], M. E. ADAMS[2];
[1]Cell, Molecular, and Developmental Biol., [2]Neurosci., Univ. of California-Riverside, Riverside, CA

Abstract: Understanding the neuronal wiring that governs has been studied for decades, but how perception can be altered by hormonal context is often overlooked. Here we describe how Ecdysis Triggering Hormone (ETH), originally discovered and characterized for its critical role in ecdysis, plays a post-metamorphosis role as a regulator of courtship behavior during the adult stage. Elimination of ETH through cell ablation or inhibition of vesicular release results in disinhibition of male courtship, as well as complete abolition of the post copulation refractory period. Furthermore, courtship inhibitory neurons GR32A, OR67D, and antennal interneurons, previously implicated in courtship inhibition, express the ETH receptor (ETHR). Cell-specific RNAi knockdown of ETHR results in relief of courtship inhibition, evidenced by increased courtship toward other males and refractory females. Taken together, our findings implicate ETH signaling in regulation of courtship inhibition through stimulation of courtship-inhibitory neurons.

Title: Temporary depletion of microglia early in development has enduring consequences for social and cognitive behaviors

Authors: *J. W. VANRYZIN[1], S. J. YU[2], M. M. MCCARTHY[2];
[2]Dept. of Pharmacol., [1]Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: Microglia are resident immune cells of the brain and function in multiple ways outside their traditional capacity of responding to insult. During development microglia regulate tissue homeostasis, neuronal precursor populations, and synaptic circuitry. We recently implicated microglia as an integral component of sexual differentiation of the preoptic area and control of male copulatory behavior, suggesting these immune cells also function to organize sex-specific brain structure and function (Lenz *et al. J Neurosci* 33(7), 2013). Here, we further investigate the role of microglia in regulating the development of normal brain circuitry and behavior and examine their influence in early postnatal brain development. Using liposomal clodronate (LC), a drug that selectively depletes microglia, we globally depleted microglia from the rat brain for the first few days of postnatal life. Based on comparable techniques reported in the literature, we believe this depletion to be transient, with microglia regrowth occurring within 3 days. Pups of both sexes received either LC or vehicle injections i.c.v. (postnatal day 0, 2, and 4) and then underwent a developmental behavioral battery (postnatal day 5-15), a juvenile behavioral battery (postnatal day 25-33) and adult (> postnatal day 60) behavioral testing for copulatory behaviors. We find that animals whose microglia were depleted display an early hyperlocomotive phenotype indicated by a decreased latency to leave a circular testing arena (treatment x sex interaction, $F(1,370) = 4.481$, $p = 0.035$), and deficits in a two-choice nest seeking task (main effect of treatment, $F(1, 414) = 19.310$, $p = <0.001$, a marker for early social behavior. Moreover, these animals exhibit a pervasive reduction in anxiety-like behaviors with depleted animals spending more time in the center of an open field (main effect of treatment, $F(1, 34) = 7.909$, $p = 0.008$) and more time in the open arms of an elevated plus maze (main effect of treatment, $F(1, 34) = 34.065$, $p = <0.001$). Males whose microglia were temporarily depleted during early postnatal development have significantly impaired sexual behavior as evidenced by fewer mounts (Mann-Whitney $U=7$, $p = 0.007$), fewer intromissions (Mann-Whitney $U=12.5$, $p = 0.032$), and increased latency to mount (Mann-Whitney $U=61.5$, $p = 0.011$) as well as intromit (Mann-Whitney $U=61.5$, $p = 0.011$) compared to males whose microglia remained intact throughout development. Together these data indicate microglia are critical contributors to developmental programming of both sex-dependent and sex-independent juvenile and adult behaviors.

Title: Ghrelin receptor mutation leads to deficits in social behavior & food-seeking behavior in a stressful environment

Authors: *S.-B. PARK[1], A. WILSON[2], M. ELLIS[4], B. WOODSIDE[5], A. ABIZAID[3]; [2]Psychology, [3]Neurosci., [1]Carleton Univ., Ottawa, ON, Canada; [4]Univ. of Ottawa, Ottawa, ON, Canada; [5]Ctr. for the Study of Behavioral Neurobio., Concordia Univ., Montreal, QC, Canada

Abstract: Ghrelin, a gut derived peptide hormone contributes both to energy balance and the stress response. Results of some previous studies using animal models have also suggested that ghrelin has anxiolytic effects although other studies have reported anxiogenic effects of ghrelin. To further explore the role of ghrelin in anxiety behavior we compared ghrelin receptor knock-out (GHSR-KO) mice and their wild-type (WT) counterparts, on a battery of behavioral tests designed to examine different facets of anxiety behavior. Open field and light/dark preference tests were used to measure general anxiety and no significant differences between the GHSR-KO and WT mice were observed in these tests. By contrast, both the latency to approach a palatable food in a novel environment and to approach a strange mouse in the home cage was increased in GHSR-KO mice compared to WT mice. In a subsequent study, the effects of acute blockade of the ghrelin receptor on these measures were examined. The ghrelin antagonist JMV2959 (0.3mg/ml) or saline (0.1ml/10g) were administered i.p. to C57/BL6 before testing. As in the previous study, we observed no effects on the tests of general anxiety but did observe increased latency to approach both food in a novel environment and a strange mouse in the home cage. The aforementioned results of these studies suggest that the anxiolytic effects of ghrelin may be most apparent in tests of goal-directed behavior.

Title: VNO mediated pheromone signals are required for social hierarchy formation in male mice

Authors: *Y. PEN, A. SHAPIRO, T. KIMCHI;
Neurobio., Weizmann Inst. of Sci., Rehovot, Israel

Abstract: The establishment of a dominance hierarchy requires several behavioral characteristics, primarily a demonstration of aggressiveness towards other group members. TrpC2-/- male mice, which are impaired in sensing of pheromones via the vomeronasal organ (VNO), display a massive reduction in their aggression towards conspecific males. The aim of the current research was to assess the role of VNO inputs in the formation of hierarchy in group of male mice, by characterizing the development of social hierarchy in group of wild-type (WT) and mutant (TrpC2-/-) male mice. For this purpose, we employed a novel automated long-term tracking system, which allows us to analyze a large array of social behaviors within mouse colonies, under a semi-natural environment. Our data shows that the hierarchy of WT males usually comprises of two sub-hierarchical levels of a single alpha mouse alongside several submissive individuals, whereas in case of TrpC2-/- males the submissive mice were separated to two sub-groups. We also found that in addition to chasing events, locomotion behaviors such as velocity and running time significantly characterize the dominant males within groups of WT, but not in groups of TrpC2-/-. Interestingly, using a standard odor preference test, we found that naive WT males significantly prefer to check the urine containers derived from dominant mice, but no such preference was detected in TrpC2-/- male mice. To conclude, our results suggest of an important role for VNO-mediated inputs in the regulation of complex social behaviors and hierarchy formation within a group of male mice.

Abstract: Instinctive behaviors such as mating, aggression and predator avoidance are key for the survival and propagation of species. As innate behaviors manifest without prior training, there must be embryonic genetic mechanisms that specify these innate behavioral circuits. Focusing on the medial amygdala (MeA), a major target of olfactory inputs, we sought to elucidate the link between embryonic patterning and innate behaviors. We observed that the MeA progenitor niche at the telencephalic-diencephalic boundary is comprised of distinct progenitor populations differentially marked by the transcription factors *Dbx1* and *Foxp2*. In the post natal MeA, *Dbx1*-derived and Foxp2+ progenitor populations remain segregated and could be further parcellated based on their intrinsic and extrinsic electrophysiological properties and molecular profiles. Furthermore, the *Dbx1*-derived and Foxp2+ populations also differed in their activation patterns during distinct innate behavioral tasks in both lineage-specific and sex-specific manners. Therefore, neuronal subclass parcellation by transcription factor expression predicts behavioral, molecular and electrophysiological specificity.

Title: Whole genome sequencing reveals genetic variants underlying molecular differences in neuroreceptors among free-ranging rhesus macaques

Authors: *M. J. MONTAGUE[1], N. SNYDER-MACKLER[2], S. MADLON-KAY[1], J. E. HORVATH[4], L. J. N. BRENT[5], K. K. WATSON[6], J. H. SKENE[3], M. L. PLATT[1];

NC; [5]Ctr. for Res. in Animal Behaviour, Univ. of Exeter, Exeter, United Kingdom; [6]Inst. for Cognitive Sci., Univ. of Colorado at Boulder, Boulder, CO

Abstract: Evidence suggests that individual variation in social behavior arises from a combination of genetic predispositions and individual experience, yet the underlying biological mechanisms remain poorly understood. One of the hallmark features of autism spectrum disorders is dysfunction in social perception, attention, and interaction. Nonetheless, significant individual variation in these features frustrates diagnoses and challenges the development of effective treatments. Progress lags due to the lack of a suitable animal model, such as a non-human primate model, in which variation in both the underlying genetics and individual experiences generates heterogeneity in social behavior. To address this gap, we have sought to understand the genetic, developmental, and neurobiological contributions to social behavior in the Cayo Santiago (Puerto Rico) population of rhesus macaques (*Macaca mulatta*), which represents a large, free-ranging study sample with a known pedigree and deep phenotype data. Such behavioral and cognitive data, when combined with a catalog of genetic variants, offers comparative insight into human behavioral and psychiatric phenotypes. We hypothesize that genetic variants underlying molecular differences in neuroreceptors are associated with distinct suites of behaviors in this socially complex species. In order to describe the genetic variation, we generated whole genome sequences for 217 individuals using 100bp Illumina paired-end libraries. The population was sequenced to a total genome coverage of 1240X (mean 5.7X per individual), and the reads were then aligned to the rhesus macaque reference genome. With over 99% of the reads mapped to the reference genome assembly, we implemented variant detection and identified over nineteen million single nucleotide variants in the population, including 14,517 that were predicted to alter transcription factor binding sites, transcript splicing sites, or the translated protein sequences. Regarding the latter, amino acid changes were described in dopamine receptors, oxytocin and vasopressin receptors, serotonin transporters, and the opioid receptor, mu-1 (*OPRM1*). We assessed the functional impact of these amino acid changes using computational tools that predict the potential damage of missense genetic mutations, finding neutral, tolerated and deleterious impacts on the receptor and transporter proteins. With long-term implications for disease-related research and comparative population genomics, we posit that particular genetic variants within fundamental neurotransmitter pathways underlie social behavioral differences.

Title: Social modulation of defense behaviors in *Drosophila melanogaster*

Authors: *C. H. FERREIRA, R. ZACARIAS, M. MOITA;
Champalimaud Neurosci. Programme, Champalimaud Ctr. For the Unknown, Lisboa, Portugal

Abstract: Fruit flies respond to threats with defense behavioral responses. When presented with a looming stimulus, a threatening expanding shadow, individual flies typically jump or show in flight escape maneuvers. Recently, our group and others have found that flies exposed to repeated inescapable looming stimuli also run or freeze. These responses are sexually dimorphic, where females are much more likely to freeze than males. Since in rodents freezing is modulated by the social environment, which can either dampen (social 'buffering') or enhance freezing behavior, we decided to study the responses of groups of females flies to recurring unavoidable looming stimuli. In line with recent reports of social regulation of defense behaviors, we show that female flies in groups display substantially less defense responses, both in terms of freezing and running. We aim to further characterize defense behaviors in groups of fruit flies, and to study the underlying mechanisms at the molecular and circuit level.

Title: Dominance rank causally affects personality and glucocorticoid regulation in adult female rhesus macaques

Authors: *J. KOHN[1], N. SNYDER-MACKLER[2,3], L. B. BARREIRO[6], Z. P. JOHNSON[1,7], J. TUNG[4,2,9,5], M. E. WILSON[1,8];

Museums of Kenya, Inst. of Primate Res., Nairobi, Kenya

Abstract: Social inequalities in health and mortality persist worldwide, despite unprecedented improvements in modern medicine. Low social status is frequently associated with heightened exposure to social stressors and altered limbic-hypothalamic-pituitary-adrenal (LHPA) axis regulation, a possible mechanism underlying health disparities. In addition, personality differences can affect how individuals behave in response to social conditions, and thus may aggravate or protect against the effects of low status. Disentangling the relative importance of personality from the effects of the social environment on the LHPA axis has been challenging, since social status may predict aspects of personality, and both can remain stable across the lifespan. To do so here, we took advantage of an animal model for social status and social behavior, the rhesus macaque. By forming new social groups of unfamiliar females we experimentally randomized dominance rank in 45 adult females, allowing us to characterize individual personality and LHPA axis regulation (based on sensitivity to the exogenous glucocorticoid dexamethasone) in each female when she occupied two different dominance ranks. We identified two behavioral characteristics, social desirability and boldness, which were positively correlated with high social status, indicating that some personality dimensions are status-dependent. Social desirability and a third dimension, anxiousness, were both associated with dexamethasone sensitivity in low status females, suggesting that behavioral tendencies may sensitize individuals to the effects of low status on LHPA axis regulation. Finally, we evaluated whether improvements in social status causally affected the LHPA axis. We found that improvements in dominance rank increased dexamethasone-induced acute cortisol suppression and glucocorticoid negative feedback. Our findings indicate that social status causally affects both behavioral tendencies and LHPA axis regulation, and that behavioral tendencies also independently affect LHPA axis regulation. Together, they highlight the importance of considering personality and social status together when investigating their health consequences.

Title: Heterogeneity of serotonergic neuron excitability.

Authors: *B. D. ROOD[1], B. W. OKATY[2], S. M. DYMECKI[2];
[2]Genet., [1]Harvard Med. Sch., Boston, MA

Abstract: Serotonin is an important neuromodulator that regulates a diverse array of homeostatic and behavioral processes, and, not surprisingly, serotonin releasing fibers permeate nearly every region of the brain. The intricate web of serotonergic innervation derives from a relatively small population of neurons (~25,000 in the mouse) in the brainstem. Despite consisting of a modest number of neurons, the serotonergic system is remarkably diverse in terms of the molecular identity and circuit interconnections of individual serotonin neurons. A major goal of our work is to decode the heterogeneity within the serotonin system to identify discrete functional units both to increase our understanding of the biological mechanisms of physiology and behavior and also in an effort to provide insight into the potential for more targeted therapeutics. Here our question is: Do molecularly identified subsets of serotonin neurons have unique biophysical and pharmacological properties based on differential expression of ion channels and ligand activated receptors? To address this question, we are using a recombinase based intersectional strategy in mice to express green-fluorescent protein (GFP) in subsets of serotonin (i.e., Pet1-Flpe expressing) neurons using various Cre drivers. Then we target fluorescently marked cells for use in RNAseq studies to identify transcriptomes or whole cell patch clamp electrophysiology studies to explore physiological and pharmacological properties. Using this strategy, we identified a subset of dopamine responsive serotonin neurons in the dorsal raphe that when silenced increase aggressive behavior. In the median raphe, we identified neurons that differ both in their levels of excitability and in their responsiveness to various neuropeptides. Our data indicate that even within intermingled populations of serotonergic neurons specific functional units with different patterns of excitability and different sensitivity to ligands can be discerned. Our findings bring increasing granularity to our understanding of serotonin neuron identity and shed light on mechanisms of circuit level function. Ultimately, our study of serotonin neuron heterogeneity brings us closer to comprehending the complex role of serotonin in the mammalian brain.

Title: A mutation in the vasopressin gene impacts locomotor and affective behaviors of adolescent rats

Authors: *K. SCHATZ, R. F. KYNE, M. J. PAUL;
Univ. At Buffalo, Buffalo, NY

Abstract: Recent findings have implicated the neuropeptide, arginine vasopressin (AVP), in the regulation of social development. Precisely how AVP acts to influence social development, however, is not understood. We have previously found that adolescent homozygous Brattleboro rats (Hom), which lack AVP due to a mutation in the *Avp* gene, exhibit atypical social development characterized by decreased active social behaviors (e.g., social play and prosocial ultrasonic vocalizations) and increased passive social behaviors (e.g., huddling) compared to their wild type and heterozygous (Het) littermates. In the present experiment, we asked whether this atypical social development of Hom rats was associated with altered social motivation, exploratory behavior, emotional reactivity, or cognitive deficits. Because prenatal and early postnatal environments can impact social development and genotype of Brattleboro mothers (Het vs. Hom) can impact adult behaviors of her offspring, we also assessed the impact of maternal genotype on the development of these behavioral characteristics. Male and female Het and Hom offspring born to Het or Hom mothers (2 x 2 x 2 design) were run through a battery of tests: a social interaction test conducted on postnatal day (P)34 to replicate our original findings; open field and social approach/avoidance tests conducted on P38 to assess locomotor/exploratory behavior and social motivation, respectively; a marble burying test conducted on P42 to assess emotional reactivity; and an object discrimination test conducted on P75 to assess cognition. Preliminary open field analyses show that Hom rats exhibited fewer activity bouts, spent more time inactive, and ventured into the center of the open field fewer times than their Het littermates. In the marble burying test, Hom rats buried fewer marbles than Het rats. When considered together with our previous findings of decreased active and increased passive social behaviors in Hom rats, the present findings suggest that the underlying cause of altered behavioral development in adolescent Hom rats may be a general hypoaroused state. Maternal

genotype also influenced performance in these tests, but effects were often dependent upon sex or genotype and results were not always consistent across experimental measures. The findings in the present experiment suggest that AVP may influence adolescent social development, in part, through its regulation of arousal. Forthcoming analyses of the remaining tests will determine whether AVP also impacts adolescent development through the regulation of social motivation or cognition.

Title: Neural and hormonal mechanisms of cooperative defense in a cichlid fish

Authors: *H. A. HOFMANN[1], C. A. WEITEKAMP[2];
[2]Integrative Biol., [1]Univ. of Texas at Austin, Austin, TX

Abstract: Cooperative behavior is widespread among human and non-human animals. While the evolutionary processes and ecological conditions that promote cooperation are quite well understood, the underlying neural and molecular mechanisms have not been examined in detail. However, without understanding how the brain processes information during cooperative behavior, our knowledge of cognition in the complex social situations individuals often encounter remains limited. Here, we use cooperative territory defense in a cichlid fish to examine neural activity in principal forebrain regions of the vertebrate social decision-making network. Using the African cichlid fish *Astatotilapia burtoni*, a model system in social neuroscience, we first show that upon repeated exposure to a familiar male, levels of aggression, androgens, and cortisol decrease over time. We then demonstrate that a familiar neighbor will engage in cooperative territory defense based on the perceived threat of the intruder. Further, we show that the resident male modulates his behavior dependent on whether help is received from the neighbor. By measuring induction of the immediate-early gene c-Fos, we then identify neural correlates of cooperative behavior in several principal nodes of the Social Decision-Making

network, and specifically within dopaminergic cell populations in the preoptic area. Covariance networks of neural activity, hormone levels, and behavior are strikingly different between male partners, such that the response to a territorial intrusion largely depends on an individual's role in the cooperative situation. Our results provide for the first time insights into the neuromolecular basis of cooperative behavior and add a novel dimension to our understanding of social cognition in general.

Title: Role of the nonapeptides, arginine vasotocin and isotocin, in social behaviour of male Pelvicachromis pulcher

Authors: *J. HOANG, C. SEAVER, P. HURD;
Psychology, Univ. of Alberta, Edmonton, AB, Canada

Abstract: *Pelvicachromis pulcher* is a cichlid fish native to Nigerian freshwater bodies. Male *P. pulcher* display at least three alternative male phenotypes (red, yellow, and blue), each strongly linked with alternative mating tactics. The red morph males will tend towards haremic breeding, while yellow morph males tend towards monogamous breeding or functioning as satellite males. The current experiment looks at the relationship between the male morphs, the expression of sex typical male behavioural traits, and endogenous levels of nonapeptides, arginine vasopressin and isotocin, two hormones known to influence adult social behaviour networks in the pre-optic area of the hypothalamus.

Title: Modulation of PMV activity during social interactions in female mice

Authors: *A. J. DIAS, S. Q. LIMA;
Champalimaud Neurosci. Programme, Champalimaud Fndn., Lisboa, Portugal

Abstract: Choosing a suitable partner with whom to mate is one of the most important decisions an animal has to make during its lifetime. In most species, females are the choosier sex and their decision is influenced by a variety of elements. These include the female's own reproductive state, e.g. whether she is sexually receptive or not, and cues from potential mating partners, e.g. vocalizations and pheromones. In rodents, the activity of several brain areas is modulated during sociosexual behavior. However, the role of each one of those areas and especially how they work together to orchestrate complex behavioral decisions is still largely unknown. Our lab has previously shown that neurons in the ventrolateral region of the ventromedial hypothalamus (VMHvl) of female mice, a region fundamental for the execution of female sexual behavior, are activated during social interactions between conspecifics, with a preference for male-associated stimuli. One of the major input areas to the VMHvl is the ventral portion of the Premammillary Nucleus (PMV). Previous work using immediate early genes has shown that the PMV increases its firing when animals are exposed to soiled-bedding from conspecifics. This suggests that the PMV could play an important role in the neuronal circuitry processing olfactory cues relevant for sexual behavior. Using fiber photometry to measure calcium transients in PMV neurons, we are investigating the activity of this brain region during social and sexual interactions with conspecifics. Preliminary results show that the activity of female PMV neurons is modulated by male, but not female, stimuli.

Title: Sex differences in the endocannabinoid system direct development of the amygdala and impact juvenile social play behavior in the rat

Authors: *K. J. ARGUE, M. M. MCCARTHY;
Pharmacol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: A universal feature of rough-and-tumble juvenile play behavior is the higher frequency and longer duration exhibited by males relative to females. We previously showed that males have a higher endocannabinoid tone than females and that administration of a combined CB1 and CB2 agonist, WIN, on postnatal days 0-3 masculinizes play behavior in females (PNAS 107; 2010). This change in play correlates with a sex difference in the number of BrdU+ cells in the developing amygdala, an important brain region for the sexual differentiation of juvenile play behavior. Females have more BrdU+ cells compared to males and treatment with WIN decreases the number to that of males. We now seek to discern the relative role of CB1 versus CB2 receptor activation in both play behavior and cell genesis in the developing amygdala. Treatment with highly selective agonists for either CB1 (ACEA) or CB2 (GP1a) significantly decreased the number of BrdU+ cells in the medial amygdala of females to levels observed in males (ANOVA $F(3, 80) = 16.76$, $p < 0.001$), but had no impact on subsequent play behavior. Surprisingly, co-administration of ACEA and GP1a masculinized juvenile female play behavior (Kruskal-Wallis$(3,289) = 14.07$, $p < 0.001$) and neonatal co-antagonism of CB1 (AM281) and CB2 (AM630) feminized male play behavior (Kruskal-Wallis$(4,192) = 16.29$, $p = 0.001$), indicating activation of both receptors is required for normal masculinization. Preliminary analysis finds more newly proliferated cells in the female neonatal amygdala that contain both CB1 and CB2 receptors (t test $t(7) = 2.264$, $p < 0.05$). Despite reports that CB2 is not detected in the brain, our immunohistochemical analysis demonstrated CB2 co-localization on neurons, astrocytes, and microglia in the developing and adult amygdala, and quantitative PCR detected expression of CB2 in the amygdala throughout the lifespan. Preliminary data suggest neonatal CB2 agonism may alter neuronal morphology in juveniles. We are currently validating the presence of CB2 in the brain using a transgenic CB2 knockout mouse to replicate immunohistochemical and PCR findings, and utilizing a peripheral endocannabinoid receptor agonist (CB13) that does not cross the BBB to verify that endocannabinoids alter juvenile play behavior through a central mechanism.

Title: The insular cortex is necessary for social affective behavior in rat

Authors: *M. M. ROGERS, K. B. GRIBBONS, M. T. MCGOEY, J. A. VARELA, J. P. CHRISTIANSON;
Dept. of Psychology, Boston Col., Chestnut Hill, MA

Abstract: Numerous psychiatric conditions including autism and schizophrenia are characterized by aberrant social cognition. An elementary component of social cognition is the ability to detect the emotional state of another individual, termed social affect. Social affect gives way to more sophisticated faculties including empathic helping and perspective taking. We introduce a rodent Social Affective Preference (SAP) test in which an adult male rat is presented with a pair of unfamiliar male juvenile (PN 28) conspecifics, one of which is exposed to stress (2 brief footshocks) and the other naïve to treatment. Social affect is evident in the adult male rat's preference to interact with the stressed juvenile. The insular cortex (IC) is a site of multisensory integration positioned to process social affect and so IC is implicated in both healthy and disordered social cognition. To test the role of IC in the SAP test, we inactivated the IC by bilateral injection of muscimol (50ng/side) prior to testing and optogenetic silencing of IC projection neurons with halorhodopsin (CamKII-eNpHr3.0). Both manipulations abolished the preference for the stressed juvenile. Moreover, intra-insula inhibition of the Protein Kinase C (PKC) signaling cascade by Gö-6893 (500ng/side) prevented social affective preference. Ongoing experiments will determine the effect of conspecific age (juvenile or post-pubescent) on SAP behavior. These data suggest that the insular cortex is critical for the display of elementary social affective behavior in rats.

Title: Social exposure robustly enhances the modulation of oxytocin-sensitive reward pathways by a melanocortin agonist

Authors: *K. A. KITTELBERGER[1,2,3], H. WALUM[1,2,3], L. J. YOUNG[1,2,3];
[1]Emory Univ., Atlanta, GA; [2]Silvio O. Conte Ctr. for Oxytocin and Social Cognition, Atlanta, GA; [3]Yerkes Natl. Primate Ctr., Atlanta, GA

Abstract: Oxytocin (OT) enhances several aspects of social cognition and the OT system is an important therapeutic target for improving social function in disorders such as autism. Melanocortin 4 receptor (MC4R) agonists stimulate local release of OT in the hypothalamus and potentiate OT release in distal target brain areas in response to a physiological stimulus. Both OT and MC4R agonists rescue social deficits in mouse models of autism and facilitate partner preferences in socially monogamous prairie voles. In the absence of social exposure, Melanotan II (MTII), a selective MC4R agonist, enhances Fos activation in OT neurons, but only evokes detectable OT release in the nucleus accumbens (NAcc) in response to hypertonic saline. Given this priming effect of MTII, we predict that MTII will enhance OT release in response to social exposure, thereby modulating neural activity of OT-sensitive brain regions mediating social behaviors, including NAcc and prefrontal cortex (PFC). We used Fos immunohistochemistry (IHC) to assess neural activity in female prairie voles in response to central infusion of MTII in two contexts, MTII alone and MTII with exposure to a novel stimulus male. First, ICV MTII (3nmol, 2μL) or aCSF (vehicle control, 2μL) was administered to adult female prairie voles, followed by immediate return to an empty homecage. Ninety minutes later animals were perfused and brains were processed for Fos IHC. In this condition, central MTII infusion resulted in a significant increase in Fos positive cells in the basolateral and central amygdala (BLA and CeA, $p < 0.001$). No differences were observed in the NAcc, PFC, lateral septum (LS), medial amygdala (MeA), or paraventricular nucleus of the hypothalamus (PVN). In the second condition, females receiving the same treatments as above received 30 minutes of social contact

with a novel stimulus male and brains were collected 90 minutes after the initial social exposure. In the social contact condition, MTII resulted in a significant increase in Fos positive cells, compared to aCSF, in the BLA and CeA, as before, but also in the NAcc, LS and PFC ($p < 0.001$), regions known to be involved in social attachment. Thus social contact, a presumed facilitator of central OT release, changes neural activation in the pair bonding network in response to MC4R stimulation. Future experiments will determine whether OT receptor signaling is necessary for the interaction of MTII and social exposure in these brain regions. These findings have important implications for ongoing clinical studies examining the efficacy of a MC4R agonist in enhancing OT-dependent social cognition in autistic populations.

Title: Anxiety-like behavior and neurochemical expression in male and female prairie voles: the effects of stress and social buffering

Authors: *M. L. DONOVAN, Y. LIU, Z. WANG;
Psychology, Florida State Univ., Tallahassee, FL

Abstract: Social bonds are a critical aspect of human health – strong social support systems can lessen a wide variety of negative health outcomes. This effect, defined as 'social buffering', has been demonstrated in various studies examining different health factors. One focus of the research has been on the impacts of social buffering after a stressful experience. For example, recent studies using the socially monogamous prairie vole (*Microtus ochrogaster*) have shown that reuniting with a bonded partner after a stressor can reduce behavioral and hormonal stress responses; such effects are mediated by the neuropeptide oxytocin (OT) in the brain (Smith & Wang 2014; Burkett et al. 2016). We have been conducting a study using the prairie vole model to examine whether the presence of the bonded partner during a stressful event can reduce stress responses. We are focusing on potential sex differences in social buffering effects on the stress

response as well as correlative changes in neurochemical expression in selected brain areas. Adult female and male voles were paired with an opposite sex mate for two weeks to establish a stable pair bond. Subjects then experienced a 1-hr immobilization stressor either alone or with their partner, followed by a 5-min elevated plus maze (EPM) test to measure their anxiety-like behavior. Our data indicate that when the partner was present during the stressor, subjects spent more time in open arms of the EPM compared to voles stressed alone. These results indicate a social buffering effect from the partner on stress-induced anxiety-like behavior. Interestingly, this social buffering effect seems to be sex-specific – a significant social buffering effect was found in males but not in females. We are in the process of measuring protein expression of several neurochemicals including OT, vasopressin (AVP), corticotropin-releasing hormone (CRH), and brain-derived neurotrophic factor (BDNF), as well as OT receptor (OTR), AVP 1a receptor (V1aR), CRH receptors (CRHR1, CRHR2), and BDNF receptor (TrkB) in several brain regions associated with stress responses and social buffering.

Title: Restricted high fat diet can improve social avoidance induced by social-defeat stress as same as ad libitum high fat feeding

Authors: *A. OTSUKA[1], T. SHIUCHI[2], S. CHIKAHISA[2], H. SEI[2];
[1]Dept. of integrative physiology, Tokushima Univ., Tokushima City, Japan; [2]Dept. of integrative physiology, Tokushima Univ., Tokushima, Japan

Abstract: Exposure of psycho-social stress is one of the important risk factor for depressionAs previously announced intake of comfortable foods, such as high-fat diet, improve depressive behavior. However, to continue to eat comfortable food induces excess body weight gain, and leads to be obesity. Social-defeat stress (SDS) model is one of famous paradigm for psycho-social stress in human simulant. Rodents exposed to SDS show a variety of behavioral changes, including social avoidance.In this study, we determined whether restricted high-fat diet which did not affect body weight was able to improve social avoidance induced by SDS, and investigated its mechanism. Male C57BL/6J mice were attacked by retired ICR mice for 2.5 min

every day. One group was given high fat diet (60% kcal) as a comfortable food for 2 hours (HF); another group was given high fat diet ad libitum (HFA). Ten days later, we performed behavioral tests and checked the effect of high fat diet on psycho-social behavior in SDS-exposure mice. SDS-exposure mice showed social avoidance, compared to non-stressed control group. Ad libitum feeding of high fat diet improved this negative social behavior with increase of body weight whereas restricted high fat diet feeding showed similar improvement of social interaction without change of body weight. SDS-exposure mice showed higher plasma corticosterone concentration and adrenal gland weight than those of control group. Adrenal gland weight was decreased by both high fat diets feeding without decreasing plasma corticosterone level. Interestingly, mRNA level of CRH was elevated in hypothalamus in SDS-exposed HF and HFA groups, although it wasn't elevated SDS-exposure only. Additionally, mRNA level of TRH was also elevated in amygdala, which had sensitive for fear, in SDS-exposed HF and HFA groups. These results suggest that restricted high fat diet feeding, which makes no change of body weight and body composition, is enough to improve social avoidance in SDS-exposure mice. Moreover, the expression of CRH in the hypothalamus and TRH in the amygdala may affect the high fat diet-induced improvement of social activity in SDS-exposure mice.

Title: Sex-dependent effects of arginine vasopressin on Richardson's ground squirrel social behavior and communication

Authors: *A. FREEMAN[1], J. F. HARE[2], W. G. ANDERSON[2], H. K. CALDWELL[1,3]; [1]Biol. Sci., Kent State Univ. Dept. of Biol. Sci., Kent, OH; [2]Dept. of Biol. Sci., Univ. of Manitoba, Winnipeg, MB, Canada; [3]Sch. of Biomed. Sci., Kent State Univ., Kent, OH

Abstract: In nearly every vertebrate taxa arginine vasopressin (Avp) and its homologues modulate behavior, and thus provide an elegant system for comparative research. In rodents, Avp is best known for its modulation of social behavior, in particular affiliative behaviors such as grooming and sniffing, the formation of social bonds and memories, and social communication (e.g. ultrasonic vocalizations in mice). However, research on Avp's effects on behavior have been limited to laboratory models and a few experiments using large outdoor enclosures. To evaluate the role of Avp in the modulation of social behavior and communication in an ecologically-valid context, we examined the effects of Avp on behavior in a wild, free-living rodent. Richardson's ground squirrels (*Urocitellus richardsonii*) are social rodents in which alarm calling constitutes a proximate manifestation of sociality. Therefore, to test the hypothesis that Avp influences social behavior and communication, we implanted osmotic minipumps into Richardson's ground squirrels and administered Avp or saline intracerebroventricularly. To test our hypothesis we used three different behavioral experiments, each before and after Avp or saline administration: a general behavior survey, a predator model presentation, and a social challenge experiment. In males, Avp administration increased the propensity for males to vocalize when approached by a conspecific, but not when exposed to our predator model. Avp-treated females exhibited fewer whistle-type vocalizations with conspecifics compared to saline-treated females. In males, social aggression decreased, but predator vigilance increased with Avp administration. Finally, Avp-treated females showed fewer 'anxiety-like' behaviors during the social challenge test. Our sex-specific responses could be due to differential expression of Avp receptors or seasonal effects, since females were raising young and males had completed breeding. Avp's observed effects may be due in part to our species' life history, or species-specific interactions with particular neural substrates. Our discovery of Avp's effects on ground squirrel social behavior highlights Avp's extensive influence on social behaviors in a variety of species.

Title: A prolonged inflammatory response in the cerebellum of rats treated with lipopolysaccharides at 2 weeks of age

Authors: *C. L. WRIGHT[1,2], M. M. MCCARTHY[1,2];
[1]Pharmacol., Univ. of Maryland, Baltimore, MD; [2]Program in Neurosci., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Early life inflammation is the most prevalent environmental risk factor for developing neuropsychiatric disorders. In individuals with Autism Spectrum Disorders and in animal models of the disorder, the development of the cerebellum is unfailingly abnormal. Abnormalities include deficits in Purkinje cell number, prolonged activation of microglia and elevated cytokines. We have identified a critical period of rat cerebellar development during the 2nd postnatal week whereby exposure to lipopolysaccharides (LPS) to induce inflammation triggers PGE2 production which then causes local estradiol synthesis. Excess estradiol blunts the outgrowth of Purkinje cell dendrites of both males and females that week. Yet, when animals exposed to week 2 inflammation are assessed behaviorally later in life, only males exhibit deficits in behavior, particularly a reduction in juvenile social play. No deficits in motor behavior are observed in either sex. The inability of females to show deficits in social play is likely not due to a basement effect, as conditions in which female play can drop further have been identified (Argue & McCarthy, Biol. Sex Dif. 2015). Thus, it remains to be determined whether there is a mismatch between the behavioral and neuronal phenotypes at later ages across sex or whether females have some compensatory mechanism that restores Purkinje cell morphology to normal after the initial week 2 inflammatory insult. To that end, animals treated week 2 with LPS were assessed for cerebellar elevations in mRNA for cytokines, inflammatory mediators, and proxy markers for types of cells. Not only is IL-1β mRNA higher in males (F_{sex}=10.83 p=0.002) and with LPS treatment (F_{lps}=39.82, p<0.001), but CD11B, a marker for microglia, is also higher after LPS treatment (F_{lps}=23.3, p<0.001). TNF-α levels are also higher in males (F_{sex}=12.35 p=0.001). In contrast, IL-6 levels are higher in females (F_{sex}=4.33 p=0.041) and are also lower in LPS-treated animals (F_{lps}=13.23, p<0.001). COX-2 levels are higher in LPS-treated males compared to either vehicle treated males or LPS-treated females (F_{int}=5.57 p=0.002). When CD11B levels are modeled with a step-wise automatic linear regression algorithm, its levels are best predicted by IL-1β mRNA levels (p<0.001), LPS exposure (p<0.001), and levels of COX-1 (p<0.001), aromatase (p=0.026) and COX-2 (p=0.1) in that order. Ongoing morphological reconstruction of Golgi-Cox impregnated Purkinje cells of juvenile males and females treated week 2 with LPS will also be presented. The potential still exists for a prolonged neuroinflammatory response that is sex specific and triggered by week 2 developmental pathways of the cerebellum.

Title: Increased glucocorticoid receptor activity in the medial prefrontal cortex prevents the expression of empathy in mice

Authors: *L. J. MARTIN[1], S. SIVASELVAACHANDRAN[2], S. ABDALLAH[2], C. CHO[2], A. CHANDIRAMOHAN[2], S. TOHYAMA[2], F. SETAK[2];
[1]Univ. of Toronto, Mississauga, ON, Canada; [2]Univ. of Toronto Mississauga, Mississauga, ON, Canada

Abstract: The relationship status between individuals is known to modulate pain behaviors in many different species. We have recently reported that an increased stress response precludes the expression of rodent empathy in unfamiliar conspecifics–a mechanism likely dependent on glucocorticoid (GR) and mineralcorticoid (MR) receptors. Here, we sought to uncover the neurobiological mechanisms by which stress prevents empathy using a rodent model and pain as a stimulus. Mice were habituated for 30 min to a Plexiglas cylinder in either pairs (cage-mates or strangers) or in isolation. Following the habituation period mice received a single intraperitoneal injection of 0.9% acetic acid and the number of abdominal constrictions was recorded for 30 min in order to assess nociceptive sensitivity. Immediately following the 30 min observational period, mice were sacrificed and their brains removed. The brain was then microdissected and brain areas known to be involved with empathy were isolated (medial prefrontal cortex (mPFC), anterior cingulate cortex (ACC)) and amygdala. We then determined whether glucocorticoid receptor phosphorylation was altered in mice that do not engage in empathy behaviours. We did not find glucocorticoid receptor changes in the ACC, PVN or BNST. However, there was a significant upregulation of glucocorticoid receptors in the mPFC of unfamiliar mice (i.e., those that do not express empathy) compared with familiar mice and isolated controls. Pre-treatment with metyrapone, an inhibitor of the corticosterone/stress response reduced the phosphorylation of GRs in the mPFC and amygdala, while increasing the "empathy" response in unfamiliar mice. We suspect that an increased stress response prevents the expression of rodent empathy in unfamiliar mice by through a mechanism that involves glucocorticoid receptor activity in a mPFC/amygdala circuit.

Title: Neuromolecular mechanisms of learning in a social dominance hierarchy

Authors: *M. RODRIGUEZ SANTIAGO[1], L. A. JORDAN[2], H. A. HOFMANN[3];
[1]Inst. for Neurosci., Univ. of Texas At Austin, Austin, TX; [2]Dept. of Collective Behavior, Max Plack Inst. for Ornithology, Konstanz, Germany; [3]Dept. of Integrative Biol., Univ. of Texas at Austin, Austin, TX

Abstract: The social context in which animals find themselves can greatly influence their behavior, learning, and decision-making. Social learning, the acquisition of information about the environment through direct or indirect observation of others, is one of the primary processes by which the social context can affect subsequent behavior. Aggressive interactions in a social group often result in dominance hierarchies that strongly influences how individuals perceive and acquire information. While there is a good understanding of emergent properties of social influence in animal groups, and studies examining learning mechanisms at the individual level are common, the mechanisms by which social learning is translated into neural plasticity and memory have not been studied in much detail. Here we examined how dominance and aggression influences learning of an associative task by group members. Using the African cichlid fish *Astatotilapia burtoni*, a model system in social neuroscience, we first show that the presence of a demonstrator individual enhances social group learning in comparison to groups of all naïve animals as well as those trained individually, and this depends on the agonistic efficiency of these demonstrators. To gain insight into the neural substrates that mediate social learning, we analyzed the induction of the immediate-early gene c-Fos in candidate brain regions known to play a role in social behavior or learning and memory. Our results show that the aggressive behavior of dominant and subordinate male demonstrators has a marked effect on group learning. Independent of demonstrator rank, expression of c-Fos in pallial area Dm-1 (putative homolog of the mammalian basolateral amygdala, which is important for processing

fearful stimuli) was lower in groups that successfully learned the task, while c-Fos expression was higher in the Dlg (putative homolog of the mammalian hippocampus) in groups that acquired the association. Dopaminergic activity was also higher in area Vc (putative homolog of the mammalian striatum, a region associated with motivation and reward) in groups that learned the task. These results provide fundamental insights into the behavioral and neural mechanisms underlying social learning in animal groups.

Title: The impact of aging on sexual dimorphism in social and odor preference behavior in mice

Authors: *H.-W. TSAI, C. CHAO, M. E. REYES, B. HUYNH, C. NWEKE, Z. AFZAL; Dept. of Biol. Sci., California State University, Long Beach, Long Beach, CA

Abstract: Whereas various cognitive and behavioral dysfunctions have been reported in old mice, relatively little is known about the effect of aging on sex differences in social behaviors. To address this, we investigated social and odor preference behaviors in male and female C57BL/6J mice at 3-18 months of age. To measure sociability, each subject mouse was placed in an open arena and scored for the time spent on investigating a wire-mesh cage containing an unfamiliar male or female conspecific (a stimulus) and an empty cage. Meanwhile, these animals were also evaluated for the olfactory preference for female-soiled, male-soiled, or clean bedding. Both behavioral tests were performed every 3 months from young adulthood to old age. First, we observed that male and female mice displayed normal sociability with spending more time investigating and interacting with the stimulus mouse than the empty cage, associated with an olfactory preference for soiled bedding over clean bedding. Interestingly, in the presence of a female, not male, stimulus, young, male subjects not only were more investigative to explore both cages, but also displayed a stronger preference for the stimulus than females of the same ages, suggesting that the sex of the stimulus mouse might be an important cue for eliciting sexual dimorphism in social approach behavior. The males also showed a preference for female-soiled bedding over male-soiled bedding while females spent equal amounts of time investigating each soiled bedding. As age advanced, male and female mice became less investigative in sociability,

and the male-biased increase in exploration and preference of a stimulus declined. These changes coincided with a decrease in soiled bedding investigation in males at 15 and 18 months of age and diminished preference for female-soiled bedding by 12 months of age. Our findings strongly suggest that the process of aging interplays with gender in the control of social and odor preference behavior. This model will be used for future studies to investigate molecular and neural mechanisms that regulate the development and function of dimorphic brain structures and circuits underlying social behaviors between the sexes as well as behavioral changes induced by aging.

Title: A naturalistic paradigm to study social learning among rhesus macaques in the laboratory

Authors: *K. M. SHARIKA, M. PLATT;
Dept. of Neurosci., Univ. of Pennsylvania, Philadelphia, PA

Abstract: In our day to day lives, we often depend on others' opinions and perspectives to help us make our own choices. This is particularly true for situations that are novel to us but probably not so much to more experienced others. How does our brain rely on socially acquired information to make individual decisions with uncertain outcomes? To address this, we proceeded to develop a naturalistic task for rhesus macaques that would examine their decision-making about a novel food item with vs. without their observation of a conspecific's preferences for the same. In the demonstration phase of the task, we presented monkeys brightly colored pearls made of edible gel which were either sweet or bitter tasting while an 'observer' monkey looked on. In the test phase of the task, we examined if the observer monkey relied on the demonstrator's preferences to make choices about pearls it had not tasted itself. To further validate the robustness of this paradigm against causal experimental manipulations, we tested the effect of inhaled oxytocin - associated with decreased vigilance among macaques in the past - on

the observer's social learning and subsequent decision-making. Our preliminary results suggest that observer monkeys tend to make associations about the desirability of novel pearls based on demonstrator's preferences.

Title: Voluntary exercise ameliorates the expression of neurofilament and myelin basic protein due to androgen receptor antagonist in the mouse brain

Authors: *Y. MOMOTA;
Dept. of Hlth. Sci., Akita, Japan

Abstract: *Introduction:* exercise-dependent brain plasticity has been known to increase the structural proteins like neurofilaments and synaptophysin. Neurosteroids are now widely accepted to have many benefical and protective effect in nervous system. Here it was examined the relevance of voluntary exercise and need of androgen receptor activation. *Methods:*Male mice were divided into wheel running exercise (E group) or non-exercise (N) group.For inhibition of androgen receptor activation, flutamide was used as its antagonist. Each group (N and E) was treated with flutamide(D) or vehicle (V).Experimental four groups were shortly described as NV, ND, EV and ED. Dosage of the drug was 20mg per body weight(kg) every day for 8 weeks. Animals in EV or NV were set in cages equipped with running wheel every second day for 8 weeks. In last three days, the ability of postural stability and passive avoidance were confirmed.Postural stability was assessed by staying time upona thin rod. after this assessment, mice were dropped off quickly from the rod into water bowl. Next day, the same postural stabilitytest was performed for estimation of learning ability of passive avoidance.Later all mouse was anesthetized and perfused with 4% paraformaldehyde. Immunohistochemistry was done for detection of MBP and neurofilament (H type). *Results:* Body weight did not significantly change by flutamide, however, was significantly decreased by wheel running. From the postural stability test, the staying time was significantly longer in EV and ED groups while from the passive avoidance test the time was not significantly changed between groups.The immunoreactivity of neurofilament and MBP was detected stronger in EV >NV > ED > ND in descending order. *Discussions:* The dose of flutamide evoked neither significant change in body weight nor the learning ability aganst the aversive stimulus. Daily voluntary exercise improved

the performance of postural activity (possibly the strengthen in fore or hind limb muscles). The physical activity would induce the expression of neurofilament and MBP in motor and somatosensory cortex areas. Flutamide elicited the obvious decrease in immunoreactivity of the proteins in those areas especially without voluntary exercise. Therefore, physical exercises might regulate the exression of neurofilament and MBP in the cortex possibly through an activity dependent way under normal androgen action.

Title: Acute estrogen receptor beta activation in the hippocampus affects anxiety differentially in male and female rats

Authors: *S. M. SATO, J. ZHANG, E. G. ZBLEWSKI, K. M. MCFADDEN, C. S. WOOLLEY;
Neurobio., Northwestern Univ., Evanston, IL

Abstract: The prevalence of affective disorders, including anxiety disorders, differs by sex, but the reasons for this are unclear. One possibility is that the neural circuitry involved in anxiety responds differently to specific neuromodulators in each sex. Neurosteroid estrogens are good candidates for sex-dependent modulation related to anxiety: Estrogen receptor (ER) β agonists infused into the hippocampus are reported to be acutely anxiolytic in females, and we have found that ERβ agonists activate distinct pre- versus postsynaptic mechanisms in the hippocampus of males versus females. Therefore, to investigate possible sex differences in acute ERβ-dependent regulation of anxiety, we tested how the ERβ agonist, DPN, infused bilaterally into the dorsal hippocampus of adult gonadectomized male and female rats affects anxiety-related behaviors 20 min later. We used a battery of five tests, including tests that are more and less dependent on locomotor activity: open field (OF), elevated plus maze (EPM), and light-dark (L-D) box tests are heavily dependent on locomotion, whereas defensive-burying (DB) and novelty-induced hypophasia (NIH) depend less on locomotion. The results showed that, compared to vehicle, DPN reduced anxiety in the majority of tests in females, whereas it was either ineffective or slightly anxiogenic in males. In females, DPN significantly decreased time spent and distance

traveled in the center of an OF testing arena ($t_{16}=3.00$, $p<0.01$ and $t_{16}=2.17$, $p<0.05$, respectively), without affecting total locomotion. DPN was also anxiolytic in the L-D box in females, evidenced by more time spent on the light side ($t_{14}=2.37$, $p<0.05$) and a higher number of L-D transitions ($t_{14}=2.69$, $p<0.05$). In the DB test, DPN was anxiolytic in females, in that it significantly reduced the time spent burying a shock probe ($t_{16}=3.11$, $p<0.01$). No effects of DPN were observed in females in the EPM or NIH tests. In males, there were no effects of DPN in OF, DB, or NIH tests. DPN was slightly anxiogenic in the L-D box in males, significantly reducing L-D transitions ($t_{11}=2.64$, $p<0.05$). Preliminary results in the EPM suggest that DPN also reduces time spent and distance traveled on the open arms in males, an indication of increased anxiety. These results demonstrate that sex differences in acute ERβ-dependent neuromodulation in the hippocampus are paralleled by sex differences in the acute effects of ERβ activation in the hippocampus on anxiety-related behaviors. Thus, the possibility of sex-specific effects should be considered in any future development therapeutics based on ERβ modulation.

Title: A behavioral and molecular analysis of membrane-initiated estrogen receptor signaling in the hypothalamus

Authors: *M. BUTLER, L. NIKONOVA, R. HILDEBRANDT, L. ECKEL;
Psychology, Florida State Univ., Tallahassee, FL

Abstract: A growing literature supports the involvement of membrane-bound estrogen receptors (mERs) in mediating many of estradiol's (E2's) behavioral effects. Thus, our group has begun to investigate the involvement of two mERs, the G protein-coupled estrogen receptor (GPER) and mERα, in the estrogenic control of food intake. We have shown that activation of GPER or ERα alone decreases food intake in ovariectomized (OVX) rats within 1 h of drug treatment. Based on

evidence that GPER may facilitate ERα signaling at the membrane, we investigated whether GPER plays a role in mediating the rapid (within 1 h) anorexigenic effect of the ERα agonist PPT. OVX rats (n=8) were injected with PPT (50μg) or vehicle 30 min following pretreatment with the GPER antagonist G-36 (10μg) or vehicle. Food intake was monitored for 4 h after drug treatment. The lack of GPER signaling blocked PPT's anorexigenic effect during the first 2-h of chow access ($p<0.05$), suggesting that GPER plays a critical role in mediating ERα-dependent rapid decreases in food intake. To investigate the underlying cellular mechanism, we conducted a second study in which OVX rats (n=12) were euthanized 30-min after injection of the GPER agonist G-1 (0.5μg) or vehicle. The arcuate nucleus (Arc) was dissected and processed via western blot for detection of STAT3 and phosphorylated STAT3 (pSTAT3). We targeted STAT3 based on studies showing that GPER activates the JAK-STAT signaling pathway *in vitro*. Rats treated with G-1 had increased pSTAT3 protein in the Arc relative to controls ($p<0.05$). Additionally, we utilized a hypothalamic proopiomelanocortin (POMC) cell line to investigate the cell-specificity of E2-induced STAT3 activation. Five min following 10 nM E2 exposure, POMC cells were lysed and processed via western blot for STAT3 and pSTAT3. Preliminary data suggest that E2 increased pSTAT3 in POMC neurons relative to vehicle. Taken together, these data provide the first evidence that E2's anorexigenic effect may be mediated via combined GPER-ERα signaling, and that GPER-dependent activation of pSTAT3 within the Arc, and in POMC cells specifically, may account for the rapid (within 1 h) anorexigenic effect following acute administration of selective mER agonists in OVX animals.

Title: The ERα splice variant, ERαΔ4, interacts with mGluR2 and caveolin-3 in female rodent ARH

Authors: *A. M. WONG, P. E. MICEVYCH;
Dept. of Neurobiology, Lab. of Neuroendocrinology, UCLA, Los Angeles, CA

Abstract: ERαΔ4 is an alternative splice variant of ERα in which exon 4 has been deleted from ESR1 mRNA, resulting in a truncated 52 kDa protein. Compared to full-length ERα, this splice

variant is highly expressed in membrane fractions derived from cultured cells; however, in hypothalamic tissue, full-length ERα is the predominant isoform. The nuclear localization sequence located in exon 4 is missing, which may explain ERαΔ4 in the membrane. ERαΔ4 and full-length ERα are trafficked and internalized in parallel so we have used ERαΔ4 as a marker to monitor membrane ERα internalization during estrogen mediated signaling (EMS) in cell culture studies where full-length ERα is difficult to visualize. In the most common form of estradiol membrane-initiated signaling (EMS), caveolin-1 (CAV1) mediates the interaction of full-length (65 kDa) ERα with mGluR1a. While previous studies have shown that estradiol induces ERαΔ4 trafficking to the membrane and EMS, the question of which proteins mediate these events has not been resolved. Trafficking of ER to the membrane is dependent on CAV proteins, which also determine the mGluR that is associated with the ER for EMS. We demonstrated that ERαΔ4 does not associate with CAV1 or mGluR1a. However, in tissue from the female arcuate nucleus of the hypothalamus (ARH), co-immunoprecipitation suggested interactions between mGluR2/3, CAV3, and ERαΔ4. CAV3 siRNA microinjected into female rat ARH reduced CAV3 protein by 50% leading to a 60% decrease in ERαΔ4 in the membrane fraction. Full-length ERα levels were not changed. Moreover, interactions between mGluR2/3 and CAV3 were reduced by 40% in EB-treated female rats (5 μg EB systemically every 4 days; 3 cycles). RT-PCR detected signal for mGluR2 but not mGluR3. Since ERα interactions with mGluR2/3 are inhibitory (e.g., in DRG neurons), these results suggeset a pathway negative regulated by estradiol. At present, the biological significance of ERαΔ4 signaling is not known, but may indicate a pathway through which estradiol inhibits kisspeptin expression in the ARH that mediates estrogen negative feedback.

Title: Hippocampus-synthesized estrogen and androgen modulate dendritic spines and LTP in non-genomic manner

Authors: *S. KAWATO, G. MURAKAMI, Y. HOJO;
Univ. of Tokyo, Tokyo, Japan

Abstract: We have demonstrated (1) hippocampal synthesis of estrogen and androgen, and (2) non-genomic synaptic modulation by these sex-steroids. [Synthesis] We showed expression as well as neuronal/synaptic localization of essential enzymes (mRNA and protein) in the adult male rat hippocampus. Mass-spectrometric analysis demonstrated that exact levels of estradiol (E2), testosterone (T), dihydrotestosterone (DHT) were 8 nM, 18 nM and 7 nM, respectively, which are much higher than their levels in plasma. Castration significantly decreased T and DHT in the hippocampus, indicating that plasma-derived T is efficiently converted to DHT within the hippocampus. Even after castration to deplete circulating T, the male hippocampal E2 level was not decreased, indicating that E2 is mainly synthesized from hippocampal T. Female hippocampal levels of E2 (0.5-4 nM), and T (1 nM) were less than those of male, but much higher than those in plasma. [Synaptic Modulation] E2-induced rapid non-genomic modulation (1- 2 h) was demonstrated by analysis of spinogenesis and LTP of adult male rat hippocampal slices (steroid-depleted slices after recovery incubation). Spine analysis was performed for pyramidal neurons in hippocampal slices. The density of spines and their head diameters were obtained by mathematical and automated software Spiso-3D which identifies spines by calculating geometrical parameters (Mukai et al., Cerebral Cortex, 2011). E2 at 1 nM rapidly increased the density of small-head spines, in CA1 pyramidal neurons. T and DHT at 10 nM increased the density of middle-head spines and large-head spines, respectively. Signaling pathways are: synaptic ERalpha or AR→ PKA, PKC, MAPK, LIMK → cortactin or coffilin → actin polymerization→ new spines. LTP analysis showed that 1 nM E2 induced full-LTP (E2-LTP) upon weak sub-threshold stimulation, although without E2 the weak sub-threshold stimulation did not induce full-LTP. Kinase inhibitors against MAPK, PKA, PKC blocked E2-LTP. Only 20 min application of letrozole (aromatase inhibitor) suppressed full-LTP upon full teta-burst stimulation, indicating rapid E2 synthesis is necessary for LTP in hippocampal slices.

Title: Sex-differences in rapid, 17beta-estradiol-induced potentiation of glutamate uncaging-evoked dendritic calcium transients in the hippocampus

Authors: *J. G. OBERLANDER, C. S. WOOLLEY;
Neurobio., Northwestern Univ., Evanston, IL

Abstract: Subsets of excitatory synapses on hippocampal CA1 pyramidal cells are rapidly potentiated by 17-β estradiol (E2) through pre-and postsynaptic mechanisms that are mediated by a distinct combination of estrogen receptor (ER) subtypes in each sex (Oberlander and Woolley, 2016). Two-photon glutamate uncaging-evoked EPSCs and calcium transients (CaTs) in ~25% of dendritic spines are enhanced by E2 in both sexes, which can be mimicked by GPER1 activation selectively in females and by ERβ activation selectively in males. It is unclear, however, how activation of different ER subtypes yields similar effects on synaptic transmission. Interestingly, in both sexes, E2- and ER agonist-induced potentiation of uncaging-evoked EPSCs correlates with a spine's proximity to other E2-sensitive spines, such that neighboring spines respond to E2 more similarly than spines that are further apart. This suggests that E2 may activate postsynaptic signaling that is shared between nearby spines. Here we used the calcium indicator, Oregon Green, to investigate whether calcium could be a shared factor. We analyzed dendritic CaTs at various distances from spines targeted for glutamate uncaging before, during, and after application of E2 or an ER-selective agonist to hippocampal slices from each sex to investigate how E2 or selective ER activation influences dendritic calcium dynamics and whether there are sex-differences. In both sexes, E2 potentiated dendritic CaTs evoked by uncaging at a subset of spines, though potentiation was greater in females (36±4%) than males (24±3%; $p<0.01$). In females, the GPER1 agonist, G1, potentiated dendritic CaTs (by 34±3%), whereas in males, the ERβ agonist, WAY200070, potentiated dendritic CaTs (by 23±2%). Interestingly, specifically in females, the magnitude of E2- or G1-induced dendritic CaT potentiation was related to distance from the spine targeted for uncaging. In females, dendritic CaTs <4μm from a targeted spine (44/87 spines) or 4-8μm from a targeted spine (20/43 spines) were potentiated, whereas dCaTs >8μm away were not (38 spines). Also, dendritic CaT potentiation in females was greater <4μm (27±4%) than 4-8μm (20±3%; $p < 0.05$) from a targeted spine. In contrast, in males, there was no relationship between dendritic CaT potentiation and distance from the spine that was targeted for uncaging, up to 16μm, the

maximum distance tested. These sex differences in the magnitude and distance-dependence of dendritic CaT potentiation by E2 and ER-selective agonists suggests that acute E2 signaling modulates distinct postsynaptic calcium sources and/or calcium buffering mechanisms in the hippocampus of females versus males.

Title: Molecular interactions that may underlie sex-specific estrogen receptor alpha-dependent modulation of hippocampal synapses

Authors: *N. TABATADZE[1], R. M. MAY[2], C. S. WOOLLEY[2];
[1]Neurobio., [2]Northwestern Univ., Evanston, IL

Abstract: Previously, we showed that a key estrogen, 17-β estradiol (E2), acutely suppresses perisomatic inhibitory synaptic transmission in the hippocampus of adult female but not male rats. This E2 modulation of inhibition evident in females depends on estrogen receptor α (ERα), mGluR1, IP3R and requires endocannabinoid signaling through CB1 receptors. Further biochemical studies showed that ERα-mGluR1 and mGluR1-IP3R complexes exist in the hippocampus of both sexes, but are regulated by E2 only in females. Additionally, analysis of the PLC/IP3 pathway showed that E2 induces a greater increase in IP3 levels in the hippocampus of females than of males. Despite these results, the molecular basis for sex-specific inhibitory synaptic modulation by E2 is unknown. The goal of the current study was to test candidate proteins that may interact with ERα differentially in males and females and therefore confer sex-specific modulation by E2.
To investigate sex differences in basal levels and acute E2 regulation of ERα-interacting proteins, we prepared brain slices from adult gonadectomized male and female rats and treated half the slices from each rat with either vehicle (0.1% DMSO) or E2 (100 nM) for 10 min. The hippocampus was dissected from each slice and then membrane fractions were subjected to immunoprecipitation using antibodies to ERα, flotillin-1 or striatin. In order to study ERα-caveolin-1, ERα-flotillin-1, and ERα-striatin interactions, western blots of immunoprecipitated material were probed for ERα, caveolin-1, flotillin-1, or striatin. Preliminary results showed that

each of these complexes is present in the hippocampus of both sexes. Additionally, E2 treatment increased the amount of ERα pulled down with striatin in females but not in males ($p < 0.01$). In contrast, E2 had no effects on the amount of either caveolin-1 or flotillin-1 that was associated with ERα in either sex, indicating that neither caveolin-1 nor flotillin-1 is likely to be involved in ERα-dependent synaptic modulation in the hippocampus. Experiments to further investigate ERα-striatin interactions are ongoing. Although these results are promising, it is not feasible to test all potentially relevant proteins using a candidate-screening approach. Therefore, future studies will use unbiased proteomics, including 2D gel separation of ERα-interacting proteins followed by mass spectrometry to identify potential molecular interactions that may underlie sex-specific E2 modulation of synaptic transmission in the hippocampus. Identification of sex-specific molecular interactions may deepen our understanding about brain disorders that differ between the sexes.

Title: Characterization of estrogen-producing and estrogen-responsive neurons in the songbird forebrain

Authors: *A. A. KRENTZEL[1], M. Z. IKEDA[2], T. J. OLIVER[3], G. B. SCARPA[4], L. REMAGE-HEALEY[4];
[1]Neurosci. and Behavior, [2]Mol. and Cell. Biol., [3]Biochem. Dept., [4]Psychological and Brain Sci., Univ. of Massachusetts Amherst, Amherst, MA

Abstract: The enzyme aromatase converts testosterone to estradiol which can act locally and rapidly in discrete brain regions. Songbirds, like the zebra finch, have robust aromatase expression in the forebrain, particularly in regions involved in audition. A membrane-bound estrogen receptor (GPER1), is thought to mediate some of the rapid neuromodulatory effects of estradiol observed in aromatase rich brain regions. This study directly examines the identity of both aromatase and GPER1 expressing cells in the auditory forebrain and whether these cell types overlap. Characterization of this relationship anatomically can provide insight into the mechanism by which rapid estradiol signaling is involved in auditory-motor integration. Previous

work indicates a role for interneurons in auditory responsiveness, and that estradiol rapidly enhances the auditory-evoked activity of forebrain neurons. Traditional interneuron markers such as parvalbumin (PV) and calbindin (CALB) were used to determine the extent of interneuron cell identity for aromatase and GPER1. We co-labeled aromatase and GPER1 with PV and CALB in adult male and female zebra finches using immunofluorescence labeling and imaged with confocal microscopy. We quantified expression in representative subregions of several brain nuclei including the caudal nidopallium, HVC shelf, caudomedial mesopallium, and the hippocampus. Aromatase cells in all regions were either PV-positive or single labeled, and aromatase was not co-expressed with CALB. Up to 15% of aromatase cells are parvalbumin-positive depending on region. These findings are comparable to the human temporal cortex, which demonstrates high co-expression of aromatase-positive cells with both cell types. Preliminary findings indicate that GPER1-positive cells do not co-express either interneuron marker but may be co-expressed with aromatase. Males and females were mostly similar in expression levels of aromatase, parvalbumin, and calbindin across subregions with a few exceptions. Finally, the zebra finch brain is organized with dense expression of GPER1 in song motor circuits (HVC and RA) and aromatase expression surrounds these regions in auditory nuclei, suggesting a role for rapid estrogen signaling in auditory-motor integration. Overall, neuroestrogen signaling is supported by the organization of cells in the auditory and motor song circuit. Though some PV interneurons express aromatase, largely aromatase and GPER1 neurons are not calbindin or parvalbumin interneurons and may instead be categorized as other excitatory or inhibitory cell types.

Title: Effects of estrogen receptor manipulations on the neonatal expression of tyrosine hydroxylase and vasopressin in the highly prosocial prairie vole

Authors: J. M. LANDEROS[1], A. N. PERRY[1], P. ZUSHIN[2], A. T. FRITZ[1], *B. S. CUSHING[1]; [1]Biol. Sci., Univ. of Texas At El Paso, El Paso, TX; [2]Biol. Sci., Univ. of Akron, Akron, OH

Abstract: Estrogen receptors (e.g., ERα and ERβ) play critical roles during neonatal development in the organization and expression of sociosexual behaviors in males and females. Using the prairie vole as the model system we have previously demonstrated that manipulation of estrogen receptors can not only influence the ultimate expression of prosocial behavior, but also influences neonatal social interactions. However, the mechanisms regulating prosocial behavior downstream of ERα and ERβ have not been elucidated. The goal of this study was to determine the effects of estrogen receptor activation (ERα and ERβ) on the potential mechanisms that regulate the expression of prosocial behavior, specifically tyrosine hydroxylase (TH) and vasopressin (AVP). ERα expression in the medial amygdala (MeA) and bed nucleus of the stria terminalis (BST) is a critical determinant of prosocial behavior. In addition to ERα, the prairie vole MeA and BST also contain populations of neurons expressing tyrosine hydroxylase (TH). The TH neurons in the MeA and BST are activated during social interactions and are regulated by gonadal steroids and a significant proportion also expresses ERα. Therefore, we hypothesized that ERα may regulate prosocial behavior via effects on TH expression in the MeA and BST. In contrast to ERα, the role of ERβ in male prosocial behavior has received less attention. We have recently demonstrated that ERβ is primarily expressed in the paraventricular nucleus of the hypothalamus (PVH) in prairie voles, with relatively little expression in the MeA and BST. Therefore, if ERβ influences prosocial behavior it may be through the regulation of vasopressin (AVP) in the PVH. In order to test these hypotheses, we treated male voles with an aromatase inhibitor to block endogenous estradiol production in conjunction with selective agonists for either ERα or ERβ between postnatal days (PD) 8-14. Social behavior in a dyadic encounter was assessed on PD15 and brains were collected on PD16. TH in the MeA and BST and AVP in the PVH were visualized via immunohistochemistry and compared in males and females.

Title: Rapid effects of estradiol on the surface movement of AMPA receptor molecules in living neurons.

Authors: *J. PALHALMI[1,2], M. PENZES[2], P. AVAR[2], K. BARABAS[2], I. ABRAHAM[2]; [1]Inst. of Physiol., MTA NAP-B Mol. Neuroendocrinology Res. Gr, Pecs, Hungary; [2]MTA NAP-B Mol. Neuroendocrinology Res. Group, Ctr. for Neuroscience, Szentagothai Res. Center, Med. School, Univ. of Pecs, Pecs, Hungary

Abstract: Alterations in the diffusion properties of AMPA receptors within the cellular domains and synaptic microdomains play a crucial role in the modulation of synaptic plasticity. While the mechanisms of estradiol (E2) promoted synaptic plasticity through genomic mechanisms has been more intensively researched, little if any attention has been given to rapid action of E2 on the surface movement of AMPA receptors. Accordingly, our aim was to examine the effects of E2 on the lateral diffusion properties of single AMPA receptor molecules in the plasmamembrane of living neurons. *In vivo* labeling of AMPA receptors was performed by means of ATTO-488 conjugated antibody raised against the extracellular domain of GluA2 subunits of the receptor. In order to follow ATTO-488 labeled single AMPA receptor molecules total internal reflection fluorescence microscopy was used on differentiated PC12 cells. Reconstructed single AMPA receptor molecule trajectories were separately tracked and analyzed on the soma and on the neurits and mean square displacement (MSD) as well the diffusion coefficient was determined. Statistical properties of the diffusion coefficients (D: μm^2/sec) were compared based on self-similarity and best fit components. The effect of 100 pM E2 administration within the first 5 minutes was tested against independent control samples. Ten seconds long recordings were collected in every 30 seconds. The trajectories collected from the somatic and dendritic domains were compared: E2 significantly altered the diffusion coefficients in both the somatic and dendritic domains (two sample Kolmogorov-Smirnov test, soma: p=5.210e-08, n=250, mean (control D: 0.04812, E2 D: 0.01424), median (control D:0.01965, E2 D:0.005650) dendrit: p=3.597e-04, n=262, mean (control D:0.06926, E2 D:0.08727), median (control D:0.03160, E2 D:0.04735). Based on the population statistics the AMPA receptor lateral diffusion properties were shifted towards the confined motion on the soma and became more mobile on the dendrits. These findings demonstrated that the AMPA receptor molecules show compartment specific lateral diffusion in neurons. Importantly, E2 altered and rearranged the diffusion patterns of AMPA receptor molecules respectively. Our results suggest that E2 may have a short term effect on synaptic plasticity via altering the surface movements of AMPA receptors.

Title: Wild-caught meadow voles show seasonal changes in cell proliferation, neurogenesis, and cell death within the hippocampus

Authors: *M. D. SPRITZER, E. C. B. JAEGER, A. E. CASLER, S. M. ENGELMAN, J. E. GEORGAKAS, L. R. NELSON, A. PANNING, W. T. PRINCE, E. A. ROY, B. A. WAGNER; Dept. of Biol. and Program in Neurosci., Middlebury Col., Middlebury, VT

Abstract: Past research indicates that female meadow voles (*Microtus pennsylvanicus*) show decreased cell proliferation and cell death within the hippocampus during the breeding season relative to the non-breeding season, whereas male voles show no such seasonal changes. We expanded upon these results by quantifying a variety of endogenous cell proliferation and neurogenesis markers in wild-caught voles. Adult male and female voles were captured in both the summer (breeding season) and fall (non-breeding season) using a grid of live-traps in a wetland near Middlebury, Vermont. Only reproductively active voles were collected during the breeding season and only reproductively inactive voles were collected during the non-breeding season. Immediately following capture, voles were euthanized, blood samples collected, and brains extracted. Brains were then sectioned and stained using immunohistochemistry. Four histological markers were used: cresyl violet staining (pyknotic cells), Ki67, pHisH3, and DCX. Marked cells were counted on every tenth section throughout the extent of the dentate gyrus, using either fluorescent or light microscopy. Blood serum was analyzed for testosterone and estradiol concentrations using ELISA's. We observed a consistent decrease in all markers during the breeding season relative to the non-breeding season, indicating a significant decrease in cell proliferation (Ki67 and pHisH3), neurogenesis (DCX), and pyknosis. In contrast to previous findings, we observed no differences between the sexes during either season for any of the cell markers. During the breeding season relative to the non-breeding season, males and females showed the predicted significant increases in testosterone and estradiol, respectively. Among male voles, serum testosterone concentration was a significant negative predictor of the number of DCX-labeled and pHisH3-labeled cells. Among female voles, serum estradiol concentration was a negative predictor of number of pyknotic cells. Overall, these results suggest higher levels of cell turnover and neuronal plasticity across both sexes during the non-breeding season relative to the breeding season. Additionally, our results suggest that elevated sex steroids reduce neurogenesis and cell death within the hippocampus of both sexes. Alternatively, these results

could be due to the over-riding effects of elevated stress during the breeding season, as elevated glucocorticoids are known to impair adult neurogenesis.

Title: Progestin receptors complex with synaptic proteins from female mouse hypothalamus in a ligand-dependent and isoform-specific manner

Authors: *K. D. ACHARYA[1], S. A. NETTLES[1], C. F. LICHTI[3], M. HARLING[2], C. PATTANAYAK[2], L. DENNER[3], M. J. TETEL[1];
[1]Neurosci. Program, [2]Quantitative Analysis Inst., Wellesley Col., Wellesley, MA; [3]Intrnl. Med., Univ. of Texas Med. Br., Galveston, TX

Abstract: Progestins affect a variety of processes in brain and behavior, including development, sexual differentiation of the brain, cognition, neuroprotection and female reproduction. Progestins primarily act through the progestin receptor (PR) isoforms: full length PR-B and the N-terminally truncated PR-A. These two isoforms mediate different effects in brain and reproductive tissues by mechanisms that are not fully understood. *In vitro* studies reveal that PR associate with multiple proteins to form functional complexes that modulate the functions of these receptors. In the present study, affinity-pull down assays using GST-tagged mouse PR-A and PR-B were done to isolate proteins from female mouse hypothalamus that associate with PR. Using large scale proteomic approaches of reverse phase protein array (RPPA) and mass spectrometry, we identified proteins that interact with the PR isoforms in a ligand-dependent and isoform-specific manner. Interestingly, synapsin-1 and synapsin-2 interact with both PR isoforms when activated by the agonist (R5020), suggesting a role for both isoforms in synaptic transmission and plasticity. Synaptogyrin and synapsin-3 interact with PR-A and PR-B, respectively, suggesting PR isoform-specific functions in aspects of synaptic modulation. Activated PR also interact with kinases, including c-Src (PR-A and PR-B); mTOR, c-Raf (PR-A) and MAPK1 (PR-B), proposing roles for PR in fast-acting, dynamic changes in the brain through

phosphorylation-dependent pathways. Consistent with the function of PR in transcriptional regulation, PR associates with a variety of transcription factors including FoxO1 (PR-A and PR-B); c-Fos, c-Jun, STAT3, EEF1β, KLF4 (PR-A); the nuclear receptor coactivators SRC-1, SRC-2 (PR-A and PR-B) and MED12 (PR-A). Some of these identified interactions with PR have been confirmed by western blot, including synapsin-1, synapsin-2, SRC-1 and SRC-2. These novel findings that show association of PR with multiple synaptic proteins from female hypothalamus that function in synapse and spine remodeling as well as synaptic transmission and plasticity, suggest new roles for progestins in brain function and disease.

Title: Caveolin-1 is palmitoylated by the same DHHC enzymes as steroid hormone receptors

Authors: *K. R. TONN, P. G. MERMELSTEIN;
Dept. of Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Palmitoylation is a reversible post-translational addition of a 16-carbon lipid chain that is involved in trafficking and compartmentalizing target proteins. This regulatory mechanism is important for many neuronal functions, including the signaling of membrane-localized estrogen receptors. Specifically, palmitoylation of ERα is necessary for surface membrane localization and mediation of downstream signaling through metabotropic glutamate receptor activation. Mutation of the single palmitoylation site on ERα prevents its physical association with the integral membrane protein caveolin-1 (Cav1), which in turn is required for the formation of the estrogen receptor-mGluR signaling complex. Interestingly, siRNA knockdown of either of two palmitoylacyltransferases, DHHC-7 and DHHC-21, also eliminates this signaling mechanism. As ERα has only one palmitoylation site, we hypothesized that one of these seemingly redundant DHHCs palmitoylates another protein in this signaling complex, namely Cav1. We investigated this using an acyl-biotin exchange assay in HEK293 cells in

conjunction with DHHC overexpression, and found that DHHC-7 increased Cav1 palmitoylation. Mutation of the palmitoylation sites on Cav1 eliminated this effect, but did not disrupt the ability of the DHHC enzyme to associate with the protein. Somewhat surprisingly, siRNA knockdown of DHHC-7 alone was not sufficient to decrease Cav1 palmitoylation, but rather required simultaneous knockdown of DHHC-21. Together with previous findings from our laboratory suggesting that Cav1 affects the presence of ERα at the plasma membrane, these data expose a broader role of palmitoylation in membrane-initiated estrogen signaling than previously understood. Future work will explore Cav1 palmitoylation in the context of functional ER-mGluR activation in neurons as well as the effects of palmitoylation on the cellular distribution of Cav1 and its ability to influence plasticity and behavior.

Title: An investigation of steroidogenic acute regulatory protein (StAR) gene expression in the green anole lizard brain and gonad

Authors: *C. E. KLECKER, R. E. COHEN;
Minnesota State University, Mankato, Mankato, MN

Abstract: Seasonally breeding animals reproduce during certain times of the year and, subsequently, behaviors, steroid hormone levels, and brain morphology changes seasonally. The green anole lizard (*Anolis carolinensis*) is an excellent model to study the regulation of steroid hormone production because they have distinct hormonal and behavioral differences between sexes and seasons. As in other vertebrates, steroidogenesis in anoles is under the control of the hypothalamus-pituitary-gonadal (HPG) axis. In this system, the anterior pituitary produces luteinizing hormone (LH), and follicle-stimulating hormone (FSH). One function of LH is the activation of steroidogenesis, specifically by triggering an increase in steroidogenic acute regulatory protein (StAR). StAR regulates the delivery of cholesterol from the outer to the inner mitochondrial membrane, the rate-limiting step in the steroid synthesis pathway. StAR is able to function and produce steroid hormones in many different organs and tissues such as the gonads, brain, adrenal cortex, and adipose tissue. We tested the hypothesis that season and sex differences in the green anole lizard will impact mRNA expression levels of StAR in the gonads and brain. Adult male and female lizards were wild-caught during both the breeding (BS) and

non-breeding (NBS) seasons. Gonad and brain were collected and stored at -80 °C. RNA from brain and gonad was extracted, reverse transcribed into cDNA and then StAR gene expression was measured by qPCR (normalized to β actin). Preliminary results of StAR expression in the brain revealed a trend for season such that StAR expression levels decreased in BS when compared to NBS lizards ($F_{1,8} = 4.77$, $p = 0.060$, $n = 3$). There was no effect of sex or an interaction (all $F < 1.52$, $p > 0.252$). Preliminary results for gonad StAR expression levels showed no significant effect of sex, season or interaction (all $F < 1.42$, $p > 0.267$, $n = 3$). These preliminary results suggest that StAR gene expression is potentially expressed differently between the green anole BS and NBS brain. StAR may play a role in the production of steroid hormones in the NBS brain due to decreased circulating steroid hormones during the NBS.

Title: Androgen Receptor Splice Variant expression in neuronal cells

Authors: J. G. CONTRERAS[1], P. DUONG[1], L. DOWNS[1], *R. L. CUNNINGHAM[2]; [1]Univ. of North Texas Hlth. Sci. Ctr., Ft. Worth, TX; [2]Pharmacol. & Neurosci., Univ. North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstract: Men have a two-fold risk for Parkinson's disease (PD) than women. We have previously shown that testosterone, the major male sex hormone, can increase calcium influx and cell death in dopamine neurons via a putative membrane androgen receptor. Androgen receptor (AR) splice variants, such as AR45, have been observed in non-neuronal tissues. It has been observed that testosterone can have damaging effects via AR45 and not the classical AR. Therefore, we hypothesize that the putative membrane androgen receptor is the AR45 splice variant that acts through a g-protein coupled receptor (GPCR). To test our hypothesis we examined the expression of AR45 and classical AR in the whole cell lysate and the fraction (membrane, cytosol, nuclear) lysate of a dopaminergic N27 cell line and rat substantia nigral, hippocampal, and cortical tissues. We also examined if AR45 is a GPCR. Our results showed that AR45 is present in the N27 cell line and the substantia nigral tissue, but classical AR was not observed. However, both classical AR and AR45 were observed in hippocampal and cortical

tissues. Further, we found that in dopaminergic neurons, AR45 is associated with GPCR subunits, which is consistent with prior observations showing testosterone increases calcium influx. Our data indicates that the membrane androgen receptor in neurons is the AR45 splice variant. This is the first observation of an AR splice variant in neuronal tissue, a novel therapeutic target.

Title: Altered brain networks in congenital adrenal hyperplasia revealed using multimodal MRI

Authors: *R. TANAKA[1], R. HORIKAWA[2], T. OGATA[3], Y. YOTSUMOTO[1];
[1]Grad. Sch. of Arts and Sci., The Univ. of Tokyo, Meguro, Tokyo, Japan; [2]Div. of Endocrinol. and Metabolism, Natl. Ctr. for Child Hlth. and Develop., Setagaya, Tokyo, Japan; [3]Hamamatsu Univ. Sch. of Med., Hamamatsu, Shizuoka, Japan

Abstract: Congenital Adrenal Hyperplasia (CAH) is characterized by excessive adrenal production of androgens and a decreased ability to produce cortisol. Consequently, the brains of patients with CAH are continuously exposed to a higher level of androgens as well as supraphysiological doses of iatrogenic glucocorticoids. The effects of excessive amount of androgens and other hormones on the behavior of participants have been repeatedly documented (e.g. masculinized preference of activities in childhood or increased incidence of gender dysphoria in female patients with CAH). However, the long-term effects of hormonal excess on the human brain, especially on its structure as a complex network, are not well understood. Therefore, in this study, we compared the brains of patients with CAH with those of healthy controls (both male and female), using three different MRI techniques: anatomical morphometry, functional connectivity, and diffusion tractography. In the course of the analysis, we assumed that the features that shifted from female- to male-type in the patients were affected by androgens, and those that deviated in other ways were affected by other excess hormones including iatrogenic corticosteroids. We aimed to identify factors that correlated with gender dysphoria, and asked participants to answer the Gender Identity Questionnaire. Altered gray mater volume (GMV) and cortical thickness (Cth) was found in the brains of patients in areas such as the post central gyrus, insula, pallidum, and putamen. This was mostly in accordance with previously reported male-type proportion. Functional connectivity analysis revealed

positively and negatively intensified connectivity between the amygdala, which is rich in androgen receptors, and various regions in patients. Further, we found that the modularity of structural brain networks constructed with diffusion tractography was higher in male than in female controls, and even higher among the patients. Finally, a few edges of functional and tractography-based brain networks showed significant correlation with the scores on the Gender Identity Questionnaires among both patients and controls. This indicated potential dissociation between the general masculinization of the nervous system and neural underpinnings of gender (in)consistency. To summarize, the brains of patients with CAH showed various deviations from those of the controls. A considerable portion of these deviations could be regarded as 'masculinization'. Our result might shed light on the etiology of sex differences in the human brains and their relationship with psychological gender identity.

Title: Neuroanatomical distribution and characterization of Dek oncogene in male and female rodent brain

Authors: *V. GHISAYS[1,2,5,3,4], N. A. PEASE[5], M. FITZGERALD[2], C. ESTRADA[2], E. T. NGUYEN[4], L. PRIVETTE VINNEDGE[3], M. B. SOLOMON[2];

Abstract: The Dek oncogene is a chromatin-associated non-histone phosphoprotein essential for genome stability. Dek is expressed in proliferating cells in almost all tissues. The cellular proliferative effects of Dek are mediated, in part, via the activation of the canonical Wnt/β-catenin signaling pathway. To date, research on the functional role of Dek signaling is limited to the periphery (e.g., breast, prostate, & colorectal tissue). In the brain, the canonical Wnt/β-catenin signaling pathway plays a critical role in learning and memory as downregulation of this pathway in the hippocampus is associated with cognitive dysfunction. Based on this information, we tested the hypothesis that Dek loss would be associated with impaired cognition. To test this

hypothesis, six to eight month old female Dek knockout mice and their wild-type littermate controls were used. Consistent with our hypothesis, Dek loss was associated with impaired object recognition in the novel object recognition (NOR) task. Of note, the decrease in object recognition in Dek knockout mice was not due to differences in overall activity or anxiety-like behaviors in the open field test. Given the cognitive-like impairment in Dek knockout mice, Dek distribution in cortico-limbic structures associated with learning and memory was assessed in the murine male and female brain using immunohistochemistry. In both males and females, Dek was expressed throughout the medial prefrontal cortex with robust staining in layers 2 & 3 and higher expression in the prelimbic compared with the infralimbic areas. Dek expression in the dorsal hippocampus was highest in the granule cell layer of the dentate gyrus and CA1 and lower in the CA3. Notably, there was a significant sex difference in Dek expression in the CA1 with females having higher expression. Dek was also robustly expressed in the ventral hippocampus (subiculum) and widely expressed in a number of other brain regions including the basolateral complex, central, and medial amygdala, entorhinal cortex and interpeduncular nucleus. Further analyses of cellular co-expression of Dek in the dorsal hippocampus revealed that Dek is co-expressed with all cell types (neurons, astrocytes, and microglia) with an approximate 1:1 ratio for microglia. To our knowledge, this is the first study to characterize the neuroanatomical distribution of Dek in the male and female rodent brain. Studies are currently underway to determine a molecular basis for the cognitive impairment in Dek knockout mice.

Title: The role of microglia and mast cells in sculpting the sexually dimorphic nucleus (SDN) of the POA

Authors: *L. A. PICKETT[1], K. M. LENZ[3], M. M. MCCARTHY[2];
[1]Pharmacol., [2]Univ. of Maryland Sch. of Med., Baltimore, MD; [3]The Ohio State Univ., Columbus, OH

Abstract: The sexually dimorphic nucleus (SDN) was the first neuroanatomical sex difference detected in the brain and was named for its larger size in males compared to females (Brain Res. 148:333, 1978). The SDN is a dense collection of calbindin-expressing neurons (J. Neurobiol. 42:315, 2000) located within the central division of the medial preoptic nucleus (MPNc) of the preoptic area (POA), a critical brain region for the control of partner preference and maternal behaviors (Horm. Behav. 55:611, 2009; Neurosci. Bull. 30:863, 2014). Previous studies have established that both sexes generate the same number of neurons in the SDN and they selectively die off early in development in females due to a lack of the endogenous survival factor, estradiol (Brain Res. 353:7, 1985; Brain Res. Dev. Brain Res. 52:17, 1990). This system is an excellent model for naturally occurring cell death versus neuroprotection in the developing brain but the involvement of non-neuronal cells in this model system has been largely ignored. We have previously established that innate immune cells of the brain, microglia, and inflammatory mediators such as prostaglandins direct the development of sex-specific synaptic patterns in the neonatal POA that correlate with sexual behavior in the adult rat (Nat. Neurosci. 7:643, 2004; J. Neurosci. 33:2761, 2013). We now turn our attention to mast cells, which like microglia are immune cells of myeloid cell lineage with origins outside the nervous system. We determined there are more mast cells in the POA of neonatal males than females and this sex difference was mediated by estradiol. We have found that pharmacological activation of mast cells in newborn females induces a male-typical microglial morphology, with higher numbers of ameboid microglia and lower numbers of ramified, phagocytic microglia. In addition, we discovered that brain mast cells express estrogen receptors and degranulate upon exposure to estradiol, as measured by histamine release, in vitro. We are currently investigating whether mast cells modulate microglial primary phagocytosis (phagoptosis) and whether this contributes to the sexual differentiation of SDN volume by phagoptosis of neurons in the female SDN. Collectively these results indicate non-neuronal cells are crucial and unappreciated factors shaping brain development and sex-specific physiological and behavioral outcomes. Understanding the role of these cells in apoptotic and neuroprotective cascades during normal brain development will allow for further studies of novel therapeutic strategies and potential sex differences in efficacy of estradiol and/or immune cell inhibitors as neuroprotective agents.

Title: Identification of genes regulated by progesterone receptor in the neonatal medial preoptic nucleus using RNAseq.

Authors: *D. LALITSASIVIMOL[1], D. M. WALKER[2], R. M. RICCIARDELLI[1], E. J. NESTLER[2], C. K. WAGNER[1];
[1]Psychology, Univ. At Albany, Albany, NY; [2]Fishberg Dept. of Neurosci. and Friedman Brain Inst., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: The brain is sensitive to gonadal steroid hormones, beginning in fetal development and continuing throughout the lifespan. Like other nuclear steroid hormone receptors, progesterone receptor (PR) is a transcription factor that can permanently alter fundamental processes of neural development. Differential exposure of males and females to testosterone and its metabolites during perinatal development induces a sex difference in progesterone receptor (PR) expression in the medial preoptic nucleus (MPN). The male MPN expresses significantly higher levels of PR than females from E19 through at least P14. This suggests a developmental window during which males are more sensitive to progesterone and implicates PR in the sexual differentiation of the MPN. Inhibition of PR activity or lack of PR expression during development attenuates the effects of testosterone in masculinizing MPN morphology and reproductive and aggressive behaviors regulated by MPN circuitry. Presumably, the transcriptional activity of PR regulates the expression of a set of genes in the developing male MPN that it does not regulated in the female MPN. In the present experiment, RNA-sequencing was performed on MPN tissue from postnatal day 7 (P7) progesterone receptor knockout (PRKO) male mice and their wildtype (WT) counterparts to identify genome wide transcriptional changes in PRKO mice and identify novel gene targets for PR transcriptional activity in the MPN. Additionally, we identified potential upstream regulators of differentially expressed genes using Ingenuity Pathway Analysis (IPA) to look for enrichment of PR regulated genes. A subset of candidate genes will be validated using qRT-PCR. To our knowledge, this is the first study to examine specific genes regulated by PR activity in the developing MPN and can be used to generate future hypotheses about how PR generates sex differences in the brain.

Title: Neonatal masculinization blocks increased excitatory synaptic input in female rat nucleus accumbens core

Authors: J. CAO, D. M. DORRIS, *J. MEITZEN;
Biol. Sci., North Carolina State Univ., Raleigh, NC

Abstract: Steroid sex hormones and genetic sex regulate the phenotypes of motivated behaviors and relevant disorders. Most studies seeking to elucidate the underlying neuroendocrine mechanisms have focused on how 17β-estradiol modulates the role of dopamine in striatal brain regions, which express membrane-associated estrogen receptors. Dopamine action is an important component of striatal function, but excitatory synaptic neurotransmission has also emerged as a key striatal substrate and target of estradiol action. Here we focus on excitatory synaptic input onto medium spiny neurons (MSNs) in the striatal region nucleus accumbens core (AcbC). In adult AcbC, miniature excitatory postsynaptic current (mEPSC) frequency is increased in female compared to male MSNs. We tested if increased mEPSC frequency in female MSNs exists before puberty, if this increased excitability is due to the absence of estradiol or testosterone during the early developmental critical period, and if it is accompanied by stable neuron intrinsic membrane properties. We found that mEPSC frequency is increased in female compared to male MSNs pre-puberty. Increased mEPSC frequency in female MSNs is abolished after neonatal estradiol or testosterone exposure. MSN intrinsic membrane properties did not differ by sex. These data indicate that neonatal masculinization via hormone action is sufficient for downregulating excitatory synaptic input onto MSNs. This suggests that testosterone aromatization to estradiol may masculinize/defeminize AcbC function. We conclude that excitatory synaptic input onto AcbC MSNs is organized long before adulthood, providing new insight into a mechanism by which sex differences in motivated behavior and other AbcC functions may be generated or compromised.

Title: Regulation of sexually dimorphic activity-dependent neuroprotective protein (Adnp) mRNA expression in the developing mouse cerebellum is independent of sex steroids

Authors: *T. MOTA, H.-W. TSAI;
Biol. Sci., California State University, Long Beach, Long Beach, CA

Abstract: The cerebellum is important for motor coordination and non-motor functions, and there is mounting evidence of cerebellar involvement in autism, a male-biased neurodevelopmental disorder characterized by deficits in social behavior and interpersonal communication. Activity-dependent neuroprotective protein (*Adnp*), a transcription factor that regulates hundreds of genes during embryonic development, is highly expressed in the rodent cerebellum and important for brain development. In addition, mutations in *Adnp* have been recently identified as a frequent cause of autism. Since a perinatal rise in testosterone secreted by the developing testes acts directly on androgen receptor (AR) or indirectly on estrogen receptors (ERs) via estradiol synthesized locally by aromatase to masculinize brain structures and behaviors, we hypothesized that *Adnp* expression in the mouse cerebellum during early development might be sexually dimorphic, which is regulated by the activation of AR and/or ERα. To test our hypothesis, we first measured mRNA levels of *Adnp* in male and female mouse cerebella collected on the day of birth (PN0), and 7 (PN7), 14 (PN14), and 21 days (PN21) after birth by quantitative RT-PCR. While *Adnp* levels significantly increased with age ($p<0.001$), they were male-biased on PN0 ($p=0.049$), but female-biased at PN14 ($p=0.032$). We next determined if the male-biased expression of *Adnp* in the neonatal mouse cerebellum was regulated by AR and/or ERα by treating pregnant female mice daily with vehicle, testosterone propionate (TP), or estradiol benzoate (EB) starting on embryonic day 16 until PN0. The cerebellum was collected from vehicle-, TP-, and EB-treated, male and female neonatal pups. As compared to vehicle-treated controls, there was no effect of TP ($p=0.439$) or EB ($p=0.924$) on *Adnp* expression, suggesting that sex steroids might not be required for the control of *Adnp* expression. Our data show that the sexually dimorphic *Adnp* expression in the neonatal mouse cerebellum is transient, followed by a robust change with age during early development. Although *Adnp* expression in the neonatal cerebellum does not seem to be regulated by sex steroids and their receptors, sex- and age-specific expression of *Adnp* might still be involved in

the cerebellar control of cognitive behaviors between the sexes and the etiology of sex-biased neurological disorders and mental illnesses caused by cerebellar dysfunction.

Title: Inactivation of AdipoR1 in the dentate gyrus induces sex-specific behavioral phenotypes

Authors: *X. FANG[1], J. LIU[2], X. Y. LU[1];
[1]Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX; [2]Binzhou Med. Univ. Hosp. / IMND, Shandong, China

Abstract: Previous studies suggest that the adipocyte hormone adiponectin has antidepressant-like activity. However, the receptor specificity and neural circuit that mediate adiponectin action on depressive-like behaviors remain to be determined. In this study, we investigated the effects of the adiponectin receptor 1 (AdipoR1) in the dentate gyrus (DG) on emotion-related behaviors in both male and female mice. Mice with DG-specific disruption of AdipoR1 were generated using the Cre-loxP system. Male and female AdipoR1 conditional knockout mice and their littermate controls were evaluated in a series of behavioral tests. We found that male AdipoR1 conditional knockout mice exhibited anhedonia in a female urine sniffing test, but showed no difference from control mice in the sucrose preference test. In contrast, female mutant mice displayed significantly reduced sucrose preference. In the forced swim and tail suspension tests, male but not female mutant mice showed decreased behavioral despair. Both male and female mice displayed normal locomotor activity, and normal performance in the learned helplessness test and elevated plus maze test. The cellular mechanisms underlying sex differences in behavioral phenotypes caused by loss of AdipoR1 are currently being investigated. It is postulated that sex-associated differences in the adiponectin/AdipoR1 system in the DG may cause differential cellular responses and result in overlapping but different behavioral phenotypes in male and female mice.

Title: Sex differences in endocannabinoid signaling at hypothalamic ventromedial/arcuate proopiomelanocortin synapses

Authors: *C. FABELO;
Western Univ. of Hlth. Sci., Pomona, CA

Abstract: The endocannabinoid system regulates a variety of biological processes such as antinociception and energy balance. Previous studies have demonstrated that cannabinoid-induced changes in energy intake and expenditure are sexually differentiated - with males being more sensitive than females. These sex differences are further modified by steroid hormones via changes in excitatory transmission in proopiomelanocortin (POMC) neurons originating from the hypothalamic arcuate nucleus (ARC) mediated through various signaling pathways. One likely source of this excitatory input is the population of steroidogenic factor (SF)-1 neurons emanating from the dorsomedial portion of the ventromedial nucleus (VMN). These neurons are glutamatergic, and also express CB1 receptors in a SF-1-sensitive fashion. We tested the hypothesis that retrograde inhibition of excitatory input occurring at VMN /ARC POMC synapses occurs to a greater extent in males than in females. Electrophysiological recording were performed in hypothalamic slices from castrated guinea pigs using biocytin-filled electrodes. The baseline amplitude of evoked excitatory postsynaptic currents (eEPSCs) generated by electrical stimulation of the dorsomedial VMN was significantly greater in females than in males. In both male and female slices, depolarized-induced suppression of excitation (DSE) caused a time-dependent reduction in the amplitude of these eEPSCs. The DSE-induced reduction in eEPSC amplitude was blocked by the CB1 receptor antagonist AM251 (1μM), and potentiated in slices from male animals treated with the dihydrotestosterone mimetic, Cl-4AS (100nM). This latter effect was completely abolished by the diacylglycerol lipase (DAGL) inhibitor, Orlistat (3μM). These data reveal that excitatory input onto POMC neurons occurs to a greater extent in females than in males, and is subject to retrograde endocannabinoid-mediated inhibition via DSE. Androgens increases endocannabinoid tone in males, thereby further relieving POMC neurons from excitatory input emanating from the VMH to cause an increase in energy intake. These findings provide important insight into sexually differentiated and steroid sensitive endocannabinoid regulation of the hypothalamic energy balance circuitry.

Title: Role of sex chromosome complement in the regulation of aromatase expression in developing mice brain

Authors: *C. D. CISTERNAS[1], M. A. AREVALO[2], L. M. GARCIA-SEGURA[2], M. J. CAMBIASSO[1];
[1]Inst. de Investigación Médica Mercedes y Martín Ferreyra. INIMEC-CONICET, Córdoba, Argentina; [2]Inst. Cajal, CSIC, Madrid, Spain

Abstract: During the critical period of sexual differentiation there are sex differences in brain aromatase expression that are time and regionally specific. Some of these sex differences cannot be explained by organizational actions of gonadal hormones because they occur before exposition to testosterone *in utero*. Previous results from our group using the four core genotype mouse model (FCG) demonstrate that XY neurons from amygdala express higher levels of aromatase and Cyp19a1 than XX neurons of E15 mice independent of gonadal sex. The present study explores the regulation of aromatase in amygdala neurons from E15 mice brain and the role of estrogen (ERα and ERβ) and androgen receptors (AR) in this regulation. Our results show that E2 (10^{-10}M) or dihydrotestosterone (DHT, 10^{-10}M) *in vitro* increases aromatase expression in amygdala neurons derived from XX embryos, but not in those derived from XY embryos. This effect was independent of gonadal sex and the final outcome was to abolish the basal sex chromosome-induced sex difference. The effect of hormone treatments was not imitated with a selective ERα agonist-PPT [4,4',4″-(4-propyl-[1H]-pyrazole-1,3,5-triyl)trisphenol] or G1, a ligand of G protein receptor 30／G protein-coupled ER. By contrast, a selective ERβ agonist-DPN [2,3-bis(4-hydroxyphenyl)-propionitrile] fully reproduced the effect of E2 and DHT on aromatase expression. Moreover treatment with a selective ERβ antagonist-PHTPP (4-[2-phenyl-5,7-bis(trifluoromethyl)pyrazolo[1,5-a]pyrimidin-3-yl]phenol) blocked this effect. As E2 and

DHT regulate transcription of target genes via estrogen or androgen receptors we studied if aromatase regulation involves a change in steroid receptor expression. Our results show that in a way that resembles aromatase expression, amygdala neurons from XY brain have a higher expression of ERβ mRNA than XX neurons and hormonal treatments increase ERβ mRNA only in XX neurons (male and female). No effects were observed on ERα and AR expression. In summary, our findings indicate that sex chromosome complement determines a higher expression of aromatase and ERβ in XY neurons from amygdala. Also, these results indicate that ERβ is involved in aromatase regulation in a mechanism regulated by sex chromosomes. Given that it is a key enzyme necessary for organizational actions of gonadal testosterone these findings imply that genetic and gonadal factors interact in the generation of sex differences in some structures of the developing rodent brain.

Title: Involvement of androgen, but not estrogen, receptors in the masculinization of the oxytocin receptor in the bed nucleus of the stria terminalis

Authors: *N. B. WORLEY, K. M. DUMAIS, J. C. YUAN, L. E. NEWMAN, A. G. ALONSO, A. H. VEENEMA;
Psychology, Boston Col., Chestnut Hill, MA

Abstract: The neuropeptide oxytocin (OT) often regulates social behavior in sex-specific ways. This may be due to sex differences in the brain OT system. In support, our lab has recently demonstrated that adult male rats have higher OT receptor (OTR) binding density than females in various forebrain regions, including the posterior bed nucleus of the stria terminalis (BNSTp). Understanding the origin of this sex difference may advance our understanding of the sex-specific development and regulation of social behavior. Sex differences in the brain are organized by testosterone (T), primarily via actions of its metabolite estradiol during critical periods (perinatal and pubertal) in development. The BNSTp is a sexually dimorphic region of the rodent brain in which males have a larger volume than females. This sex difference is dependent on perinatal testosterone and can be eliminated by early postnatal castration. While the sexual dimorphism in size doesn't appear until postnatal day 12, we find that the sex

difference in OTR binding density in the BNSTp appears at postnatal day 5. This suggests that the sex difference in OTR binding density is also organized during the perinatal critical period. We hypothesized that the sex differences in pBNST size and OTR binding density are regulated by androgen and/or estrogen receptor signaling during the early postnatal period. To test this, we determined whether masculinization of BNSTp size and OTR binding density is dependent on androgen receptor or estrogen receptor activation. We predicted that blockade of endogenous neonatal testosterone-dependent signaling would decrease the pBNST size and OTR binding density in the of males to the level seen in females. We find that neonatal androgen receptor antagonism in males decreased OTR binding density in the pBNST as well as pBNST volume, but neither to the point of female levels. Furthermore, we find that estrogen receptor antagonism did not significantly alter OTR binding density or pBNST size. These findings suggest that the sex differences in BNSTp size and OTR binding density are partially mediated by testosterone-induced AR activation during the postnatal period.

Title: DNA methylation promotes hippocampal cell genesis in neonatal male rats while histone deacetylation suppresses it in female rats

Authors: *S. L. STOCKMAN, M. M. MCCARTHY;
Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Neuronal proliferation, a critical component of early brain development, persists into neonatal life in multiple brain regions including the hippocampus. Our laboratory has established that newborn male rats make nearly twice as many new cells in the dentate gyrus of the hippocampus compared to female littermates and that more of these new cells in males differentiate into neurons (Bowers et al., Biol. Sex Diff., 2010). Hippocampal steroid content does not differ by sex during the period of elevated proliferation in males indicating hormones are not the source of the sex difference (Konkle et. al, Endocrinology, 2011). Maintenance of a proliferative state requires suppression of anti-proliferative factors, in favor of pro-proliferative

gene expression. Epigenetic regulation significantly contributes to this coordination. We hypothesized that sexually differentiated epigenetic regulation is responsible for the observed sex difference in cell proliferation in the early postnatal hippocampus. Canonical modes of epigenetic regulation include direct modification of the DNA, primarily through methylation, as well as alteration to histone tails that modify the state of chromatin. Pharmacological manipulation to demethylate DNA or block deacetylation of lysines found in histones effected proliferation in a sex dependent manner ($F[3,21]=5.496$; $p=0.006$). Inhibition of DNA methylation via treatment with Zebularine (300ng i.c.v.) on PN0 and PN1 reduced cell proliferation in males without effecting proliferation in females (Newman-Keuls post-hoc $p<0.05$), as measured by BrdU immunohistochemistry (100mg/kg; administered 2 hrs post-drug injection on PN1). Conversely, increased histone acetylation via administration of the HDAC inhibitor, Trichostatin A (0.5mg/kg i.p.) under a similar schedule, elevated proliferation in females, but did not affect cell proliferation in male dentate gyrus (Newman-Keuls post-hoc $p<0.05$). Quantification of DNA methylation on PN1 found levels in the dentate gyrus to be twice as great in males relative to females ($t[10]=2.728$; $p= 0.0213$). Therefore we conclude DNA methylation promotes proliferation in males and histone deacetylation suppresses proliferation in females. Further analysis of the expression and activity of enzymes crucial to maintenance of these epigenetic marks throughout development provide important information regarding sex dependent epigenetic regulation of early postnatal proliferation in the dentate gyrus. Title: Micro RNAs are differentially expressed in the androgen responsive bulbocavernosus and levator ani skeletal muscles

Authors: M. ALTEMUS[1], J. MOORE[1], *J. A. JOHANSEN[2];
[1]Neurosci. Program, [2]Col. of Med., Central Michigan Univ., Mount Pleasant, MI

Abstract: The spinal nucleus of the bulbocavernosus (SNB) is a sexually dimorphic group of motor neurons that innervate the perineal muscles, which surround the base of the penis in

rodents and control copulation. This entire neuromuscular system is highly dependent on androgens, and a powerful model for understanding androgen mediated sexual differentiation. Androgens act indirectly through the muscle to keep SNB motor neurons alive. The bulbocavernosus and levator ani (BCLA) perineal muscles have similar levels of androgen receptor (AR) mRNA when compared to other skeletal muscles; however, the BCLA muscles have much more AR protein than other skeletal muscles. This suggests that the amount of AR protein is regulated by translational or post-translational mechanisms in the muscle. Whether increased levels of AR protein per se in muscle confers androgen responsiveness to the BCLA skeletal muscles, and what mechanisms in muscle promote survival of the SNB motor neurons remain unclear. One important mechanism of translational regulation implicated in skeletal muscle development and function are microRNAs. A microRNA (miRNA) can regulate mRNA targets by degrading target mRNA molecules or inhibiting their translation. We hypothesized that miRNA's are differentially expressed between androgen responsive and unresponsive muscles. Using NanoString technology we assessed the gene expression of 603 miRNAs in wildtype male mouse BCLA and extensor digitorum longus (EDL) skeletal muscles. We found 13 miRNAs that were 2-fold greater in the BCLA muscles, and 41 miRNAs that were 2-fold or greater in the EDL muscles compared to BLCA. Eight of the miRNAs elevated in the EDL are predicted to bind to AR. Our results suggest that miRNAs may provide a potential mechanism for the differential androgen receptor protein expression among skeletal muscles and demonstrate a role for miRNA's in sexual differentiation of the SNB system.

Title: Developmental expression of ER_{beta} in the dorsal raphe and frontal cortex of male and female mice

Authors: *M. A. HOLSCHBACH, R. J. HANDA;
Biomed. Sci., Colorado State Univ., Fort Collins, CO

Abstract: Estrogen signaling is paramount in organizing sex differences in numerous brain functions, including stress responses, social behavior, and neurobehavioral disorders such as

depression and anxiety. Midbrain regions, such as the dorsal raphe nucleus (DR), express estrogen receptors, particular estrogen receptor (ER) β, but few studies have examined their ontogeny or looked for sex differences. The DR is the main source of forebrain serotonin, which plays a critical role in many components of behavior and physiology. Moreover, sex differences in developmental expression of ERβ may contribute to, and potentially program, serotonergic output to many forebrain regions, including the frontal cortex (FC), a major efferent target of the DR. In this study, we used immunohistochemistry to label serotonergic neurons within the DR of ERβ-EGFP transgenic mice to compare the distribution of ERβ in serotonergic and nonserotonergic populations of DR neurons in male and female mice on postnatal days 2, 4, and 14. Results suggest that young male mice have more serotonergic DR neurons than female mice do, but neonatal mice of both sexes have many ERβ-EGFP DR neurons that exist in both serotonergic and nonserotonergic neurons. We also measured differences in ERβ distribution in the FC of these mice and used immunohistochemical labeling of doublecortin to assess whether ERβ was expressed in undifferentiated neurons. Preliminary results suggest that although both male and female mice express ERβ in many FC neurons, patterns may differ across development and between the sexes. Moreover, neither male nor female mice of any age had ERβ within undifferentiated neuroblasts (doublecortin-immunoreactive) in the FC. These differences in ERβ expression indicate time- and sex-dependent mechanisms for lasting effects of estrogens on cognition, behavior, and physiology during adulthood.

Title: Sexually dimorphic effects of early postnatal genistein administration on kisspeptin system

Authors: *M. MARRAUDINO[1,2], G. PONTI[3,1], A. FARINETTI[2,1], E. MACCHI[3], S. GOTTI[2,1], M. KELLER[4], G. PANZICA[2,1];

Abstract: Genistein (GEN), a phytoestrogen contained in soy and other legumes, may interfere with the endocrine system in multiple ways. Therefore, it may induce permanent alterations of estrogen sensitive circuits as the Kisspeptin system. In rodents, this system is clustered in two hypothalamic populations located within the rostral periventricular area of the third ventricle (RP3V) and the Arcuate nucleus (ARC), and it regulates both the timing of pubertal onset and estrous cycle. Kisspeptin neurons project primarily to the GnRH neurons, but also in a few other locations, including the Paraventricual nucleus (PVN), the most important center for the regulation of food intake and energy expenditure. We analyzed the effects of the early postnatal treatment (from PND1 to PND8) of CD1 pups of both sexes with GEN (50 mg/kg body weight dissolved in sesame oil) or with the vehicle (control, CON) on the Kisspeptin system and other physiological parameters of 2 month-old mice. Kisspeptin was revealed by immunohistochemistry (antibody AC#566, Tours, France), and quantified (Image J) by calculating the Fractional Area (FA) covered by the immunoreactivity (in PVN, RP3V and ARC), and the positive cell number (in RP3V). Early postnatal exposure to GEN, in a dose comparable to the exposure level in babies fed with soy based formulas, induced sexually dimorphic effects. While GEN treated males showed only a minor decrease of testicles' weight, probably related to the significant decrease of testosterone's concentration we measured in feces ($P<0,001$), the treatment affected multiple parameters in females. GEN treatment induced an advanced pubertal onset in females (premature vaginal opening) and altered the development of reproductive system (increased urogenital distance and increased uterus' weight). In addition, GEN females showed an increased weight and an altered estrous cycle. Kisspeptin immunoreactivity was significantly reduced in adult GEN females compared to CON females (FA, RP3V, $P<0,01$; ARC, $P<0,001$; PVN, $P<0,001$; cell number, RP3V, $P<0,001$), whereas no changes were observed in males. In conclusion, the early postnatal exposure of CD1 mice to GEN determines long-term sex specific effects on the Kisspeptin system, female pubertal timing, fertility and metabolism.

Title: Sex differences in neural activation following different routes of oxytocin administration in awake adult rats

Authors: *K. M. DUMAIS[1], P. KULKARNI[2], C. F. FERRIS[2], A. H. VEENEMA[1];
[1]Psychology Dept., Boston Col., Chestnut Hill, MA; [2]Ctr. for Translational Neuroimaging, Northeastern Univ., Boston, MA

Abstract: The neuropeptide oxytocin (OT) regulates social behavior in sex-specific ways in humans and rodents. OT has been found to have promising effects on alleviating social deficits in patients with sex-biased neuropsychiatric disorders, however little is known about potential sexually dimorphic effects of OT on brain function. Therefore, using the rat as our model organism, we aimed to determine whether OT via central administration (most common in animal studies) or via peripheral administration (most common in human studies) induces sex differences in neural activation. Functional magnetic resonance imaging was used to examine blood oxygen level-dependent (BOLD) signal intensity changes in the brains of awake male and female rats over a period of 20 min after intracerebroventricular (ICV; 1µg/5µl) or intraperitoneal (IP; 0.1mg/kg) administration of OT. Following ICV OT administration, sex difference in BOLD activation were observed in 26 brain regions, with 20 regions showing higher activation in males, and 6 regions showing higher activation in females. Among these were the nucleus accumbens and insular cortex showing higher activation in males, and the lateral and central amygdala showing higher activation in females. Interestingly, compared to ICV OT, IP OT elicited fewer sex differences in BOLD activation (12 brain regions), but in the same overall direction as ICV OT, with all regions showing higher activation in males compared to females. Furthermore, sex differences in BOLD activation in response to IP OT were found in different brain regions than in response to ICV OT. Overall, these results indicate that exogenous OT modulates neural activation differently in males and females, and that the pattern and the magnitude of sex differences in BOLD activation depends on the route of administration. These results highlight the need to include both sexes in basic and clinical studies to fully understand the role of OT on brain function. This research is supported by NIMH F31MH100891 to KMD and NIMH R15MH102807 to AHV.

Title: Localization and characterization of the brain stress system in the toothed whales

Authors: *S. SACCHINI[1], C. BOMBARDI[2], M. ARBELO[1], A. FERNÁNDEZ[1], Y. BERNALDO DE QUIRÓS[1], J. DÍAZ-DELGADO[3], E. SIERRA[1], P. HERRÁEZ[1];
[1]Univ. Inst. of Animal Hlth. and Food Safety (IUSA), Univ. of Las Palmas De Gran Canaria, Arucas, Las Palmas de Gran Canaria, Spain; [2]Dept. of Vet. Med. Sci., Univ. of Bologna, Ozzano dell'Emilia, Bologna, Italy; [3]Dept. of Vet. Pathobiology, Col. of Vet. Med. and Biomed. Sci., Texas A&M Univ., College Station, TX

Abstract: Dolphins' brain is almost an undiscovered world due to the limited access to fresh brain samples. There is lack of information concerning neuroanatomy of cetaceans. Previous studies have demonstrated the susceptibility of cetaceans to post-capture stress during active strandings and in cases of entanglement in fishing gears. The elicited reaction (alarm reaction) is seen in live-stranded cetaceans as a capture-response characterized by massive catecholamine release from the adrenals glands (Cowan & Curry, 2008). A major alarm reaction-related pathologic outcome, in severe and prolonged events, includes degenerative cardiac lesions (Herráez et al., 2007, Cowan & Curry, 2008, Herráez et al., 2013), which appears to play a central role in this disease process. A major role of the central nervous system is also hypothetized. For a better understanding of the central control of the stress system, we identified some of its basic brain components: the amygdala with especial emphasis on the central nucleus of the amygdala (CeA), the paraventricular nucleus (PVN) and the supraoptic nucleus (SON) of the hypothalamus, and the *locus coeruleus* (LC). The CeA mediates the behavioral and physiological reactions associated with fear and anxiety and the hypothalamus-pituitary-adrenal responses by modulating brain corticotropin releasing factor (CRF) activity. The hypothalamus acts releasing the CRF, produced primarily by the parvicellular population of the PVN, as well as by the SON. The CRF acts as a neuromodulator in the brainstem and neocortical regions in stress responses. There are no published neuroanatomical references of these brain nuclei in toothed whales. The LC is the largest catecholaminergic nucleus and it supplies norepinephrine to the entire brain. The LC has only been examined in a bottlenose dolphin (Manger et al., 2003) to date. For the study of these nuclei, 13 animals of 8 different odontocete species were used: bottlenose dolphin, striped dolphin, common dolphin, Atlantic spotted dolphin, short-finned pilot whale, Risso's dolphin, Blainville's beaked whale, and Cuvier's beaked whale. Our results indicate that the CeA extended mainly dorsal to the lateral nucleus of the amygdala and ventral to the most ventral part of the *corpus striatum*. The PVN was located in the periventricular region of the hypothalamus, from the preoptic to the suprachiasmatic region. The SON extended from the preoptic area to the hypothalamic tuberal area. The LC was composed of five subdivisions: A6d, A6v, A7, A5, and A4. The examined animals presented the A4 subdivision, which had not been described in the only odontocete wherein this nucleus was investigated.

Title: Acute glycemic stressors differentially alter glutamatergic and GABAergic inputs to the neuroendocrine paraventricular nucleus of the hypothalamus in an intensity dependent manner

Authors: *C. S. JOHNSON[1], J. S. BAINS[2], A. G. WATTS[1];
[1]USC, Los Angeles, CA; [2]Univ. of Calgary, Alberta, AB, Canada

Abstract: Neuroendocrine corticotropin-releasing-hormone (CRH) neurons are found in the medial parvocellular part of the paraventricular nucleus of the hypothalamus (PVHmp). They are the final common pathway for adrenocortical stress responses. These neurons initiate hypothalamic-pituitary-adrenal (HPA) axis activity, resulting in glucocorticoid (GC) release from the adrenal cortex. GCs mobilize energy stores and provide negative feedback to CRH activity, among other modulatory responses. Along with GCs, CRH neurons are controlled by a variety of inputs, including catecholamines (CA), GABA, glutamate, and various peptidergic effectors. We have shown that CA-dependent mechanisms are required for a full HPA response to glycemic stressors, and that these mechanisms track stimulus intensity, in terms of release and synthesis. While we have a basic understanding of how neural inputs impact neuroendocrine CRH neurons, detailed structural and functional relationships remain unclear, particularly those conveying stimulus type and intensity. Clarifying these mechanisms and their interactions will provide a greater understanding of CRH regulation, in both health and dysfunction. To elucidate the mechanisms that control CRH activity, adult male rats received intravenous administration of either saline, insulin, or 2-deoxyglucose (2DG) through a jugular vein catheter. These three treatments generate increasing GC responses: saline<insulin<2DG. We used immunocytochemistry combined with high spatial resolution image analyses of pre-synaptic terminals in the PVHmp to determine what structural relationships exist between CA, glutamatergic, and GABAergic inputs, and how these inputs interact to differentially encode various acute glycemic stressors. This was done by analyzing the 3D spatial relationships between the CA markers DBH and PNMT, vesicular glutamate transporters 2 (VGluT2), vesicular GABA transporter (VGAT), phospho-Synapsin I (pSynI), and synaptophysin, as well as pERK1/2 and CRH.
We found that VGluT2 colocalizes with CA markers in PVHmp pre-synaptic terminals, significantly more so with PNMT than with DBH. We also found that acute glycemic challenges

have opposite effects on the number of detectable VGluT2 (increase) and VGAT (decrease) terminals in the PVHmp, as well as increasing the number of pSynI-labeled terminals. Additionally, the number of terminals expressing both pSynI and VGluT2 increased in response to 2DG. Overall, it appears as though acute glycemic challenges alter fast neurotransmitter input to the PVHmp in a way that favors excitation, as well as resulting in an activity-dependent increase in SynI phosphorylation.

Abstract: Wnt signaling through the transcriptional effector Lef1 is required for hypothalamic neurogenesis, however the specific cellular and molecular targets remain unknown. By analyzing homozygous null *lef1* zebrafish mutants, we find that Lef1 cell autonomously promotes the differentiation of multiple periventricular neuronal subtypes from Wnt-responsive progenitors. RNAseq analysis supports these results, showing decreased expression of known Wnt target genes and markers for defined neuronal subtypes that regulate anxiety. Indeed, we find that zebrafish *lef1* mutants display enhanced anxiety in a novel tank diving test, and gain weight more slowly than control siblings, consistent with elevated anxiety levels. Analysis of a hypothalamus-specific *Lef1* knockout mouse also shows defects in embryonic neurogenesis, with specific loss of hormone-secreting neurons. Similar to zebrafish, knockout mice gain weight more slowly than controls and display enhanced anxiety in open field and elevated plus maze tests. Together, these data suggest a conserved role for Lef1 in regulating the development of hypothalamic circuits that mediate anxiety. We believe that our genetic models may prove useful in clinical medicine for the diagnosis and treatment of anxiety-related mental disorders.

Title: The hypothalamic-pituitary-gonadal transcriptome of the rock dove and its response to capture-handling stress

Authors: *R. M. CALISI[1], S. H. AUSTIN[1], A. LANG[2], M. D. MACMANES[2];
[1]Neurobiology, Physiol. and Behavior, Univ. of California - Davis, Davis, CA; [2]Molecular, Cellular, and Biomed. Sci., Univ. of New Hampshire, Durham, NH

Abstract: Stress is a known inhibitor of reproductive function. The mechanisms by which stress acts to influence the hypothalamic-pituitary-gonadal (HPG), or "reproductive", axis have been intensely studied. Now, burgeoning high-throughput sequencing technologies are driving a genomic revolution that can permit one of the most in-depth investigations of the effects of stress on the HPG axis. We constructed an annotated *de novo* transcriptome assembly from male and female rock dove (*Columba livia*) hypothalamus, pituitary and gonadal tissues. We characterized patterns of expression for each, and, using a highly replicated RNAseq-type experiment, report differentially expressed genes and gene networks of the HPG axis in males and females after 30 minutes of capture-handling stress as compared to controls. These data provide an essential foundation for which future hypothesis-driven approaches and examinations of bidirectional interactions between genes and the stress response can occur.

Title: Activation of $5HT_{1A}$ receptors in the dorsomedial hypothalamus inhibits stress induced activation of the hypothalamic pituitary adrenal axis.

Authors: *C. STAMPER[1], J. E. HASSELL, Jr.[1], A. J. KAPITZ[1], K. J. RENNER[2], M. ORCHINIK[3], C. A. LOWRY[1];
[1]Univ. of Colorado Boulder, Boulder, CO; [2]Univ. of South Dakota, Vermillion, SD; [3]Arizona State Univ., Tempe, AZ

Abstract: Acute activation of the hypothalamic-pituitary-adrenal (HPA) axis, leading to the release of corticosteroid hormones into the circulation, is crucial for dealing with perceived threats. Paradoxically, persistent activation of this stress response can lead to impaired physiological or behavioral function. Thus, efficient control and termination of stress responses is also essential for well-being. However, inhibitory control mechanisms governing the HPA axis are poorly understood. Previous studies have suggested that serotonergic systems, acting within the medial hypothalamus, play an important role in inhibitory control of stress-induced HPA axis activity. To test this hypothesis, we surgically implanted chronic jugular cannulae in adult male rats and conducted bilateral microinjections of vehicle or the $5\text{-}HT_{1A}$ receptor agonist, 8-hydroxy-2-(di-n-propylamino) tetralin hydrobromide (8-OH-DPAT; 8 nmol, 0.2 μL, 0.1 μL/min, per side) into the dorsomedial hypothalamus (DMH) immediately prior to a 40 min period of restraint stress. Repeated blood sampling was conducted using an automated blood sampling system and plasma corticosterone concentrations were determined using enzyme-linked immunosorbent assay. Bilateral intra-DMH microinjections of 8-OH-DPAT suppressed stress-induced increases in plasma corticosterone immediately after the onset of restraint, and as measured by area-under-the-curve analysis of plasma corticosterone concentrations during the 40 min period of restraint. These data support an inhibitory role for serotonergic systems, acting within the DMH, on stress-induced activation of the HPA axis.

Title: Hypothalamic CRH neurons orchestrate complex behaviors after stress

Authors: *T. FUZESI[1], N. DAVIU[1], J. I. WAMSTEEKER CUSULIN[1], K. SIMONE[2], D. ROSENEGGER[1], K. MURARI[2], J. S. BAINS[1];

Abstract: All organisms possess innate behavioral and physiological programs that ensure survival. By definition, these programs are not learned, but in order to have maximum adaptive benefit, they must be sufficiently flexible to account for changes in the animal's environment. In mice a distinct behavioral repertoire emerges after a short exposure to stress that includes increased grooming, walking and rearing in a temporally organized fashion. This pattern is vastly influenced by the environment, however aspects such as increased arousal and the appearance of grooming are highly reliable. Classical electrical stimulation studies implicated the paraventricular nucleus of the hypothalamus (PVN) as a locus for rapid and intensive self-grooming behavior. The principal controllers of the neuroendocrine response to stress, corticotropin releasing hormone synthesizing (CRH) neurons are located in the PVN, raising the possibility that CRH neurons play a role in the organization of behaviors after stress. To address this we performed meticulous behavioral analysis combined with optogenetics utilizing a CRH-Ires-Cre mouse strain. We found that optical silencing of PVN CRH neurons after stressful exposure disrupts the emerging behavioral pattern, while in the absence of stress, photostimulation of CRH neurons partially recapitulated behaviors similar to those observed after stress. In a series of experiments utilizing electrophysiology and tract-tracing we identified a pathway from PVN CRH neurons to a subset of lateral hypothalamic cells and demonstrated that optical activation of this projection is sufficient to induce grooming behavior. Furthermore, we found that the environmental sensitivity on behavior is blunted by activation of PVN CRH neurons.

Title: Non-cannonical endocannabinoid-dependent ltd at hypothalamic gaba synapses

Authors: *P. L. COLMERS[1], J. S. BAINS[2];
[1]Neurosci., [2]Physiol. and Pharmacol., Univ. of Calgary, Calgary, AB, Canada

Abstract: Parvocellular neurosecretory cells (PNC) in the paraventricular nucleus of the hypothalamus (PVN) are tightly regulated by inhibitory tone, but the contributions of individual neuronal populations to these cells remains unclear. The fusiform nucleus of the bed nucleus of the stria terminalis (BNSTfu) represents a major source of inhibition to the PVN; here we characterized inhibitory inputs from the BNSTfu onto PNCs by injecting a rAAV2 containing channelrhodopsin tagged to an eYFP reporter directly into this region of VGAT-IRES-Cre mice. Fourteen days post-injection, coronal brain sections containing the PVN were prepared. Photostimulation of BNSTfu afferents in the PVN elicited synaptic currents in PNCs that both readily interrupted PNC spiking, and were completely abolished by application of the $GABA_A$ antagonist, gabazine. Previous reports have shown that depolarization of PNCs liberates endocannabinoids (eCB), which rapidly inhibit GABA release. This depolarization-induced suppression of inhibition (DSI) is transient and sensitive to stress. Similar protocols to assess eCB signaling in response to photostimulation of BNST GABA synapses revealed DSI that was significantly longer-lasting than DSI of synapses that are recruited following electrical stimulation. Peak DSI is not different when synapses are recruited optically or electrically (optical: 63.4±6.4% of baseline, n= 11 vs electrical: 60.9±4.2 % of baseline, n=8, $p>0.05$). Interestingly, synapses recruited by photostimulation fail to recover following postsynaptic depolarization (72.3±5.3% of baseline, n=11). The CB1R antagonist, AM251, blocked both phases of the synaptic depression. Since GABA and glutamate synapses onto PNCs are not spatially segregated, we hypothesized that liberation of glutamate, which occurs during bulk non-specific electrical stimulation of afferents but not during selective optical stimulation of GABA inputs, may be responsible for curtailing DSI. We conducted two sets of experiments: In the first, synapses were recruited by electrical stimulation in the presence of the mGluR5 antagonist, MTEP. Under these conditions, we observed long-term synaptic depression. Then we recruited GABA synapses with photostimulation in the presence of the mGluR agonist, DHPG. A postsynaptic depolarization now revealed a brief DSI that recovered completely within one

minute. These observations suggest that heterosynaptic actions of glutamate play a key role in controlling the temporal window of DSI. These actions may powerfully affect functional circuit connectivity in the brain.

Title: Homeostatic synaptic scaling as a response to HPA dysfunction

Authors: *N. RASIAH, N. DAVIU, J. S. BAINS;
Hotchkiss Brain Inst. - Univ. of Calgary, Calgary, AB, Canada

Abstract: Corticotropin-releasing hormone (CRH) neurons in the paraventricular nucleus of the hypothalamus (PVN) drive the neuroendocrine response to stress that culminates in an increase in circulating corticosteroids (CORT). This response is typically self-limiting, but pathological conditions associated with persistent elevations of CORT suggest the potential for escape from negative feedback. Here, we use a model of prolonged CORT exposure to examine the effects on the intrinsic and synaptic properties CRH neurons in the PVN. To examine the mechanisms of CORT feedback, mice were given access to 25µg/ml CORT in the drinking water for up to 7 days. In addition to monitoring plasma CORT levels, we assessed a number of electrophysiological parameters *ex-vivo* including, basal firing rate, paired-pulse ratio (PPR), AMPA:NMDA, and quantal glutamatergic event frequency and amplitude. Following CORT treatment, mice exhibited a blunted CORT response to a 15min swim stress (19.3 ng/ml ± 5.29 CORT (n=10) vs 98.6 ng/ml ± 13.7 naïve (n=12), p = 0.0002). We then used on-cell and whole-cell electrophysiology to study CRH neuron activity and synaptic properties respectively. Following the 7 day CORT treatment, there was a decrease in the firing rate of CRH neurons (0.248Hz ± 0.086 CORT (n=16) vs 3.13Hz ± 0.380 naïve (n=23), p<0.0001). Interestingly, there was an increase in mEPSC amplitude (naïve: 21.4 ± 0.8 pA (n=12) vs CORT: 26.1 ± 0.9 pA (n=12), p = 0.0026) with no effect on mEPSC frequency (naïve: 5.6 ± 1.00 Hz (n=12), vs CORT: 4.7 ± 0.81 Hz (n=12), p=0.467), AMPA:NMDA (naïve: 2.62 ± 0.261 (n=9) vs CORT: 2.72 ± 0.24 CORT (n=6), p=0.81), or PPR (naïve: 0.78 ± 0.058 (n=9) vs CORT: 0.81 ± 0.058 (n=6), p= 0.74). The decrease in firing accompanied by increased glutamatergic strength is reminiscent of

homeostatic changes in synaptic drive that have been reported following persistent activity blockade. To determine if there is a multiplicative increase in glutamatergic synaptic strength consistent with synaptic scaling, we compared cumulative distributions from naïve and CORT treated animals. We observed a significant rightward shift in the distribution of mEPSCs following CORT treatment ($p<0.0001$) that was completely reversed by applying a single scaling factor (1.33) to the amplitude distribution. This is one of few accounts of homeostatic synaptic scaling in adult animals *in-vivo*, and is the first to establish a role for homeostatic plasticity in neural stress circuits. These observations also provide new insights into the neuronal mechanisms that may contribute to altered hypothalamic-pituitary adrenal axis activity observed in affective pathologies.

Title: Alternative mechanisms forHPA axis regulation following selective paraventricular nucleus (PVN) deletionof estrogen receptor beta 3rd exon

Authors: *M. G. OYOLA[1], A. ACEVEDO-RODRIGUEZ[3], A. M. MALYSZ[3], D. CARBONE[4], S. K. MANI[3], R. J. HANDA[2,4];
[1]Neurosci., [2]Colorado State Univ., Fort Collins, CO; [3]Baylor Col. of Med., Houston, TX; [4]Univ. of Arizona, Phoenix, AZ

Abstract: The Hypothalamo-Pituitary-Adrenal (HPA) axis is controlled by a complex network of brain regions, that are integrated at the level of the PVN to coordinate an appropriate response to stressors. The PVN is the main integratory node of the HPA axis and it expresses estrogen receptor beta (ERβ) at high levels; activation of which has been shown to decrease HPA axis response to stress. In this study, we aimed to elucidate the actions of ERβ in the PVN in male and female mice. For this, we used a Sim1-Cre transgenic mouse crossed to a reporter line where loxP flanked the ERβ 3rd exon to target the deletion of the 3rd exon of ERβ to Sim1-Cre-

expressing neurons, which are densely present in the PVN. Immunohistochemistry of these mice (ERβCKO) showed complete knockout of ERβ in the PVN, but not in other brain areas that express Sim1. Interestingly, although the ERβ 3rd exon codes for the downstream half of the DNA binding domain utilized in classical estrogen response element (ERE) signaling pathways, treatment of mice with the ERβ selective agonist, R-DPN (1 mg/kg BW for 4 days), still reduced the corticosterone (CORT) to restraint stress, albeit with slightly less efficacy in the ERβCKO mice compared to WTs. These data suggest that the DNA binding domain is not required for ERβ signaling within the PVN, at least in the control of HPA axis function. Furthermore, deletion of ERβ 3rd exon resulted in an increase in exon 4-8 transcripts which corresponds with the ability of the 3rd Exon deletion variant to utilize an activator complex-1 (AP-1) mediated signaling pathway rather than ERE-dependent signaling *in vitro*. Alternatively, the PVN receives inputs from the bed nucleus of the stria terminalis (BnST), a region that serves as a major information hub, to inhibit the HPA axis. Using a CRH-cre mouse crossed to a loxP-STOP-loxP-TdTomato reporter strain (Ai14), we found a large cluster of CRH neurons in the BnST. IHC using the Z8P ab against ERβ showed that over 23% of BnST CRH neurons expressed ERβ. Moreover, in the mouse PVN, 31% of CRH neurons also express ERβ. Thus, BnST may serve as a limbic-PVN bridge, integrating excitatory signals from upstream brain sites. In turn, the BnST uses GABAergic or CRH projections to the medial parvocellular PVN, to regulate the HPA axis. These findings suggest a potential ERβ-ergic circuit involving BnST and PVN CRH neurons, and also give insight to an alternative ERβ signaling pathway that may rely on AP-1 mediated transcriptional activation, potentially through the recruitment of ERβ splice variants encoded by exons downstream of the 3rd exon.

Title: Molecular characterization of oxytocin neurons in the paraventricular nucleus and supraoptic nucleus of the hypothalamus

Authors: *J. GUO[1,2,3], A. MENIGOZ[1,2,3], D. G. RAINNIE[1,2,3];
[1]Dept of Psychiatry, [2]Silvio O. Conte Ctr. for Oxytocin and Social Cognition, [3]Ctr. for Translational Social Neuroscience, Yerkes Natl. Primate Res. Ctr., Emory Univ., Atlanta, GA

Abstract: The nanopeptide neurotransmitters oxytocin (OT) have been shown to play a role in modulating aspects of social behaviors, including social recognition, pair bonding, maternal behaviors, and anxiety. Dysfunction of OT system is believed to play a role in the pathophysiology of autism. The main source of OT in the brain is the magnocellular cells in the paraventricular nucleus (PVN) and supraoptic nucleus (SON) of the hypothalamus. Although previous electrophysiological studies have identified two subtypes of OT neurons in the PVN and SON, it is unclear if these two groups also differ in their neurochemical profile. To address this knowledge gap, we have used patch clamp recording in conjunction with single cell quantitative PCR, and immunohistochemistry to examine the physiologic and genetic phenotype of OT neurons in the SON and PVN. The majority of magnocellular neurons in the SON (79%) and PVN (83%) express the mRNA for OT, which is consistent with our immunofluorescence observations. In agreement with earlier studies OT neurons of the PVN and SON could be subdivided into two electrophysiological subtypes based on their intrinsic membrane properties. Hence, 27% PVN and 54% SON OT neurons have prominent outward rectifying potassium current ($I_{K(OR)}$) and delayed firing, whereas the rest of neurons have fast-onset firing. OT neurons in both areas have high expressions of mRNA for CRFR2, vGluT2, CaMKIIα, and low expressions of mRNA for vasopressin, CRFR1, OTR and vGluT3. Both PVN and SON OT neurons express mRNA for multiple subtypes of 5-HT receptor, including 5-HT1a, 5-HT1b, 5-HT2a and 5-HT7. However, 5-HT3a expression was only detected in PVN OT neurons and 5-HT2C was not detected in neurons from both nuclei. Genes encoding low threshold calcium current (I_T) are differently expressed in PVN and SON OT neurons, with Cav3.2 only detected in PVN neurons and Cav3.3 only detected in SON neurons. Taken together, OT neurons in the PVN and SON may contain heterogeneous cell types. Moreover, our preliminary data show potential transcriptomic differences between the PVN and SON OT neurons. We are now screening mRNAs for encoding intrinsic ion channels and and will expand this study to autistic animal models to understand mechanisms of autism disorders and find new therapy targets.

Title: Glucagon-like peptide 1 receptor (GLP1R) signaling promotes excitation of limbic forebrain neurons innervating the hypothalamic paraventricular nucleus (PVN)

Authors: N. V. POVYSHEVA[1], H. ZHENG[1], *L. M. RINAMAN[2];
[1]Dept. of Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Univ. of Pittsburgh Dept. of Neurosci., Pittsburgh, PA

Abstract: Physiological and behavioral stress responses are generated, in part, by neural signaling within the anterior ventral bed nucleus of stria terminalis (avBST) and the hypothalamic PVN. The avBST innervates the PVN, and both regions receive relayed visceral sensory input from stress-responsive hindbrain GLP1 neurons. Since central GLP1 signaling promotes stress responses, we hypothesized that GLP1 acts specifically on avBST neurons that innervate the PVN. To test this, red fluorescent retrobeads were stereotaxically injected into the PVN in young adult male rats. One week later, whole-cell recordings were made in red-labeled and unlabeled neurons in brain slices containing the avBST. The synthetic GLP1 analogue Ex-4 (200-600 nM) was bath applied to activate GLP1R's. To assess Ex-4 effects on neuronal excitability, cells were recorded in current-clamp mode and shifts in baseline and intrinsic membrane properties were quantified. Ex-4 produced an upward baseline shift in labeled ($p<0.01$; n=9) but not in unlabeled neurons ($p>0.1$; n=7). This specific effect was occluded by the GLP1R antagonist Ex-9 (900 nM; n=5). Ex-4 also decreased medium and slow afterhyperpolarizations in labeled neurons ($p<0.01$; n=6). Ex-4 did not affect the amplitude or frequency of sEPSCs (-70 mV holding potential, 10 mM gabazine in Cs-based intracellular solution), but decreased the frequency of sIPSCs (+12 mV holding potential, 10 mM CNQX, 50 mM AP-5; 10.6±4.5 Hz vs. 7.7±3.9 Hz, $p<0.05$; n=7). Thus, GLP1R activation increases neural excitability and reduces inhibitory drive to PVN-projecting avBST neurons, consistent with GLP1 effects to promote centrally mediated stress responses.

Title: Sexual diergism in rat hypothalamic-pituitary-adrenal axis responses to the selective muscarinic antagonists pirenzepine and methoctramine prior to cholinergic stimulation by physostigmine

Authors: *M. E. RHODES[1], M. A. SMAIL[1], C. A. WYLIE[1], J. L. SOLES[1], R. K. CZAMBEL[2], R. T. RUBIN[3];
[1]St. Vincent Col., Latrobe, PA; [2]Allegheny Gen. Hosp., Pittsburgh, PA; [3]VA Greater Los Angeles Healthcare Syst., Los Angeles, CA

Abstract: Central cholinergic systems regulate the hypothalamic-pituitary-adrenal (HPA) axis differentially in males and females (sexual diergism). We previously reported that plasma adrenocorticotropic hormone (ACTH) and corticosterone (CORT) concentrations were enhanced by physostigmine (PHYSO), an acetylcholinesterase inhibitor, in male and female rats pretreated with scopolamine (SCOP), a non-selective muscarinic antagonist. ACTH responsiveness to SCOP was greater in males than in females. CORT responsiveness to SCOP was greater in females, but percent increases over baseline were greater in males. These results suggested that the SCOP + PHYSO effects may have resulted from an indirect nicotinic effect caused by muscarinic antagonism, and/or differential effects of SCOP antagonism on M1 vs. M2 receptors. In the present study, we explored specific muscarinic influences on HPA activity in male and female rats by determining the dose-response effects of pretreatment with (1) the M1-selective muscarinic antagonist, pirenzepine (PIREN), followed by PHYSO (PIREN + PHYSO), and (2) the M2-selective muscarinic antagonist, methoctramine (METHO), followed by PHYSO (METHO + PHYSO). Control and comparison groups included rats pretreated with SCOP or saline, followed by PHYSO or saline. Blood sampling occurred before and at intervals after PHYSO or saline. ACTH and CORT were determined by highly specific immunoassays. PIREN + PHYSO resulted in dose-dependent increases in ACTH and CORT in both male and female groups, which were sustained at all time points. METHO + PHYSO resulted in higher ACTH responses in the female groups and had little effect in the male groups. CORT responses to METHO + PHYSO were modest, slightly higher in female groups, and less sustained following treatments.
The results of the present study support our previous findings with SCOP + PHYSO and provide additional evidence to support the hypothesis that muscarinic pretreatment prior to PHYSO results in an indirect nicotinic effect that enhances HPA responses. Whereas SCOP + PHYSO produced higher HPA responses in males, PIREN + PHYSO produced similar responses in males and females, and METHO + PHYSO produced higher responses in females. These results suggest that muscarinic cholinergic receptor subtypes can influence HPA axis activity differentially in male and female rats (sexual diergism).

Title: Channelrhodopsin-assisted circuit mapping of medial amygdala connectivity to the paraventricular hypothalamus

Authors: *C. D. ADAMS[1], J. YEOH[1], E. J. CAMPBELL[1], J. S. BAINS[2], B. A. GRAHAM[1], C. V. DAYAS[1];
[1]Univ. of Newcastle, Newcastle, Australia; [2]Univ. of Calgary, Calgary, AB, Canada

Abstract: The amygdala plays a central role in the generation of adaptive responses to stressful stimuli including modulation of the hypothalamic-pituitary-adrenal (HPA) axis. Previous work using traditional axon sparing lesions has determined that an intact medial amygdala (MeA) is necessary for HPA axis responses to psychological stressors (noise, restraint) whereas, in the case of physiological stressors (haemorrhage, immune challenge) this role is served by the central nucleus of the amygdala (CeA). These actions are thought to be mediated by parallel relays via the bed nucleus of the stria terminalis (BNST) or the nucleus of the solitary tract (NTS). However, we have previously identified, using tract tracing, the existence of a direct, psychological stressor-sensitive projection from the MeA to the medial parvocellular paraventricular nucleus (mpPVN). Here, using a targeted optogenetic approach, we investigated MeA mediated control of mpPVN neuroendocrine cells through this putative direct projection. Adult male Sprague-Dawley rats (n= 25) were prepared with bilateral, MeA targeted injections of the light-sensitive cation channel, channelrhodopsin-2 (AAV5-CaMKIIa-hChR2(H134R)-EYFP or AAV5-hSyn-hChR2(H134R)-EYFP) or control virus (AAV5-EYFP) with a subset receiving bilateral MeA fiber optic probes (n= 16). Animals were then allowed a 7 week incubation period. In experiment 1, AAV-ChR2 and AAV-EYFP animals implanted with fiber optic probes received blue light stimulation (473 nm, 20 Hz, 30 s on and 30 s off × 30) and after 1.5 hours were overdosed with anaesthetic and brains processed for Fos-protein immunohistochemistry. In experiment 2, AAV-ChR2 animals were sacrificed and slices of the hypothalamus incorporating the PVN were prepared for whole cell patch clamp electrophysiology and an examination of blue light evoked (473 nm, 5ms pulses) post-synaptic currents.
Blue light delivered to the MeA in behaving animals significantly increased numbers of Fos-positive cells in the MeA ($p < 0.05$) and mpPVN ($p < 0.05$). In hypothalamic slices, blue light stimulation evoked post-synaptic currents in 41% of recorded neurons (n= 24/58). 22% of these neurons received excitatory inputs (CNQX-sensitive), 12% received inhibitory inputs (picrotoxin-sensitive) while 7% received both excitatory and inhibitory inputs. Together our

findings demonstrate a functionally relevant direct projection from the MeA to PVN capable of eliciting direct control over of the apex of the HPA axis.

Title: Dominance relationships in Syrian hamsters modulate neuroendocrine responses to stress

Authors: *B. N. DULKA, R. KOUL-TIWARI, J. A. GRIZZELL, A. V. CAMPBELL, S. DATTA, M. A. COOPER;
Univ. of Tennessee, Knoxville, TN

Abstract: Stress is a well-known risk factor for psychopathology, and rodent models of social defeat stress have strong face, construct, and predictive validity for these conditions. One example of striking behavioral changes that result from social defeat occurs in Syrian hamsters. Male Syrian hamsters are highly aggressive and territorial animals, but after a social defeat experience they become submissive and no longer defend their home territory, even from a smaller, non-aggressive intruder. This defeat-induced change in social behavior is called conditioned defeat (CD). We have shown that dominant hamsters exhibit less submissive and defensive behavior at testing compared to subordinates, which indicates that they show a reduced CD response. Dominant animals also exhibit increased neural activity in the ventromedial prefrontal cortex following social defeat stress compared to subordinates. Although the ventromedial prefrontal cortex can inhibit the neuroendocrine stress response, it is unknown whether dominant and subordinate hamsters differ in stress-induced activity of the extended hypothalamic-pituitary-adrenal (HPA) axis. In this study, we paired male Syrian hamsters in daily agonistic encounters for 2 weeks, during which they formed stable dominance relationships. Twenty-four hours after the last pairing animals were exposed to acute social defeat stress. After social defeat tissue was collected from the central/basolateral amygdala (CeA/BLA), bed nucleus of the stria terminus (BNST), and paraventricular nucleus of the hypothalamus (PVN). Blood plasma was also collected following social defeat stress. Preliminary data indicate that dominant and subordinate hamsters do not significantly differ in

plasma cortisol concentrations. Quantitative reverse transcription PCR (qRT-PCR) is being used to test for status-dependent changes in defeat-induced CRH mRNA expression. We predict that dominant hamsters will show reduced CRH mRNA expression in the CeA/BLA and BNST compared to subordinates and controls.

Abstract: There have been mixed findings regarding how stress influences false memory development. Depending on the type of stress and when it is administered relative to learning or memory testing, stress can increase, decrease or have no effect on false memory. Previous work has shown that stress exerts a biphasic effect on learning and memory. After stress, there is an immediate excitatory phase, during which learning is enhanced, followed by a delayed inhibitory phase, during which learning is impaired. In light of this time-dependent relationship between stress and learning, we predicted that stress administered immediately prior to learning would enhance the ensuing memory and protect it from being distorted by misinformation, thus preventing false memory development. In the present study, participants submerged their non-dominant hand in a bath of ice cold (stress) or warm (no stress) water for 3 min. Then, they watched an 8-min clip from the Disney movie *Looking for Miracles*. The next day, participants were interviewed and asked to answer several questions about the movie, some of which were false-event questions that forced participants to confabulate answers. Participants completed a recognition test about the movie three days later and then completed a free recall test three weeks

after that. Overall, the results revealed a misinformation effect - that is, participants falsely identified information that they confabulated during the interview as actually having occurred during the movie. Stress, overall, did not have a significant effect on this result. However, stressed participants exhibiting a blunted cortisol response to the stressor (i.e., cortisol non-responders) did not display the misinformation effect. These results suggest that an autonomically-driven stress response, without a concomitant cortisol increase, may protect memories from being distorted by misinformation.

Title: Optogenetic induction of plasticity in the medial prefrontal cortex to study mechanisms of stress-related cognitive dysfunction in rats

Authors: *S. E. BULIN, D. J. LODGE, D. A. MORILAK;
Pharmacol., UT Hlth. Sci. Ctr. at San Antonio, San Antonio, TX

Abstract: Stress-related mood and anxiety disorders, like depression and PTSD, are highly prevalent yet poorly treated. Relapse and residual symptoms remain problematic, and a poor understanding of the neurobiology underlying these illnesses has limited the development of new treatments. One brain region detrimentally affected in stress-related mood and anxiety disorders is the medial prefrontal cortex (mPFC). This is associated with deficits in executive function, including impaired cognitive flexibility. We have shown previously that chronic unpredictable stress (CUS) induces a deficit in cognitive flexibility and attenuates the mPFC Fos response to afferent stimulation of the mediodorsal thalamus (MDT). We hypothesize that cognitive flexibility requires neural plasticity in the mPFC and that chronic stress disrupts that plasticity. Thus, in ongoing experiments we are recording electrical responses evoked in the mPFC by stimulation of the MDT before and after CUS, to gain insight into mechanisms underlying the cognitive deficit and mPFC hyporeactivity previously shown. In addition, we will explore if directly potentiating evoked responses after CUS will be sufficient to restore healthy behavior.

However, it has not yet been demonstrated that plasticity can be induced in the mPFC by optogenetic stimulation of the MDT afferent, the purpose of the present experiment. We selectively infected glutamatergic neurons in the MDT with the ChETA variant of blue light-sensitive excitatory channelrhodopsin using an AAV5-CAMKII-ChETA-YFP viral vector. After 6 weeks to allow expression and trafficking of the channel to mPFC terminals, rats were anesthetized with chloral hydrate and baseline field potentials evoked by MDT stimulation were recorded in the mPFC for 15 min at 75% of maximum response. Optical LTD was induced by stimulating terminals with 900 pulses of 493 nm blue light, 2 msec pulse width at 1 Hz, for 15 min. The mean amplitude of evoked responses recorded for 3 hr after stimulation was 75% of baseline, indicating a depressed response. In other animals, optical LTP was induced by stimulating the terminals with 5 x 1 sec trains of light, each consisting of 100 pulses, 2 msec pulse width, at 100 Hz, with 3 min between trains. The mean amplitude of evoked responses recorded for 3 hr was 138% of baseline, indicating potentiation of the MDT-mPFC pathway. Thus, using these procedures, optogenetic induction of both LTP and LTD will allow for future experiments to explore if directly inducing plasticity in the mPFC will restore cognitive flexibility compromised by CUS.

Title: Psychosocial stress induces oscillatory activity changes during an attentional task reflecting different cognitive strategies.

Authors: *I. PALACIOS[1], M. VILLENA[1], G. CAMPOS[1], C. ARTIGAS[1], J. SILVA[2], E. RODRIGUEZ[1];
[1]Pontificia Univ. Catolica De Chile, Santiago, Chile; [2]Univ. del Desarrollo, Santiago, Chile

Abstract: One of the most important cognitive function on driving cognition is attention. Attention is being constantly reoriented by means of either top-down or bottom-up factors in a process that can be referred as attentional control. Some studies have suggested that stress-related states like anxiety can disturb the balance between those factors. However the neural mechanism underlying these changes and their potential relationship with different components of the stress response (Physiological/Psychological stress), has not been completely elucidated. Here we search for neural correlates of psychosocial stress during an attentional task and the possible differential influences of the stress components separately. 42 healthy participants were exposed to either an electroencephalogram-compatible version of the Trier Social Stress Test (TSST) or a control protocol. Additionally, immediately before and after those protocols, participants performed an attentional task. The induced stress response was verified by measuring changes on heart rate, salivary cortisol concentration and the score in the STAI scale (state version). As expected, psychosocial stress induced an increase of salivary cortisol, heart rate and self-reported anxiety. Additionally, we found a reduction in accuracy for stress group in the attentional task. Interestingly, when correct trials between groups after both protocols were compared, correct trials in the control group were associated with an increase of gamma activity (30-65 Hz), usually involved in highly focalized performances. Conversely, correct trials of stress group correlated with an increase of beta activity (12-30 Hz), which is associated with continuous top-down monitoring. Finally, we found that beta band activity correlates positively with the state of anxiety and negatively with attentional accuracy. We showed that psychosocial stress induces behavioral changes that are reflected on the oscillatory activity. Moreover, both attentional accuracy and anxiety acquisition were directly related with beta band activity. Our results suggest that both groups achieve correct trials by different ways, while participant of the control group were effortless, highly focused on the task, stress group was constantly self-regulating in order to maintain the attention on task. Further research evaluating neural oscillations and its relation with psychosocial stress and cognition is necessary to better understand the brain mechanisms underlying psychosocial stress effects.

Title: Enhanced neuronal activity in monkey amygdala during goal-directed behavior in stressful environments

Authors: *K. MAEDA[1], O. HIKOSAKA[1,2];
[1]Lab. Sensorimotor Res., Natl. Eye Inst., Bethesda, MD; [2]Intramural Res. Program, Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: In some cases, our performance improves in stressful environments (e.g., emergency, close deadlines, fight-or-flight). For decades, amygdala research has been dominated by Pavlovian fear-conditioning paradigms, and has focused on the negative responses such as defensive behavior (freezing or escape). Accordingly, the neural mechanism that improves our behavior and motivation in stressful environments is still largely unknown.
To address this question, we devised a new behavioral procedure (Invader Task) in which the subject (macaque monkey) chose a good object (associated with a reward) and avoided a bad object (associated with no reward) in a particular scene (or environment). The monkey quickly learned to choose good objects in many scenes (n=56). Importantly, the scenes induced different levels of stress, because an invader may appear in some scenes (n=40), but not others (n=16). There were 3 types of invader depending on the scenes: distractor (no action, n=16), robber (trying to remove good object, n=8), and attacker (trying to remove good object and deliver airpuff, n=16). We recorded internal and external body behaviors (heart rate, pupil size, and saccade eye movements) and electrical activity of single neurons in the amygdala while the monkey performed this task.
The stress level varied among the environments: Heart rate and pupil diameter increased more strongly in the environments where more stressful invaders (attacker/robber) would appear. Yet, the monkey's performance (choice accuracy, reaction time) was better in more stressful environments. Some of amygdala neurons (n=13/37) were significantly active in more stressful environments. Typically, these neurons started firing tonically when a stressful scene appeared, increased activity in anticipation of the invader, and sometimes responded strongly to good and/or bad objects. Their activity was usually stronger in the attacker/robber-scenes than the distractor-scenes or the no-invader-scenes.
To summarize, both internal and external body behaviors were enhanced in stressful environments, and amygdala neurons changed their activity correspondingly. Our data suggests that the amygdala may play an important role in controlling both internal and external body behaviors to achieve rewarding outcomes in dangerous environments.

Title: Corticotropin releasing factor regulation of forebrain cholinergic nuclei impairs attention and learning in rats

Authors: *K. WIERSIELIS, B. WICKS, S. COHEN, M. SALVATORE, J. BERGMANN, N. DUNCAN, H. LEFEBO, D. BANGASSER;
Temple Univ., Philadelphia, PA

Abstract: Stress can disrupt a variety of cognitive processes, including learning, memory, and attention. Previous studies in rodents have demonstrated that central infusions of the stress-neuropeptide, corticotropin releasing factor (CRF), can disrupt mnemonic processes and different aspects of attention. However, where CRF is working within the brain to regulate cognition is largely underexplored. Candidate regions for direct CRF regulation include the nucleus basalis of Meynet (nbM) and medial septum (MS), because these forebrain cholinergic nuclei are critical for attention and learning, respectively, and both contain CRF receptors. Here we begin to assess whether administering CRF directly into these regions impairs cognitive processes in rats. In the first study, we assessed attention by training male and female rats on an operant sustained attention task in which they had to discriminate visual signals from non-signaled events. After attaining criterion (70% correct responses on signal and non-signal trials), one of two doses of CRF (30ng, 100ng) or vehicle (artificial cerebral spinal fluid) were administered directly into the nbM 10-min prior to the task onset. The doses were administered in a counterbalanced fashion using a within-subjects design (successive infusions were separated by at least a week). In both male and female rats, the high dose of CRF significantly reduced average response accuracies and vigilance index (a measure of overall attentional performance), supporting our hypothesis that CRF in the nbM impairs sustained attention. The second, ongoing study is designed to investigate whether CRF in the MS disrupts spatial learning, which is modulated by the cholinergic neurons found in this region. To this end, we are administering CRF or vehicle into the MS prior to testing on an object location task, in which rats are presented with two objects to explore (5 min) and then after a 5 min delay, one object is moved to a new location. Our preliminary data suggest that CRF directly infused into the MS reduces time spent exploring the displaced object, suggesting that this manipulation impairs spatial learning. Together, the studies reveal that direct infusions of CRF into forebrain cholinergic nuclei can impair attention and

learning, highlighting an unexplored mechanism by which stress can regulate cognition. Clinically, these findings suggest that drugs that block the effects of CRF represent a viable therapeutic option to treat cognitive deficits that characterize certain stress-related psychiatric disorders.

Title: Decreased expression of SGK1 in medial prefrontal cortex increases vulnerability to uncontrollable stress, resulting in cognitive impairments

Authors: *J.-C. PARK, D.-H. CHOI, J.-S. HAN;
Konkuk Univ., Seoul, Korea, Republic of

Abstract: Exposure to uncontrollable stress leads cognitive impairments observed in post-traumatic stress disorder (PTSD) and major depressive disorder (MDD). Recent study reported that serum- and glucocorticoid-regulated kinase 1 (SGK1) expression is down-regulated in the postmortem dorsolateral prefrontal cortex in patients with PTSD and rats with inhibition of SGK1 in the medial PFC (mPFC) show helplessness- and anhedonic-like behaviors. However, it is unknown whether the altered SGK1 signaling could increase the susceptibility to uncontrollable stress-memory deficits. Therefore, the present experiment was conducted to examine whether decreased expression of SGK1 affect the susceptibility to uncontrollable stress induced-memory impairments. Rats received injections of adeno-associated virus (AAV) particles expressing SGK1-shRNA or scramble-shRNA into mPFC. After 3-4 weeks, rats were received either 20-min restraint + 20 tail shock, which is ineffective in inducing memory impairments, or 60-min + 60 tail shock resulting in memory impairment. Cognitive status of these animals was examined using hippocampus-dependent hidden platform version of the water maze task. Rats with scramble-shRNA/AAV or SGK1-shRNA/AAV injections showed 60-min uncontrollable stress-memory deficits compared to unstressed animals. Whereas 20-min stress did not affect the acquisition and retention of spatial memory in rats with the scramble-shRNA/AAV injections, the 20-min stress reliably impaired the acquisition and retention spatial

memory in the SGK1-shRNA/AAV injected-rat. These findings suggest that altered SGK1 signaling in the mPFC might increase vulnerability to stress and contribute the behavioral phenotypes associated with stress pathophysiology like PTSD. Title: Effects of the JAK-STAT3 activator CNTF on cognitive flexibility and markers of plasticity in the orbitofrontal cortex

Authors: *M. GIROTTI, D. A. MORILAK;
Pharmacol., Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX

Abstract: Cognitive flexibility is the ability to modify established behaviors or previous learning in response to a change in the environment, for example, by a change in stimulus-reward contingency. Reversal learning is a specific form of cognitive flexibility predominantly mediated by the orbitofrontal cortex (OFC). Our laboratory has shown that rats exposed to chronic intermittent cold stress (CIC, 6h per day at 4°C for 2 weeks), exhibit a selective and replicable cognitive deficit in reversal learning that resembles cognitive components of stress-related psychiatric illnesses.
In previous work, we have found that endogenous activity of the JAK/STAT3 pathway in the orbitofrontal cortex is required for optimal performance on a reversal learning task under basal conditions. Moreover, we have observed that JAK/STAT3 is required for basal expression of the synaptic plasticity protein, Arc. In the present study, we determined whether ciliary neurotrophic factor (CNTF), an endogenous activator of JAK/STAT3 signaling in the brain that is known to exert pro-survival effects on both neurons and oligodendrocytes, has the capacity to increase Arc expression in primary cortical neurons in culture. We found that that administration of 5nM CNTF to primary neuronal cultures significantly activated JAK2 and STAT3 15 min post-stimulation, and increased the levels of Arc expression at 60 min, suggesting that CNTF is

capable of inducing plasticity in neurons. In ongoing experiments in vivo, we are testing the effects on reversal learning of blocking CNTF within the OFC with a neutralizing antibody. We anticipate that blockade of CNTF-mediated JAK/STAT signaling will reduce Arc expression in the OFC and impair reversal learning. In future experiments we will test if CNTF administration directly into the OFC reverses the CIC stress-induced cognitive deficit. These studies will test the potential utility of targeting endogenous JAK/STAT3 signaling as a novel approach to treating cognitive impairment in stress-related psychiatric disorders.

Title: The cognitive neurobiology of caregiver stress: impact of psychological interventions on impaired memory and attention

Authors: *G. CLARKE[1], A. P. ALLEN[1], A. NÍ CHORCORÁIN[2], J. WALL[1], P. KEARNEY[1], J. F. CRYAN[1], T. G. DINAN[1], D. W. MOLLOY[1];
[2]Ctr. for Gerontology & Rehabil., [1]Univ. Col. Cork, Cork, Ireland

Abstract: Introduction: Demographic shifts in the global population highlight the increasing need for caregivers in an aging society. There is emerging evidence that the chronic stress of caregiving for a relative with dementia may impact upon central nervous system activity in caregivers, but this remains a poorly understood area. The current study aimed to examine the cognitive neurobiology in parallel with the psychological impact of this chronic stressor in a cohort of family dementia caregivers. **Methods:** Ethical approval was obtained from the Clinical Research Ethics Committee of the Cork Teaching Hospitals. Caregivers for a spouse or parent with dementia (N = 31) and controls with low-moderate perceived stress (N = 18) completed cognitive tasks from the CANTAB battery assessing memory, attention and executive function, as well as validated tests of stress and depression. These measures were completed again in a sub-set of caregivers (N = 7) following two psychological interventions (a mindfulness-based stress reduction program; MBSR and a carer training program; CTP). **Results:** Our preliminary

study results suggest the presence of higher levels of stress and depressive symptoms in caregivers compared to controls. Caregivers made a higher number of errors on the paired associates learning task, which engages the hippocampus, suggesting poorer visuospatial memory. Caregivers also had slower response latency on a test of sustained attention (rapid visual information processing). Following both MBSR and CTP, carers performed better at both of these cognitive tasks. **Conclusions:** Caregivers for people with dementia show a subtle but significant impairment in attention and memory performance. However, this impairment may be attenuated following psychological interventions that target stress. A comprehensive physiological phenotyping of dementia caregivers before and after intervention is required to better understand the mechanisms of these effects.

Abstract: Posttraumatic stress disorder (PTSD) usually occurs after being exposed to a very traumatic event, it can be conceptualized with three main features: 1) a response to a toxic exposure that becomes generalized and maladaptive, 2) failure in "recovery" systems, and 3) a failure of extinction learning (Ursano, Zhang, Li, Johnson, Carlton, Fullerton and Benedek 2009). It also implies anatomical changes in the Central Nervous System, particularly in the hippocampus, amygdala and prefrontal cortex (Tovote, Fadok and Lüthi, 2015). Animal Models of PTSD have an important value in research because allow us to understand the pathophysiology of the disorder and provide us the possibility of developing new treatments and more effective prevention strategies. This study explores an unpredictable chronic stress protocol as a model of PTSD in laboratory animals. It were used 20 male Wistar rats (300 grams at the beginning of the experiment) in standard laboratory conditions. 10 rats were randomly selected to the 10 day protocol of stress that included stressors as restriction of movement, wet bed, forced swimming in cold water and constant light. The other 10 rats were kept in their home cages as a control group. It was used a full battery of evaluation that included tests of cognition (Barnes maze and object recognition), anxiety (zero maze and open field) and emotion (sucrose consumption and forced swimming), and an anatomical analysis of Golgi staining in hippocampus for both groups. The results show statistical differences in the performance of all the tests and significant differences in morphology between the experimental and the control group. We discuss the relevance of the protocol as a model of PTSD in both behavioral and anatomical levels.

Title: Trauma history and recent life stress predict functional connectivity between the amygdala and the anterior cingulate at rest and in response to affective scenes

Authors: *O. KLESHCHOVA[1,2], M. R. WEIERICH[1,2];
[1]City Univ. of New York, The Grad. Ctr., New York, NY; [2]City Univ. of New York, Hunter Col., New York, NY

Abstract: Background
Trauma exposure has been associated with functional differences in stress-relevant neural circuitry during affective processing and during rest. Prior data in our lab show that recent life stress is inversely associated with resting connectivity between the left amygdala and the anterior cingulate cortex (ACC) in trauma-exposed women. However, the relation between amygdala-ACC connectivity at rest and in response to affective information is unclear.
Hypotheses
We hypothesized that recent life stress and trauma history would predict functional connectivity between the left amygdala and the ACC in response to affective scenes.
We also hypothesized that functional amygdala-ACC connectivity during processing of affective scenes would be associated with resting connectivity between these two structures.
Method
We acquired task-based and resting-state fMRI data from 23 trauma-exposed women and 21 no-trauma controls. The task was viewing of novel and familiar positive, negative, and neutral scenes. We used the Perceived Stress Scale questionnaire to measure life stress over the past

month.

Results

In support of our first hypothesis, in trauma-exposed women but not controls, recent life stress was inversely associated with left amygdala-ACC connectivity during processing of novel ($F(3,39)=4.22$, $p=.011$, Adj. $R^2=.19$) and negative vs. positive scenes ($F(3,19)=3.77$, $p=.028$, Adj. $R^2=.27$).

In support of our second hypothesis, in trauma-exposed women, resting amygdala-ACC connectivity was associated with amygdala-ACC connectivity during processing of novel scenes ($F(1,21)=4.35$, $p=.049$, Adj. $R^2=.13$). In controls, however, resting amygdala-ACC connectivity was associated with amygdala-ACC connectivity during processing of familiar valenced scenes ($F(3,15)=9.65$, $p<.001$, Adj. $R^2=.59$).

Conclusion

These results suggest that negative amygdala-ACC connectivity observed in trauma-exposed women with high stress during processing of novel and negative information and during rest might underlie a tendency to perceive novel and arousing events as stressful. In trauma-exposed women, the association between amygdala-ACC connectivity during novel affective information processing and during rest might indicate sustained hypervigilance.

Title: Hippocampal gene expression and fear memory in stress-vulnerable and stress-resilient rat strains

Authors: *J. K. MECKES, P. LIM, S. L. WERT, E. TUNC-OZCAN, W. D. PASTARD, E. E. REDEI;
Psychiatry & Behavioral Sci., Northwestern Univ., Chicago, IL

Abstract: Stress responsiveness varies significantly among individuals due to differences in their vulnerability or resilience to stress. This individual stress-vulnerability or resilience is a heritable trait that is central to the etiology of stress-related disorders, including post-traumatic stress disorder. In this study, we evaluated the influence of stress-vulnerability and resilience on

hippocampus-dependent learning and memory, and hippocampal expression of stress responsive genes. Specifically, we examined the effect of chronic restraint stress (CRS) on hippocampus-dependent contextual fear conditioning (CFC) in two genetically and behaviorally distinct strains of rats: Fischer (F344) and Wistar Kyoto (WKY). F344 strain is considered more resilient and adaptable to stress compared to WKY, which is more vulnerable to stress. Animals were tested in the CFC and, four weeks later, exposed to either no stress (NS) or CRS for two hours per day for two weeks. Immediately after the CRS, their remote and reinstated fear memory was tested in the CFC. CRS resulted in strain-specific differences in remote fear memory and memory reinstatement. While no CRS-induced differences were observed in either remote memory or after reinstatement in the F344 strain, WKYs showed significantly enhanced fear memory after exposure to CRS. Previous microarray study using the same CRS paradigm identified minimal overlap of stress responsive genes between the F344 versus WKY and NS versus CRS comparisons suggesting that distinct sequence variations between the strains might be responsible for the gene expression and behavioral concomitants of stress vulnerability and resilience. For example, transcript levels of the Enoyl CoA Hydratase Domain Containing 2 (*Echdc2)* mitochondrial gene, which is transcriptionally regulated by *Nr3c1* (glucocorticoid receptor) was increased by CRS only in the hippocampus of the stress-resilient F344s with no effect on the stress-vulnerable WKYs. We propose that the distinct behavioral and hippocampal transcriptomic responses to CRS indicate independent molecular mechanisms that underlie stress vulnerability and resilience. The identification of novel gene expression profile to chronic stress in this study could be used to monitor individual stress responsiveness in the future.

Title: Interval timing and its sensitivity to stress show age-related alterations in the BACHD rat model for Huntington’s disease

Authors: *N. EL MASSIOUI[1], C. LAMIRAULT[1], D. GARCES[2], A. BONILLA[1], O. RIESS[3], H. NGUYEN[3], B. L. BROWN[2], V. DOYÈRE[1];

Abstract: Huntington disease (HD) is an autosomal dominantly inherited, progressive neurodegenerative disorder. Executive dysfunctions and emotional alteration have previously been reported in animal models of HD, mirroring the impairments exhibited by human HD patients .
To characterize the age-related progression of dysexecutive symptoms and sensitivity to stress, we assessed executive function in BACHD rats (a "full length" model of HD) using two interval timing tasks. BACHD and WT rats were trained at two different ages, 4 and 10 months, in order to compare time perception at both early symptomatic and late symptomatic stages. After magazine approach and lever-pressing were trained under a continuous reinforcement schedule for food pellets, rats were trained on a 2 vs 8-s temporal discrimination task. Subsequently, subjects were exposed to a series of bisection tests under normal and stressful (10 mild foot-shocks) conditions. The animals were then trained on a peak interval task, in which reinforced fixed-interval (FI) 30-s trials were randomly intermixed with non-reinforced probe trials. After 19 training sessions (more than 700 FI trials), the effect of stress upon time perception was again assessed. Moreover, sensitivity to foot-shocks was also assessed. The results show that the oldest BACHD animals had impaired learning in both temporal tasks. However, they reached equivalent levels of performance as WT animals at the end of training in the temporal discrimination task, while remaining impaired in the peak interval task. In that task, the younger BACHD rats also showed disruption of temporal behavior, but reached similar performance as WT at the end of training. Whereas sensitivity to foot-shock did not differ between BACHD and WT rats, delivery of foot-shocks during the test sessions had a disruptive impact on temporal behavior in WT animals, an effect which increased with age in both amplitude and duration (up to 24h). In contrast, BACHD rats, independent of age, did not show timing significantly impaired by foot-shocks.
In conclusion, BACHD rats show a disruption in temporal learning, which is more pronounced in late symptomatic animals. Our study shows also age-related modification in stress-induced impairment of temporal control of behavior, an effect which was highly reduced in BACHD animals, thus confirming previous results suggesting reduced emotional reactivity in HD animals.

Title: Neural substrates underlying alterations in fear conditioning following acute stress

Authors: *A. M. GOODMAN[1], N. G. HARNETT[1], M. D. WHEELOCK[1], T. R. OREM[1], S. MRUG[1], D. A. GRANGER[2], D. C. KNIGHT[1];

Abstract: Excessive stress exposure often leads to emotional dysfunction, characterized by disruptions in healthy emotional learning, memory, and regulation processes. Pavlovian fear conditioning is a common approach to assessing fear learning and emotion regulation. However, human neuroimaging research has yet to identify the neural substrates underlying alterations in fear conditioning following stress. Thus, an important challenge now facing the field is to determine the neural processes that mediate the detrimental impact of stress on healthy emotional function. Using a multimodal approach, prior studies (i.e., Knight et al., 2009, 2010, 2011; Wood et al., 2013, 2015) have assessed the neural substrates of Pavlovian fear conditioning via simultaneous recording of brain function (e.g., functional magnetic resonance imaging; fMRI), and psychophysiology (e.g., skin conductance response; SCR). These multimodal assessments have shown that a prefrontal cortex (PFC)-hippocampus-amygdala circuit underlies fear learning processes. Given that prior work (for review, see: Raio & Phelps, 2015) has shown stress disrupts this process, we hypothesized that stress-induced changes in PFC-hippocampus-amygdala function mediate stress-related disruption of emotional learning. The current study assessed this hypothesis using a variant of the Montreal Imaging Stress Task (MIST) and a fear conditioning task during fMRI. Participants completed the MIST, followed (20 minutes later) by a Pavlovian fear conditioning task. Self-reported stress experience and psychophysiological responses to the MIST were used to assess stress reactivity. Psychophysiological measures and fMRI signal during conditioning were used to assess autonomic responses and neural activity underlying fear learning. A median split of self-reported stress to the MIST was used to identify two stress reactivity groups (High vs Low). Group analysis of SCR to conditioned stimuli demonstrated greater CS+ vs CS- differences in the High vs Low Stress group. The High Stress group also demonstrated greater CS+ vs CS- differences for activity within the ventromedial PFC (vmPFC), dorsolateral PFC (dlPFC), hippocampus, and amygdala. This project offers a novel assessment of stress-induced changes in human PFC-hippocampus-amygdala function that

may mediate the detrimental impact that stress has on fear learning. This new understanding of the neural mechanisms linking stress exposure and alterations in healthy emotional processes can be used to better understand pathogenesis, treatment, and prevention of stress-related disorders.

Title: Lasting memories: Facilitating context fear in infant rats through behavioural tagging.

Authors: ***S. BAE**[1], R. RICHARDSON[2];
[1]Unsw, Unsw Sydney, Australia; [2]UNSW, Sydney, Australia

Abstract: The synaptic tagging and capturing hypothesis proposes that the formation of lasting memories requires two parallel processes: the setting of a protein synthesis-independent learning tag and the capture of plasticity-related proteins at these tagged sites. Behavioural tagging processes are analogous to synaptic tagging and capture and have been used to demonstrate how closely timed but unrelated novel experiences can transform a weak learning event into long term memory in adult animals. In the current series of experiments, we show that these behavioural tagging effects are also present in infant rats, animals that typically demonstrate poor long term context memory. Experiment 1 investigated whether novelty is sufficient to facilitate context fear memories in infant (P17) rats. Infant rats were trained to fear a context. Prior to this conditioning experience, half the rats explored a novel open field arena for 5-minutes. All animals were tested the following day. Open field exposed rats demonstrated enhanced context fear at test compared to infant rats not exposed to the open field suggesting that behavioural tagging processes may occur in the developing rodent. In order to equate the rats on their experiences, in Experiment 2 all animals were given open field exposure but half were exposed one-hour before conditioning whereas the remaining were exposed 2-hours before conditioning. Animals were tested either 1

or 3-days following conditioning. Consistent with the results of Experiment 1, infant rats exposed to the open field one hour before conditioning demonstrated facilitated context fear at the 1-day test compared to infant rats exposed to the open field 2-hours before conditioning. These differences, however, did not persist at the 3-day test. The findings of this experiment demonstrate that the facilitating effects of novelty are time-dependent. These findings also suggest that whilst novelty facilitates the long term retention of context fear memories, it does not affect the subsequent maintenance of that memory into a more remote store. Title: Neuronal encoding of imminent threat in rats performing a risky foraging task

Authors: *E. KIM[1], M.-S. KONG[1], S. PARK[3,4], M. PARK[3,4], S. MIZUMORI[1,2], J. CHO[3,4], J. J. KIM[1,2];

Abstract: By employing an ecologically relevant paradigm (Choi and Kim, 2010), we previously showed that the amygdala is necessary for encoding safety-danger boundaries that might alter the animal's perception of the environment to maximize its survival (Kim et al., 2015). However, in what manner the amygdala neurons respond to the imminent threat to regulate foraging behaviors remains unclear. Because the medial prefrontal cortex (mPFC) is also implicated in both fear expression/regulation (Sotres-Bayon & Quirk, 2010) and foraging decisions (Euston et al., 2012), we employed simultaneous single unit recordings to investigate how cells in the basolateral nucleus of the amygdala (BLA) and mPFC may process a predatory

fear signal in foraging rats. To do so, hunger-motivated rats (85% normal body weight), implanted with tetrode arrays in the BLA and mPFC ipsilaterally, underwent successive stages of nest habituation, foraging baseline, and robot testing. Tetrodes were gradually advanced towards their target structures, and neural activity was recorded as the rats exited their nest in search of food pellets placed in a large open field. Robot testing consisted of 'pre-robot,' 'robot,' and 'post-robot' recording sessions. We recorded a total of 346 BLA and 434 mPFC neurons and found that both the BLA and mPFC showed distinct categories of neural responses to either the robot ('robot' cells; BLA, n=55; mPFC, n=70) or food pellets ('food' cells; BLA, n=26; mPFC, n=64). About 49% of BLA and 43% of mPFC neurons increased their firing rates as the animal approached the robot ('robot-approach' cells). Specifically, the BLA robot-approach cells tended to maximize their firing when the rat was closer to the location of robot, while mPFC cells increased their firing earlier than BLA cells. The remaining cells exhibited their maximal responses upon the robot activation ('robot-triggered' cells) with the mPFC cells displaying more persistent firing than the BLA cells. In contrast, food-approach cells in BLA and mPFC identified during the pre-robot baseline period decreased their firing during the robot session despite animals advancing toward the pellet. These results illustrate that distinct BLA and mPFC neuronal populations increase their firing prior to or subsequent to predatory attack with different time courses, suggesting that the BLA signals imminence of threat while the mPFC anticipates the presence of threat to subserve adaptive anti-predatory behavior.

Title: A causal role for the ventrolateral periaqueductal grey in aversive prediction error signaling

Authors: *R. A. ZACHARIAS, M. A. MCDANNALD;
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Prediction error signaling is a crucial mechanism for proper fear regulation, especially in situations of uncertainty. Positive aversive prediction errors are generated when a received

outcome is worse than expected, and they function to increase fear upon future encounters. Evidence suggests the ventrolateral periaqueductal grey (vlPAG) may be the source of these prediction errors. However, no studies have used temporally precise inhibition of vlPAG activity at the time of prediction error. This would provide strong, causal evidence that this prediction error originates in the vlPAG. In this study we trained male and female Long-Evans rats in a fear discrimination paradigm in which three cues were associated with three different probabilities of foot shock: safety p=0.00, uncertainty p=0.38, and danger p=1.00. Of most interest was the uncertainty cue, for which positive prediction error signaling is necessary to demonstrate appropriate fear. In order to causally link vlPAG activity to aversive positive prediction error signaling, we transfected the vlPAG with halorhodopsin under control of the human synapsin promoter or with control YFP only virus. An optical ferrule was implanted over the vlPAG and 532 nm light was delivered precisely during the time of shock receipt on reinforced uncertainty trials, exactly when positive prediction errors would be generated. Preliminary data suggest that optogenetic inhibition of the vlPAG at the time of positive prediction error decreases fear to the uncertain cue over trials. A full analysis of the effect of optogenetic inhibition of the vlPAG will be presented. This study will implicate the vlPAG as the site of aversive positive prediction error signaling for fear regulation and provides a neural locus of possible disruption in disorders, such as PTSD, that are characterized by excessive positive prediction error signaling.

Title: The effects of the estrous cycle on the development of anticipatory nausea in female rats

Authors: *D. ZEVY, M. KAVALIERS, K.-P. OSSENKOPP;
Neurosci., Western Univ., London, ON, Canada

Abstract: The relationship between the estrous cycle and the development of anticipatory nausea (AN) in female rats was examined. AN is a conditioned response acquired after multiple associations between nausea/disgust and a novel context. Rats demonstrate a learned gaping response (i.e. conditioned disgust) when re-exposed to a context previous paired with toxin (LiCl) induced nausea. Research has demonstrated that females exhibit significantly higher

frequencies of conditioned gaping responses relative to males. It has been suggested that gonadal hormones such as estrogen and progesterone may play a role in this sex difference. In order to investigate the effects of female sex hormones on the development of AN, the estrous cycles of 32 adult female Long-Evans rats were tracked. The female rat estrous cycle consists of four phases; estrus, metestrus, diestrus, and proestrus. Following establishment of the cycles, rats were injected intraperitoneally with LiCl (96 mg/kg) or saline (NaCl; 0.9%) on either proestrus (high estrogen levels) or diestrus (low estrogen levels) and immediately placed into a novel context for a period of 30 minutes. This procedure was repeated over four conditioning days, spaced 96 hours apart, to insure subjects were always conditioned on either proestrus or diestrus. Ninety-six hours following the final conditioning day, rats were re-exposed to the context drug-free for a period of 10 minutes, whereby rats were observed for gaping responses. Since rats are non-emetic species, gaping is used as the behavioural measure of nausea, which is well established in past research. Results showed that subjects in proestrus injected with LiCl displayed significantly higher frequencies of conditioned gaping responses relative to subjects in diestrus injected with LiCl. These results demonstrate that the establishment of conditioned gaping responses fluctuates across the estrous cycle. This suggests that estrogen may contribute to the higher incidence of AN in females, a hypothesis which should be further explored using direct hormone manipulation. The relationship between estrogen and AN has major implications for the treatment of AN in the human patient population undergoing chemotherapy.

Title: Inhibition of intracellular signaling cascades in the basolateral amygdala impairs consolidation of first-order conditioned fear but does not impair consolidation of second-order conditioned fear

Authors: *B. P. LAY[1], N. M. HOLMES[1], D. L. GLANZMAN[2], R. F. WESTBROOK[1]; [1]Univ. of New South Wales, Sydney, Australia; [2]UCLA, Los Angeles, CA

Abstract: First-order conditioned fear is produced by pairings of a neutral stimulus (e.g., a tone) and an aversive unconditioned stimulus (e.g., foot-shock), while second-order conditioned fear is

produced by pairings of a neutral stimulus (e.g., a light) and an aversive conditioned stimulus (e.g., the tone). Consolidation of the first-order conditioned fear memory requires an intracellular signaling cascade and protein synthesis in the basolateral complex of the amygdala (BLA). However, the role of the BLA in consolidation of the second-order conditioned fear memory is unknown. We exposed rats to pairings of a stimulus (S1: auditory or visual) and foot-shock on day 1 and then to pairings of a second stimulus (S2: visual or auditory, respectively) and S1 on day 2. Rats were tested for fear (freezing) to S2 on day 3 and to S1 on day 4. Rats were then re-trained with S2-foot-shock pairings on day 5 and were finally tested for fear to S2 on day 6. In Experiment 1, functionally inactivating the BLA immediately after S2-S1 pairings with the sodium channel blocker bupivacaine reduced the subsequent test levels of freezing to S2 relative to vehicle-treated rats, showing that the BLA was critical for consolidation of the second-order fear memory. The remaining experiments examined the role of the intracellular signaling cascade in consolidation. A BLA infusion of the MEK inhibitor, U0126 (Experiment 2), or the broad spectrum protein kinase inhibitor, H7 (Experiment 3), or the protein-synthesis inhibitor, cycloheximide (Experiment 4), failed to impair consolidation of the second-order fear memory. However, consolidation of the first-order fear memory produced by pairings of S2 and foot-shock was disrupted by infusion of either U0126 (Experiment 2), H7 (Experiment 3) or cycloheximide (Experiment 4). There are at least two explanations for these findings. The first is that the second-order association is consolidated elsewhere in the brain; the second is that proteins necessary for consolidation are already present at the time of S2-S1 training, thus allowing for protein-synthesis independent consolidation of second-order fear.

Title: Deconstructing expectancy in human aversive learning: evidence from visuocortical, physiological and behavioural dynamics

Authors: *L. F. GRUSS, A. KEIL;
Psychology, Univ. of Florida, Gainesville, FL

Abstract: The study of classical aversive, discriminant conditioning in humans provides the opportunity to investigate changes across multiple response systems simultaneously during learning of threat and safety cues. Conditioning effects across response systems indexed by autonomic, cerebral, and self-reported expectancy signals may differ in their learning dynamics. These response systems may also dynamically change their mutual influence during learning. In the current study, our aim was to characterize (1) learning dynamics in conditioning effects across response measures, (2) correlations of response measures in acquisition to expectancy ratings in extinction, and (3) oscillatory brain activity related to threat versus safety ratings. To this end, 38 human observers underwent uninstructed, discriminant aversive conditioning with Gabor patches serving as the CSs (discriminant factor: orientation) and a 96dB white noise serving as the US. The acquisition phase started with a full reinforcement schedule, tapered off to partial reinforcement (66%), and ceaselessly transitioned to the extinction phase containing one final re-exposure of the CS+/US pairing. Visuocortical signals (ssVEPs) were elicited by frequency tagged luminance-modulated Gabor patches and autonomic measures included heart rate (HR), startle and skin conductance responding. Participants rated the likelihood of hearing the loud noise (US) after every trial in acquisition and extinction (80 expectancy ratings). Results revealed significant conditioning effects for the startle response and expectancy ratings in the first block of acquisition. Significant HR deceleration and visuocortical enhancement to the CS+ were not apparent until the second block of acquisition. Conditioning effects across neurophysiological measures, but not expectancy ratings, persisted into the first block of extinction. Expectancy ratings in extinction were, however, significantly predicted by strength of reactivity to the US via skin conductance responding in the first block of acquisition. Regression analyses revealed greater skin responders to not only continue to expect the US in extinction, but to also show greater HR deceleration, as well as greater endorsement of state anxiety post-experiment. The visuocortical signature of the CS was not related to these expectancy ratings. However, preliminary findings of resting alpha activity after extinction ratings demonstrated suppression of alpha during perceived ‘threat’ (high expectancy after a CS+ trial) compared to ‘safety’ (low expectancy after a CS- trial), suggesting a difference in attention set in preparation for the next trial.

Title: Lateral hypothalamic outputs control innate defensive responses

Authors: *M. WIGESTRAND, I. AASEBØ, A. TULLY, M. LEPPERØD, T. HAFTING, M. FYHN;
Dept. of Biosci., Univ. of Oslo, Oslo, Norway

Abstract: When facing a threat, animals display defensive behaviors that are critical for survival. The hypothalamus is believed to mediate such defensive responses, but the prevailing view includes a medial/lateral separation, where medial hypothalamus is thought to influence defensive responses, while the lateral hypothalamic area (LHA) regulates feeding and arousal. Here we identify two distinct neural populations in the LHA with surprising survival functions in rats. The two neural populations, defined by their output projections to either the periaqueductal gray (PAG) or the lateral habenula (LHb) have distinct anatomical placements along the anterior-posterior axis of the LHA and express distinct biochemical markers. Optogenetic stimulation of the two LHA populations robustly induced opposite active- or passive defensive responses. Further, chemogenetic silencing of LHA and optogenetic silencing of the LHA-PAG projection disrupted innate defensive responses to a predator-like looming shadow. Using single-unit recordings in the downstream LHb and PAG, we show that the LHA-LHb projection is largely excitatory, while the LHA-PAG projection is mainly inhibitory. We are currently using a miniaturized microscope to image the calcium activity of the two LHA populations during threat processing in behaving rats. Overall, our findings identify a novel LHA circuit that is critical for appropriate defensive responses to innate visual threats. The location of the LHA defense circuits, intermingled within circuitry that governs feeding, suggests that this circuit may provide rapid cross-talk between circuits that govern foraging- and anti-predator behaviors.

Abstract: Amygdala local inhibitory circuits have been considered to play regulatory roles for threat-related memory, While intercalated cell masses of the amygdala (ITC) seem to be required for fear extinction, the functional role for acquisition and/or expression of fear memory have not been explored, in terms of the synaptic plasticity at a specific input and its behavioral effects. We provide substantial evidence that synapses at the dorsal ITC undergo input-specific spike timing-dependent long-term depression (STDP-LTD) only after exposure to less-salient threat-experience. STDP-LTD in the LA-ITC pathway depends on DrD4 activity. Mechanistically, this type of LTD is likely to be formed via presynaptic mechanisms, which would involve an increase of GABA release probably from neighboring ITC neurons. Pharmacological, genetic and optogenetic manipulations reveal that this LTD limits less salient experiences from forming persistent memory. In further support of the idea that STDP-LTD has a preventive and discriminative role, we find that in mice exhibiting PTSD-like behaviors, STDP-LTD at the dorsal ITC is impaired. These findings indicate a novel role that an inhibitory circuit in the amygdala serves to dampen and demarcate the level of fear expression.

Title: Investigating the influence of priors in human fear generalization using a Bayesian model

Authors: L. KAMPERMANN, C. BÜCHEL, *S. ONAT;
Dept. of Systems Neuroscience, Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: When organisms form associations through learning, responses often generalize to stimuli that bare resemblance to the initially reinforced stimulus (CS+). During generalization, shifts in maximal responses away from the actual reinforced stimulus are commonly observed when tested with multiple stimuli along a similarity continuum, a phenomenon known as peak shift. We have developed a Bayesian framework that can account for peak shifts observed in behavioral ratings by postulating a group-level prior that is common to all participants over the range of stimuli forming the similarity continuum. The interaction of the prior distribution with a generalization component centered on the CS+ can act as a "magnet", resulting in shifts of maximal responses depending on which stimuli was used as CS+. This formalism allows us to reverse-engineer subjects' latent prior distributions by evaluating to what extent a specific hypothesis on priors can explain the observed shifts.
We employed a fear conditioning procedure using 8 faces organized along a circular similarity continuum varying in gender and identity dimensions. Two opposite faces were randomly selected as the CS+ and CS- for each participant (n = 141). Following aversive conditioning, we obtained fear generalization gradients by asking participants for explicit UCS expectancy ratings, thus obtaining a two-sided generalization gradient ranging from CS+ to CS-. We compared the performance of the Bayesian model to fits carried out on a single-subject basis using two versions of Gaussian functions and subsequently tested different hypotheses on priors for the Bayesian model.
As expected a flexible Gaussian model with 2 parameters (width and location parameters) fitted the data significantly better than a simple Gaussian model (only width parameter) centered on the CS+ face (r = .91 vs. r = .74) underlining the presence of peak shifts in behavioral ratings. On the other hand, the Bayesian model performed significantly better than the simple Gaussian model, despite being based on only two more free parameters (flexible Gaussian: 2n parameters; simple Gaussian: n parameters; Bayesian model: n+2 parameters). Furthermore the Bayesian model explained behavioral gradients best, when a bimodal prior distribution peaking at both gender prototypes was used (r = .84). Testing different gender categories individually, a unimodal prior centered on the male category explained as much variance as one centered on female category. Overall, the predominance of a bimodal prior indicates that peak shifts can result from "magnet" effects of categorical face representatives instead of adversity attributions to a specific gender.

Title: Motivational state determines paraventricular thalamic contributions to fear memory retrieval

Authors: *E. CHOI[1], G. MCNALLY[2];
[1]Psychology department, Univ. of New South Wales - Kensington Campus, Unsw Sydney, Australia; [2]Psychology Dept., Univ. of New South Wales, Sydney, Australia

Abstract: Paraventricular thalamus (PVT), located on the dorsal midline thalamus, is involved in motivation, mood, and implicated in psychiatric disorders including anxiety, substance use, and depression. Recently, PVT has been implicated as an important part of the brain circuitry controlling retrieval of fear memories, especially remote fear memories (Do-Mente et al., 2015, Li et al, 2014, Penzo et al., 2015). Here we used chemogenetic approaches to examine the role of PVT in fear memory retrieval and the interaction of this role with motivational state. First, we replicated the finding that PVT contributes to fear memory retrieval. Hungry rats (18 g food per day) trained to lever press for food were subjected to auditory fear conditioning. Chemogenetic silencing of PVT during test 72 hr after conditioning impaired fear expression/fear memory retrieval. Next we examined some of the boundary conditions for this involvement. We asked whether chemogenetic PVT silencing would impair fear memory retrieval when animals were subjected to fear conditioning in the absence of food deprivation and lever pressing. It did not. Then we asked whether increasing motivational state and arousal would affect PVT contributions. It did. Chemogenetic silencing had no effect on fear memory retrieval when hungry rats (12 g food per day) were trained to lever press for food, subjected to auditory fear conditioning, and tested 72 hr after conditioning. Taken together, these results suggest that motivational state or arousal is a key determinant of PVT contributions to fear expression and memory retrieval. At intermediate levels of hunger, PVT silencing impairs fear memory retrieval, but at lower or higher levels of hunger, PVT silencing does not impair fear memory retrieval. These results are consistent with PVT regulating learning and memory based on motivational state.

Title: Stress enhancement of fear learning: A time of day assessment

Authors: *A. PEGUERO[1], M. R. HERBST[2], J. J. QUINN[1];
[1]Psychology, Miami Unviersity, Oxford, OH; [2]Marquette Univ., Milwaukee, WI

Abstract: Anxiety disorders such as posttraumatic stress disorder can be traced to an inappropriate regulation of fear resulting from an early life stress. The issues of how stress is affected and regulated have been explored in adulthood but less is known about the impact of stress early in development. It has been shown that when exposed to an early life stress, rats have a more adverse reaction to subsequent stress in adulthood, even when there is no explicit recollection of the early life stress. The mechanisms underlying this vulnerability to future threat is unknown. Corticosterone (CORT) is an important mediator of homeostasis and stress responses. Early life stress has been shown to impact basal CORT secretion. Specifically, footshock exposure during infancy leads to a dysregulation in basal CORT secretion in adulthood. The present experiment addressed whether this dysregulated CORT secretion impacts the stress enhancement of fear learning (SEFL) in adulthood. Rats were exposed to zero or 15 footshocks in Context A on postnatal day 17 (PND17). At approximately PND90, rats underwent 1-footshock fear conditioning in Context B. The next day, rats were tested in for freezing in Context B. Importantly, fear conditioning and testing occurred at 8am and/or 4pm. At 8am, previously stressed rats showed low levels of basal CORT secretion, similar to non-stressed rats. At 4pm, previously stressed rats showed dramatically higher levels of basal CORT secretion compared to non-stressed rats. Thus, this design allowed us to address whether the level of basal CORT secretion contributes to the magnitude of the SEFL effect. We found that previously stressed rats showed SEFL regardless of the time of day when they were trained/tested. However, when training and testing times were consistent (both 8am or 4pm), rats froze more than when training and testing times were inconsistent. These data suggest that the level of basal CORT secretion does not impact the magnitude of SEFL observed.

Title: 2-Arachidonylglycerol mobilization in the ventral tegmenjtum is required for assumable dopamine release to cause avoidance behavior

Authors: *J. M. WENZEL[1], W. N. GOVE[1], V. C. CHIOMA[1], E. B. OLESON[3], J. F. CHEER[1,2];
[1]Anat. & Neurobio., [2]Dept. of Psychiatry, Univ. of Maryland Sch. of Med., Baltimore, MD;
[3]Dept. of Psychology, Univ. of Colorado Denver, Denver, CO

Abstract: The endocannabinoid system is a canonical and ethologically conserved signaling system involved in modulating phasic dopamine release during goal-directed behavior. Utilizing a signaled operant footshock avoidance procedure, our laboratory has previously shown that the mesolimbic system is involved in negative reinforcement learning. Indeed, dopamine transients within the nucleus accumbens at the presentation of a warning signal preceding footshock delivery predict successful shock avoidance. Further, optogenetic activation of midbrain dopamine neurons during the warning signal enhances avoidance responding, suggesting a causal role for dopamine in avoidance. Here, we examined whether this causal effect of dopamine release requires 2-AG mobilization in the ventral tegmental area. Animals learned a signaled operant shock avoidance task wherein illumination of cue light served as a warning signal which was presented 2s before the onset of footshock (0.6mA over 0.5ms, occurring at 2s intervals). Execution of a single lever press during this initial 2s interval resulted in the avoidance of footshock, whereas a lever press made after the initiation of shock delivery resulted in escape from footshock. Animals were trained on this task until they reached a stable level of avoidance behavior with successful avoidance on >50% trials. To initially examine the role of cannabinoid receptor signaling, rats were administered the CB1 antagonist SR141716 (rimonabant) or vehicle directly into the ventral tegmental area (VTA) prior to either of two sessions. Intra-VTA CB1 antagonism robustly attenuated avoidance behavior. Importantly, this decrease in avoidance was rescued by optogenetic stimulation of VTA dopaminergic cells. Next, to determine which eCB was signaling at CB1 receptors to facilitate the causal effect of dopamine release, intra-VTA injections of the 2-Arachidonoylglycerol (2-AG) synthesis inhibitor tetrahydrolipstatin (THL) were performed. Consistent with a critical role of 2-AG mobilization in the VTA, THL reduced avoidance responding to a larger degree than CB1 receptor blockade. Altogether, these data

suggest that, in order for accumbal DA release to cause avoidance behavior, mobilization of 2-AG from DA neurons in the VTA needs to occur as an obligatory signaling step.

Title: Cortico-striatal connections bias choice when reward conflicts with pain avoidance

Authors: *N. SCHWARTZ, H. L. FIELDS;
Neurol., UCSF, San Francisco, CA

Abstract: Nucleus Accumbens (NAc) neurons can either promote or inhibit reward approach. However, little is known about their role when rewarding and aversive behavioral drives are in explicit conflict. Here we observe that in an experience-dependent manner, animals learn to maintain reward-directed behavior when challenged with an aversive pain-predictive cue, that this learned behavior requires cortical regulation of spiking activity in the NAc, and furthermore, that in models of chronic pain this ability is impaired. Our results indicate that cortico-NAc circuits are a key node of the circuitry that mediates choice between the conflicting motivational drives elicited by reward- and pain predictive cues.

Title: Effects of sex and estrous phase on foraging behavior of rats living in a semi-naturalistic environment

Authors: B. PELLMAN[1], M. TELLAKAT[1], J. CHAN[1], K. FUKUOKA[1], *J. J. KIM[2];
[1]Psychology, [2]Psychology and Neurobio. & Behavior, Univ. of Washington, Seattle, WA

Abstract: Typical animal models of anxiety and fear-related disorders employ rodents and behavioral paradigms, such as Pavlovian fear conditioning, open field and elevated plus maze, that assess specific responses, such as freezing, time spent in and number of entries into an open arena, for only brief periods of sampling. These studies provide only a 'snapshot' (ranging several minutes) of a limited behavioral measure, restricting the animal's repertoire of behavior and thus yielding limited information. Moreover, much of this research has predominantly used male animals because of possible confounding contributions from the estrous cycle in females. For example, different phases of the rat estrous cycle have been linked to physiological fluctuations in synapse density in the hippocampus, amygdala and prefrontal cortex, neurogenesis in the hippocampus, behavioral variations in elevated plus-maze and open field, and fear conditioning and extinction. The goal of the present research was to examine the functional aspects of fear and anxiety behaviors in both males and females in a 'closed economy' system where the need to acquire food and water and to avoid the risk of shock were an integrated part of the animals' lives. Gonadally-intact male and female, and ovariectomized female rats lived in enlarged operant boxes that contained a bedded "nest" area and a risky "foraging" area containing levers to obtain food and a water bottle and a grid floor through which shocks could be delivered. Baseline measurements were initially obtained over 14 d, followed by 14 d during which unsignaled shock was delivered randomly (~2/h) throughout each day, and then a final 14 d extinction period without shock. Estrous phase was determined via vaginal lavage in a subgroup of females to determine estrous phase-related fluctuations in foraging and avoidance behavior. Results showed that while males and females avoid shock at the same rate and reduce the number of daily meals they eat, males prevent weight loss by increasing the size of each meal whereas females do not and therefore lose weight relative to baseline. Proestrus phase was associated with increased time spent foraging and subsequently increased shocks received during the shock period relative to other phases of estrous, and

ovariectomized females generally exhibited masculinized behavior compared to intact females, suggesting ovarian hormones play a modulatory role in risky foraging behavior.

Title: Serotonin depletion impairs both expression and acquisition of context-conditioned fear

Authors: *S. M. HAGSÄTER, R. PETTERSSON, E. JOHANSSON, E. ERIKSSON;
Inst. of Neurosci., Gothenburg, Sweden

Abstract: Objectives:
The importance of serotonin for the regulation of anxiety is illustrated by the efficacy of long-term administration of selective serotonin reuptake inhibitors in most anxiety disorders. The aim of this study was to explore to what extent an anxiety-related behaviour in rat, context-conditioned fear, is dependent on brain serotonergic activity. To this end, rats were studied with respect to context-conditioned immobility in the presence or absence of brain serotonin, respectively, the latter situation being obtained by administration of a serotonin synthesis inhibitor, para-chlorophenylalanine (PCPA). The effect of PCPA both on the expression of context-conditioned fear and on the acquisition of contextual fear was evaluated.
Methods:
Rats received injections of either PCPA (300 mg/kg) or 1 ml of 0.9% saline. Injections were given on three consecutive days, i.e. a dose regimen that causes an almost complete depletion of serotonin while leaving catecholamine levels intact. In Experiment 1, rats received injections prior to testing. In Experiment 2, rats received injections prior to fear-conditioning to the context. Hence, Experiment 1 evaluated the effect of PCPA on expression of context-conditioned fear and Experiment 2 evaluated the effect of PCPA on acquisition of contextual fear. The unconditioned stimulus was electric foot-shock (5 x 1s, 0.6 mA).

Results:
Experiment 1 (expression): There was a significant anxiety-reducing effect of PCPA ($p < .001$).
Experiment 2 (*acquisition):* There was a significant anxiety-reducing effect of PCPA ($p < .05$).
Conclusion:
The results indicate that an intact serotonergic neurotransmission is important for both expression and acquisition of contextual fear. We suggest that serotonin should be regarded as an anxiety-enhancing rather than as an anxiety-reducing transmitter.

Title: Visual attention modulates socially induced threat in observational threat conditioning

Authors: *E.-H. HONG, J. KIM, J.-S. CHOI;
Dept. of Psychology, Korea Univ., Seoul-City, Korea, Republic of

Abstract: Social transmission provides survival advantage for many animal species. Recently, observational threat conditioning (OTC) in which observer (OB)'s defensive behavior could be elicited by demonstrator (DE)'s reaction to an aversive event. However, it is unclear which component of information processing in DE's defensive behavior induces OB's defensive reaction.
In the current study, we carried out several experiments to characterize the type of essential information that modulates OTC using mice (C57BL/6N). DE and OB were pair-housed for three weeks in all experiments. For OTC, they were placed in each compartment of two chamber conditioning apparatus. Following 5 min of habituation, DE received 20 footshocks (2 s) at every 12 s while the OB was allowed to observe DE's reaction. For testing, DE or OB was placed in the same chamber for 4 min and their defensive behavior including freezing was measured.
In Exp. 1, we investigated the role of DE in memory retrieval. After the conditioning, two types of test were conducted in which OB alone (OB-) and in the presence of DE (OB+). OB+ showed a significantly higher level of freezing than OB-. In Exp. 2 and 3, the specificity of socially-induced threat was tested. In Exp. 2, to modulate the amount of freezing relative to post-shock

activity burst, two types of inter-trial interval (ITI) were used. DE in Long-ITI group (60 sec) showed a significantly higher level of freezing than Short-ITI group during conditioning. However, OB in Short-ITI (12 sec) group showed a significantly high level of freezing during conditioning. In Exp. 3, to modulate the demonstrator's post-shock activity, two types of shock intensity were used. DEs in High intensity (1.0 mA) group showed a significantly high level of freezing than Low intensity (0.5 mA) group during conditioning. However, there was no difference in OB's freezing. In Exp. 4, to investigate role of visual information, we used transparent and opaque condition. OB in transparent group showed a significant higher freezing level than opaque group during conditioning and test. In Exp. 5, we modulated OB's attentional process by applying a visual distractor. OB in Non-Distractor group showed a significant higher freezing level than Distractor group during conditioning and test. Furthermore, there was a positive correlation between DE's jumping and OB's gazing behavior.
Taken together, these results suggest that certain defensive behaviors are more effective in inducing OB's defensive reaction which is modulated by the level of attention and gazing.

Title: Effects of nicotine and nicotine withdrawal on fear conditioning in male rats

Authors: E. RIDENER, C. ADAM, K. STOLL, C. WEBBER, E. G. MELONI, S. B. CAINE, *W. A. CARLEZON, Jr;
Dept Psychiat, Harvard Med. Sch./Mclean Hosp., Belmont, MA

Abstract: Nicotine can facilitate learning while also relieving feelings of stress. These two actions may have opposing effects on vulnerability to stress-related illness such as post-traumatic stress disorder (PTSD), which is thought to involve learning and memory components. The present experiments examined the effects of voluntary intravenous self-administration (IVSA) of nicotine, as well as nicotine withdrawal, on the development and expression of PTSD-like symptoms in rats using fear-potentiated startle (FPS). The FPS procedure involves an index trauma and enables quantification of exaggerated startle response and extinction deficits, two characteristics observed in humans with PTSD. Male Long-Evans rats were allowed to self-

administer nicotine (0.03 mg/inj) or saline in 12hr (overnight) extended access sessions in operant conditioning chambers. Criteria for nicotine dependence was set at SA of >0.7 mg/session for 4 out of 5 sessions and observable signs of spontaneous withdrawal 11.5 hrs post SA session. After criteria were met, rats were fear conditioned at one of two time points: either immediately or 11.5 hrs after their last SA session (i.e., during nicotine withdrawal). Fear conditioning consisted of 10 pairings of a 4-sec light (conditioned stimulus; CS) co-terminating with a 0.5-sec 0.6 mA foot-shock. Nicotine exposure was then discontinued for some rats and continued for others for a total period of 10 days. Rats were then tested with no additional treatment, immediately after SA, or 11.5 hrs post-SA three times, each test 48 hrs apart. Two metrics were examined in each of the test sessions: Context-potentiated startle (CPS) and Fear-potentiated startle (FPS). %CPS was expressed as the percent change in startle after exposure to the conditioning context relative to a pre-training baseline, and %FPS was expressed as the percent change in startle elicited in the presence of the CS relative to trials without the CS. Rats that received fear conditioning immediately after SA and then had no further nicotine access for 10 days showed reduced %CPS and normal %FPS. In contrast, rats that were fear conditioned during nicotine withdrawal followed by 10 days of no further nicotine access showed elevated %CPS and normal %FPS. The patterns of effects were broadly similar in groups of rats that had continued access to nicotine for 10 days in between fear conditioning and testing. Our data suggest that, under certain conditions, nicotine can reduce the impact of a stressful (trauma-like) event, whereas nicotine withdrawal tends to enhance the impact of a stressful event.

Title: Role of nucleus accumbens cholinergic interneuron D2 receptors in motivated behavior.

Authors: *E. F. GALLO[1], M. BAILEY[2], E. CHUN[3], T. ADAMS[3], J. JAVITCH[1], P. BALSAM[1,3], C. KELLENDONK[1];

[1]Psychiatry, Columbia University/NYSPI, NEW YORK, NY; [2]Psychology, Columbia Univ., NEW YORK, NY; [3]Psychology, Barnard Col., New York, NY

Abstract: Motivational deficits are a common and debilitating symptom of neuropsychiatric disorders, including schizophrenia, drug addiction, and attention-deficit hyperactivity disorder (ADHD). Brain imaging studies have linked these disorders to alterations in striatal dopamine D2R function, yet evidence for a causal relationship between striatal D2R levels and motivation is limited. Moreover, because different cell types expressing D2Rs operate within striatum to regulate motivated behavior, it has been difficult to disentangle the individual contributions of the D2Rs in distinct neuronal populations. Cholinergic interneurons (CINs), which express D2Rs, account for approximately 2% of the striatal cell population, but exert widespread control over striatal circuit function. *In vivo*, CINs exhibit a dopamine-dependent "pause" in firing activity in response to salient or reward-related stimuli, which is thought to be critical for learned cue-reward associations. *In vitro* studies have implicated the D2R as a key mediator of the dopamine-dependent pause recorded in CINs. However, identifying the behavioral and physiological consequences of alterations in D2Rs expressed by CINs has not been possible with conventional pharmacological or gene ablation approaches. To study the cell type-specific role of CIN D2Rs in motivation, we used Cre-dependent adeno-associated viruses (AAVs) expressing either D2R-IRES-mVenus or EGFP that were bilaterally injected into the NAc core or shell sub-regions of adult choline acetyltransferase (ChAT)-Cre BAC transgenic mice. Four weeks later, mice were trained on a progressive ratio (PR) task, which measures willingness to work for a reward, or on a Pavlovian-to-Instrumental transfer (PIT) paradigm, which measures how reward-associated cues invigorate motivation to make instrumental responses. Our preliminary findings show that D2R upregulation in CINs of the NAc core or shell does not significantly alter PR performance. While overexpression of D2Rs in CINs in either core or shell does not affect Pavlovian learning or instrumental learning, it attenuates the increase in instrumental responding during the presentation of conditioned stimuli. These findings suggest that D2R upregulation in CINs of the NAc does not alter exertion of effort or the acquisition of conditioned stimuli or reward-related instrumental actions. Instead, D2R upregulation in CINs impairs the ability of the reward-associated cues to guide instrumental actions. To understand the effects of CIN D2R upregulation on behavior, we are also addressing the impact on CIN function using *ex vivo* electrophysiological recordings.

Title: A cannabinoid receptor antagonist attenuates ghrelin-induced activation of the mesolimbic dopamine system in mice

Authors: *A. KALAFATELI[1], D. VALLÖF[1], M. HEILIG[2], J. ENGEL[1], E. JERLHAG[1]; [1]Neurosci. and Physiol., Univ. of Gothenburg, Sahlgrenska Acad., Goeteborg, Sweden; [2]Ctr. for Social and Affective Neuroscience, Div. of Neuro and Inflammation Sciences, Linköping Univ., Linköping, Sweden

Abstract: The orexigenic peptide ghrelin increases appetite as well as activates the mesolimbic dopamine system, i.e. the dopamine projection from the ventral tegmental area (VTA) to nucleus accumbens (NAc). Preclinical studies report that ghrelin receptor (GHS-R1A) antagonism decreases drug reinforcement, suggesting that this gut-brain peptide increases the incentive salience of stimuli leading to motivated behaviours. Elevated plasma levels of ghrelin are associated with craving in patients with alcohol dependence, suggesting the hormone's involvement in alcohol use disorders (AUD). The present experiments were designed to explore the involvement of cannabinoid receptors type 1 (CB1), specifically in the VTA, for the ability of ghrelin to stimulate the mesolimbic dopamine system. Mice were administered ghrelin and a CB1 antagonist (rimonabant) and subsequently locomotor activity, accumbal dopamine release and chow intake were attested. We showed that peripheral (intraperitoneal, ip) administration of rimonabant attenuates ghrelin (intracerebroventricular, icv) induced locomotor stimulation and accumbal dopamine release in mice. Ghrelin (icv) induced food intake was not altered by the CB1 antagonist. Finally, we showed that bilateral ventral tegmental administration of rimonabant blocks the ability of intra-VTA ghrelin administration to increase locomotor activity in mice. We conclude that antagonism of CB1 attenuates the activation of the mesolimbic dopamine system in mice following ghrelin administration. Moreover, the data suggest that ventral tegmental CB1 regulates this ghrelin-induced reward. Given the association of ghrelin levels with AUD, there is

an emerging clinical relevance of the present study, exposing the possible link of cannabinoid receptors with alcohol disorders.

Title: Exposure to intrauterine growth restriction (IUGR) modifies the accumbal dopamine response to palatable food intake and its modulation by insulin in adulthood in rats

Authors: *D. PEREIRA LAUREANO[1,2], M. B. ALVES[2], P. M. MIGUEL[2], T. D. MACHADO[3], A. R. REIS[2], A. B. MUCELLINI[4], F. D. CUNHA[3], R. DALLE MOLLE[6], M. G. ROSS[8], M. DESAI[8], P. P. SILVEIRA[5,7];

Inst., McGill Univ., Montreal, QC, Canada; [8]Dept. of Obstetrics and Gynecology, Los Angeles Biomed. Res. Inst. at Harbor-UCLA Med. Ctr., Torrance, CA

Abstract: Human and rodent studies show that IUGR is associated with increased preference for palatable foods at different ages, as well as altered glucose metabolism and insulin resistance. Our hypothesis was that the central modulation of dopamine by insulin is altered in individuals born with IUGR, leading to an altered response to food reward. IUGR was induced by maternal food restriction (FR: 50% food restricted diet from pregnancy day 10; control: *ad libitum* diet). At birth, pups were cross-fostered, generating AdLib/AdLib (control- CTL) and FR/AdLib (FR) groups (pregnancy/lactation). At 80 days of life (male rats), the release of dopamine facing standard chow and palatable food (Froot Loops®) was measured by chronoamperometry recordings in NAc (coordinates: 1.2 mm anterior to bregma, 0.8 mm lateral to the midline, and

7.0 mm ventral to the surface of the cortex), with or without previous systemic insulin treatment (5UI/kg). In a different set of animals, we measured SOCS-3 in the hypothalamus (HT) and VTA, AKT and pAKT in the VTA and pTH/TH ratio in the NAc after saline or insulin injection. We confirmed the hypothesis showing that serum insulin was increased in the FR. In the live recordings, there was a delayed response of dopamine release in FR in response to Froot Loops® (time to reach the peak DA release CTL: 599.8±188; FR: 1258±194 sec, p= 0.047), but not to standard rat chow (CTL: 668±317; FR: 775±246 sec, p= 0.806). Insulin treatment completely reverts the difference (CTL:1093±320; FR: 254±127 sec, p= 0.05). Western blot studies showed that SOCS-3 was increased in the hypothalamus (OR_%controls, CTL:100.0±27.27; FR: 347.3±82.72, p= 0.002) and decreased in the VTA of FR (OR_%controls, CTL: 100±7.41; FR: 46.72±11.78, p= 0.009); pTH/TH was increased in the FR in the NAc as we have previously shown (ratio pTH/TH, CTL: 1.10±0.10; FR: 1.40±0.06, p= 0.027), but similarly to the chronoamperometry findings, this was reverted by insulin (ratio pTH/TH, CTL: 1.07±0.10; FR: 0.95±0.062, p= 0.338). These results show that exposure to IUGR changes the dopaminergic response to palatable foods, as well as the modulation of insulin over DA in the mesocorticolimbic system. Differences in insulin sensitivity across various brain areas and how insulin modulates DA release may explain the increased preference for palatable foods reported previously in IUGR individuals.

Title: A new way to measure the motivational after-effect of rewarding brain stimulation

Authors: *P. SHIZGAL, C. EVANGELISTA, J. PINHEIRO CARVALHO, E. EWUSI-BOISVERT, W. BRAKE;
CSBN, Concordia Univ., Montreal, QC, Canada

Abstract: The vigor of reward-seeking behavior is boosted by exposure to free samples of the reward ("priming"). For example, rats will run faster to obtain rewarding electrical brain

stimulation in the goal box of a runway after having received free stimulation in the start box, an effect reminiscent of increased motivation. However, many other variables contribute to running speed, including stimulation-induced potentiation of locomotion. We report a new method for measuring priming based on changes in lever-pressing rates. To perform optimally, the rat must plant itself next to the lever rather than locomoting about the chamber. Thus, this method promises to distinguish the motivating after-effect from locomotor potentiation and can be executed in standard operant-conditioning setups.
Electrodes were aimed bilaterally at the lateral hypothalamus in 10, male Long-Evans rats that were subsequently trained to lever press for electrical rewards. A single response triggered retraction of a setup lever and extension of a second ("reward") lever that was armed on a variable-interval 10 (VI10) schedule. Following expiration of the VI, a response triggered retraction of the reward lever and delivery of a 0.5-s train of 0.1-ms cathodal pulses, 200-600 μA in amplitude. After a 60-s intertrial interval (ITI), the setup lever was re-extended, marking the start of a new trial. In a subset of trials, priming stimulation (ten 0.5-s trains, delivered at 1 train/s) was delivered during the ITI preceding extension of the setup lever. In Experiment 1, priming ended 5 s prior to extension of the setup lever, and primed and unprimed trials were run in separate test sessions. In Experiment 2, the priming-setup delay was 2, 5, or 10 s, and primed and unprimed trials were interleaved randomly.
In most cases, higher response rates were observed on trials preceded by priming and at shorter priming-setup delays. Thus, the priming effect is seen even when performance benefits little, if at all, from locomotor potentiation. Moreover, this motivationally significant effect is seen in standard operant chambers, rendering it readily amenable to study by means of powerful contemporary methods, such as optogenetic activation or silencing.

Title: Removal of disulfide-dependent activation of PKG1α increases food-seeking behaviour and sucrose preference in mice

Authors: *C. DURAFFOURD[1], O. BROCK[2], I. BRAREN[3], A. DELOGU[2], C. FERNANDES[4], P. EATON[1];
[1]Cardiovasc., King's Col. London, London, United Kingdom; [2]Psychology and Neurosci., King's Col. London, Maurice Wohl Clin. Neurosci. London, MRC Social Genet. and Developmental Psychiatry Centre, Inst. of Psychiatry, London, United Kingdom

Abstract: The gene coding for the Protein Kinase G (PKG) is phylogenetically well-conserved and impacts on food-seeking and -reward behaviour. Mutations in this protein modulate foraging phenotypes and sucrose preference in insects and nematodes. PKG1α can be activated by the classical nitric oxide (NO)-cGMP pathway or alternatively by endogenous oxidants, such as hydrogen peroxide (H_2O_2), which induce a disulfide bond between cysteine 42 (C42) on adjacent chains of PKG1α homodimer complex, rendering the kinase catalytically active. *S*tudies in cells and tissues suggest that cGMP binding abrogates the oxidative activation mechanism, probably due to allosteric changes. In the context of food-reward, dopamine is released and metabolised by monoamine oxidase B (MAO-B) into 3,4-Dihydroxyphenylacetic acid and the oxidant H_2O_2 which could potentially induce disulfide-activation of PKG1α. Using primary cultures and neuronal cell lines, we observed dopamine and other monoamines induced the oxidative-activation of PKG1α, which was attenuated by the MAO-B inhibitor deprenyl. Activation of NO-cGMP pathway is known to increase food-seeking behaviour and sucrose-preference. Therefore, we hypothesized that H_2O_2 derived from MAO-B breakdown of reward-evoked dopamine induces oxidative activation of PKG1α, which may block food-reward and so quell food-seeking behaviour. To assess this idea, we utilised a C42S-PKG1α knock-in (KI) "redox-dead" mouse, which is fully deficient in the oxidant-induced disulfide activation mechanism as it lacks the thiol redox sensor. Eight week old male and female KI mice were more active compared to wild-type (WT) at 19h30-21h30, which corresponds to the first 2 hours after they awake and when their food consumption is the highest, consistent with an increased foraging behaviour. KI mice also consumed their food quicker than their WT littermates in a novelty-suppressed feeding task, and showed higher sucrose preference, indicative of heighted reward seeking behaviour. These behavioural effects were specific as there were no significant differences in anxiety, explorative and risk-taking behaviour, olfactory ability, motor coordination or muscle strength in KI compared to WT mice. WT, but not KI, mice treated with a MAO-B inhibitor showed increased sucrose preference and decreased oxidative-activation of PKG1α in their brain. In contrast, WT, but not KI, mice injected with an NO synthase inhibitor (L-NAME) showed decreased sucrose preference and increased oxidative-activation of PKG1α. In conclusion, oxidative-activation of PKG1α serves as a negative regulator of food-seeking behaviour and sucrose preference in mice.

Title: VTA neurons in rat sagittal slices are predominantly excited by electrical stimulation of the fasciculus retroflexus regardless of projection target or developmental stage

Authors: *P. L. BROWN, P. D. SHEPARD;
Maryland Psychiatric Res. Ctr., Univ. of Maryland Baltimore, Catonsville, MD

Abstract: The lateral habenula (LHb), a phylogenetically conserved, epithalamic area, is activated by aversive stimuli and reward omission. Electrical stimulation of the LHb elicits a population wide inhibition of midbrain dopamine (DA) cell activity in vivo, a phenomenon that is believed to be a neuronal representation of reward prediction error. While the majority of midbrain DA neurons are inhibited by aversive stimuli, some are excited, suggesting that they are encoding environmental salience rather than prediction errors. A minority of glutamatergic efferents from the LHb directly target DA and non-DA neurons in the ventral tegmental area (VTA). Our previous work demonstrated that in slice preparations from neonatal rats the dominant response to LHb stimulation in both DA and non-DA VTA neurons is excitation. We hypothesized that this could be due to 1) sampling from a population of predominantly cortical-projecting VTA neurons that have previously been shown to receive direct LHb efferents or 2) a developmental phenotype that is unique to neonates. To test the first hypothesis, para-sagittal slices containing LHb efferents (the fasciculus retroflexus or fr), the rostromedial tegmental nucleus (RMTg), and the VTA were prepared from neonatal rats (PND 11-19) injected at least 4 days prior with retrograde-traveling microspheres in either the prefrontal cortex (PFC) or ventral striatum (VST). Whole cell recordings were conducted in microsphere-filled, tyrosine hydroxylase positive, VTA neurons and their response to electrical stimulation of the fr was determined. Both PFC- and VST-projecting neurons were present in the slice preparations and, contrary to previous findings, glutamate-dependent excitation occurred in about half of recorded neurons regardless of projection target, though the magnitude of excitation was larger in PFC- than VST-projecting neurons. To test the second hypothesis, extracellular single unit recordings

were conducted in the same slice preparations from neonatal (PND 9-21) or adult rats (PND 55-65). The extracellular recordings confirmed our whole cell recordings in that approximately half of all VTA neurons in the neonates were excited by LHb stimulation. Surprisingly, the proportion of excited cells in adult slices was not significantly different. Finally, to test for a non-specific excitation, we recorded the response of LHb-excited VTA neurons to stimulation of the adjacent thalamus and found no response. This direct LHb-VTA excitatory pathway appears to be masked in vivo by a denser LHb-RMTg-VTA inhibitory input, suggesting that this direct-excitatory pathway may become more important during RMTg inactivity.

Title: Inhibition of Wnt signalling dose-dependently impairs the acquisition and expression of amphetamine-induced conditioned place preference

Authors: *F. ISLAM[1], K. XU[2], R. J. BENINGER[2];
[1]Ctr. for Neurosci. Studies, [2]Psychology, Queen's Univ., Kingston, ON, Canada

Abstract: Reward-related incentive learning is the acquisition by neutral stimuli of the ability to produce approach responses when paired with a primary reinforcer, such as food or psychostimulant drugs. Dopaminergic neurotransmission is thought to drive incentive learning with evidences showing amphetamine (AMPH), a psychostimulant that elevates extracellular dopamine (DA) and prolongs DA receptor signalling in the striatum, producing incentive learning in rodents. However, the underlying cellular mechanisms of incentive learning remain elusive. The Wnt signalling pathway has recently been implicated in dopamine-related functioning of the brain with evidences showing that Wnt signalling is selectively altered by DA D_2 receptors and is rapidly activated by AMPH in the rat nucleus accumbens (NAc) indicating some functional interaction of the Wnt signalling pathway with the dopaminergic system. The present study assessed the role of Wnt signalling in the acquisition and expression of incentive learning using the conditioned place preference (CPP) paradigm. It was hypothesized that inhibition of Wnt signalling with Wnt palmitoylation inhibitor, IWP-2, will dose-dependently affect AMPH-induced CPP when administered during the conditioning phase or the testing

phase. When IWP-2 was administered into the NAc (0.0001, 0.001, 0.05, 1.0 μg/0.5 μl/side) in male, Wistar rats prior to conditioning with AMPH (20.0 μg/0.5 μl/side), the acquisition of AMPH-induced CPP was blocked in a dose-dependent manner. When IWP-2 was administered in the NAc (0.001, 0.05, 0.5, 1.0 μg/0.5 μl/side) during the testing phase following conditioning with AMPH, the lowest dose (0.001 μg/0.5 μl/side) did not prevent expression of CPP, while larger doses (0.05, 0.5, 1.0 μg/0.5 μl/side) blocked expression. These results suggest that the inhibition of Wnt signalling may impair the acquisition and expression of AMPH-induced CPP, and thereby implicates Wnt signalling in incentive learning and DA-mediated behaviours. Title: Persistence of the motivational after-effect of food reward following dopamine receptor antagonism

Authors: *C. EVANGELISTA, A. HANTSON, W. M. SHAMS, A. ALMEY, Y. ALQADRI, B. V. GONZALEZ CAUTELA, F. XIANG ZHOU, J. DUCHEMIN, A. HABRICH, V. LORENC, C. GAGNE, K. EL OUAFI, P. SHIZGAL, W. G. BRAKE;
CSBN, Concordia Univ., Montreal, QC, Canada

Abstract: Reward-seeking behavior is invigorated by free samples of the reward ("priming"). For example, rats run faster to reach the end of a runway where rewarding electrical brain stimulation is available after having received free stimulation. This potentiation of reward seeking suggests increased motivation. Priming has been studied primarily using electrical brain stimulation. A striking finding is that blockade of dopamine transmission by pimozide does not eliminate the priming effect. However, pimozide acts at receptors for multiple neurotransmitters, including serotonin. The goals of this study are two-fold: 1) to extend the study of priming to food reward and 2) to do so using more selective dopamine antagonists.
Ten male, Long-Evans rats maintained at 90% of their free-feeding body weights were trained to press a lever that was armed on a 10-s fixed interval (FI10) schedule. A response after expiration of the FI triggered the delivery of one chocolate pellet. A 5-min intertrial interval (ITI) preceeded

the re-extension of the lever marking the start of a new trial. On primed trials, three chocolate pellets were delivered during the ITI. Consumption of the free pellets was followed by an 18-s delay prior to the re-extension of the lever. Three pairs of alternating primed and unprimed trials were run daily on sets of four test days separated by one rest day. Before each test, rats were injected intraperitoneally with 0.9% saline or one of three doses (0.01, 0.05, 0.1 mg/kg) of either a D1-like (SCH 23390) or D2-like (eticlopride) receptor antagonist.
Operant responding for food reward was greater on trials preceded by priming. Dopamine antagonism decreased overall responding in a dose-dependent manner but did not block the priming effect. Thus, like rewarding brain stimulation, food reward produces a motivating after-effect that does not appear to be mediated by dopaminergic neurotransmission.

Title: Why do mice overeat palatable diets? A comparison of hedonic and homeostatic mechanisms

Authors: *K. P. NGUYEN, J. A. LICHOLAI, A. V. KRAVITZ;
Natl. Inst. of Diabetes and Digestive and Kidney Dis., NIH, Bethesda, MD

Abstract: Although many factors play a role in the development of obesity, a predominant factor is overeating of highly palatable foods. Such overeating can be modeled in mice by giving them *ad libitum* access to a high-fat or high-sucrose diet, which causes a spontaneous increase in daily energy intake, and concurrent weight gain. Here, we aimed to examine the contribution of hedonic and homeostatic mechanisms in driving overconsumption and weight gain. Female mice (n=24) were individually housed and given daily “pre-loads” of high-fat diet (60 kcal% fat) or high-sucrose diet (35 kcal% sucrose) equivalent to 20%, 50%, and 90% of their required daily caloric intake, determined from baseline chow intake. Mice also had *ad libitum* access to a grain-based chow diet at all times. In this way, they started their caloric intake for each day on the enriched diet and then “topped up” with regular chow to reach their homeostatic need. We hypothesized that hedonic properties of the enriched diet was driving overeating, and therefore

mice would “top up” with only enough chow to reach their caloric need. Consistent with our hypothesis, the total caloric intake (enriched + chow diet consumed) was not elevated in either enriched diet group. However, when mice were then given *ad libitum* access to enriched diets, caloric intake and body weight significantly increased. This suggests that hedonic properties, and not impaired homeostatic mechanisms, drive over-eating of enriched diets. Based on previous literature on palatable diets engaging reward circuits, we hypothesize that disrupted signaling in reward circuits, more than in homeostatic satiety circuits, drive overconsumption of palatable diets. In future work, neurophysiological recordings will be used to understand the contribution of reward circuits to over-consumption of highly palatable foods.

Title: Role of dopaminergic receptors within the CA1 and dentate gyrus regions of hippocampus in drug-primed reinstatement of morphine conditioned place preference in rats

Authors: *A. HAGHPARAST;
Neurosci. Res. Center, Shahid Beheshti Univ. of Med. Sci., Tehran, Iran, Islamic Republic of

Abstract: The dorsal (CA1) and dentate gyrus (DG) of the hippocampus serve as the key brain sites implicated in learning and memory mediating drug relapse. It has been shown that dopamine receptors are widely distributed in the hippocampus formation and involved in reward-related processes. Therefore, in the current study, the reinstatement model was used to examine the effect of SCH23390 and Sulpiride as D1- and D2-like dopamine receptor antagonists respectively within the CA1 and DG on the reinstatement of morphine-conditioned place preference (CPP). Adult male albino Wistar rats weighing 200-280 g were bilaterally implanted by cannulae into the CA1 and DG. For induction of CPP, subcutaneous (sc) injection of morphine (5 mg/kg) was used daily during a three-day conditioning phase. Then, the conditioning score (CS) was calculated. After a 24 h ‘off’ period following achievement of extinction criterion, rats were tested for drug priming-induced reinstatement by priming dose of morphine (1 mg/kg, sc). In the next experiments, animals received different doses of intra-CA1 or intra-DG administration of SCH23390 (0.25, 1 and 4 µg/0.5 µl saline) and Sulpiride (0.25, 1 and 4 µg/0.5 µl 12% DMSO per side) bilaterally and were subsequently tested for morphine-induced reinstatement. Our findings showed that intra-CA1 or -DG administrations of these

antagonists in both regions before administration of priming dose of morphine attenuated reinstatement of morphine-CPP in a dose-dependent manner. It is concluded that drug priming-induced reinstatement may be mediated, at least in part, by stimulation of dopamine receptors in these regions of hippocampus.

Title: VTA kappa opioid receptors mediate aversion learning by decreasing dopamine

Authors: *M. A. ROBBLE, M. BOZSIK, D. S. WHEELER, R. A. WHEELER;
Marquette Univ., Milwaukee, WI

Abstract: Adaptive responses to rewarding and aversive environmental events are critical to survival. Rewarding stimuli and their predictors reliably increase nucleus accumbens (NAc) dopamine (DA) signaling which promotes learning. There is mounting electrophysiological and electrochemical evidence that aversive stimuli and their predictors decrease NAc DA, and it has been proposed that such reductions promote avoidance learning. However, the mechanisms by which aversive stimuli cause reductions in mesolimbic DA signaling are not well understood. The ventral tegmental area (VTA) kappa opioid receptor (KOR) system has been studied for its role in aversion, and is perfectly positioned to serve as the mechanism by which aversive stimuli impinge on the mesolimbic DA system. Here, using fast scan cyclic voltammetry, we first showed that blockade of VTA KORs attenuated quinine-induced DA reductions in the NAc shell. To test the relevance of KOR modulation of this DA signal we examined the effect of KOR blockade on an animal's ability to learn about an aversive outcome in a punishment paradigm. Operant sucrose seeking was punished with unexpected response-contingent delivery of quinine, and this learning effect was prevented by pretreatment with intra-VTA Nor-BNI, the KOR antagonist. To determine if decreased NAc DA is a critical learning signal in this paradigm we tested impact of an intra-NAc D2 receptor agonist on punishment learning. Models of striatal signaling suggest that inhibitory, high affinity D2 receptors are preferentially sensitive to

reductions in dopamine. These reductions may permit the disinhibition of D2-expressing medium spiny neurons that convey aversive learning signals. We hypothesized that intra NAc D2 receptor agonist treatment would prevent disinhibition in this neuronal population, preventing learning. Consistent with this model, punishment learning was impaired by pretreatment with intra-NAc shell quinpirole. These results suggest that VTA kappa opioid receptors are activated by aversive stimuli and initiate aversive learning signals. These learning signals are conveyed to the NAc through reductions in DA signaling. Ongoing studies continue to test this model of aversion learning. Studies combining immunohistochemistry and in vivo optogenetics will determine whether quinine preferentially activates D2-expressing neurons in the NAc, and whether this pattern of activation can be altered by maintaining DA tone during the experience of the aversive stimulus.

Title: A neural circuit computational model to investigate distributed rewarding and aversive signaling in the dorsal raphe nucleus and ventral tegmental area

Authors: K. WONG-LIN[1], *D. WANG[2];
[1]Intelligent Systems Res. Centre, Ulster Univ., londonderry, United Kingdom; [2]Sch. of Systems Science,Beijing Normal Universit, Beijing, China

Abstract: It has been known that rewarding and aversive signals are encoded by dopamine (DA) and serotonin (5-HT) neuronal activities. Recent experiments involving advanced techniques such as optogenetics have shown that phasic activity of DA neurons (in the ventral tegmental area, VTA) signals reward prediction error, while revealing heterogeneity in 5-HT neurons (in the dorsal raphe nucleus, DRN), which have phasic activity that signals both rewards and punishments. Tonic 5-HT DRN neuronal activity also encodes reward and punishment state value over much longer timescale. This is further complicated by findings that suggest other local non-principle neurons, particularly GABAergic neurons, may also play important encoding

roles. For example, GABAergic neurons in the VTA seem to signal expected reward, while GABAergic neurons in the DRN encode aversive stimuli but inhibited with rewarding stimuli. Given the existence of reciprocal projections between the DRN and VTA, and that both regions can receive similar monosynaptic inputs from other brain regions, it may be possible that some signals are shared and distributed among the neuronal sub-populations in the DRN-VTA system. To understand how the neural connectivity contributes to the observed distributed and heterogeneous encoding of reward/aversive signals among the different neuronal types, we propose a DRN-VTA neural circuit computational model based on known experimental data. Our model consists of mutually connected DA and 5-HT neural populations, each with inhibitory autoreceptors. We found that phasic DRN 5-HT activity can lead to potent transient changes on VTA DA activity. Increasing DA-to-5-HT connectivity can lead to too high 5-HT tonic level due to 5-HT autoinhibitory saturation effect. With a sequence of input pulses sufficiently close together (~ second), tonic activities can build up due to the slow decay timescale of the couplings. In the presence of local GABAergic and glutamatergic neural populations, the DRN-VTA circuit architecture becomes more complex with indirect pathways. GABAergic populations seem to stabilize tonic 5-HT activity even with larger DA-to-5-HT couplings, and can reflect phasic activity from 5-HT neurons. Strong GABAergic neural activity can reduce tonic 5-HT level without affecting phasic 5-HT activity, which could potentially improve higher signal-to-noise ratio. Taken together, the distribution of reward/aversive signals in the DRN and VTA could potentially be due to in/direct pathways between the two, and their shared afferent inputs. We will further investigate how drugs can influence the system's behavior.

Title: Binge eating behavior for sucrose is time-of-day dependent: effects on reward brian areas

Authors: *R. I. OSNAYA, M. PALMA, C. ESCOBAR BRIONES;
UNAM, Mexico City, Mexico

Abstract: Binge eating (BE) is characterized by the consumption of big amounts of food within a discrete interval, surpassing the expected amount for the same interval and in similar circumstances. In rodent models of binge eating highly palatable foods (fats, sugars), as well as restricted food access promote compulsive ingestive responses and result in sustained dopamine stimulation and activation of the glutamatergic system within the nucleus Accumbens. In this study we investigated the role of the circadian system in the development of BE and how BE can impair the normal rhythm of neurotransmitters in the reward system. The present study explored the effect of sucrose intake during the rest phase versus the active phase on the development of BE, the influence of restricted food access on the development of BE and its effects on circadian rhythms of general activity and body core temperature. The temporal expression of dopamine D1 receptor (DR1), GluR1 subunit of AMPA receptor were assessed in the Nucleus Accumbens and TH in the VTA. Fifty six adult Wistar rats were randomly assigned to Control conditions, Restricted access to sucrose during the day (ZT5; SUC-D) or night (ZT17; SUC-N), restricted food acces to the day (RF-D) or night (RF-N) or the combination of restricted food and sucrose access in the day or night. All animals had ad libitum access to water. The experimental protocol had a duration of 5 weeks with 6 days access to sucrose per week. RESULTS: BE was 250% stronger in the SUC-N vs SUC-D and BE to sugar was not dependent of RF. RF induced overconsumption of regular chow food, an increase in locomotor activity and temperature in anticipation and response to chow access. Food restriction combined with access to sucrose increase the anticipatory response observed in general activity and core temperature. The expression of DR1 in nucleus Accumbens was increased in the groups who had access to sucrose at night but not in the day. GluR1 was not modified between groups in the night vs. light phase. Overall our results show that BE is influenced by the time of the day, with a higher response in the night; RF can potentiate anticipatory locomotor activity and body core temperature when it is combined with sucrose access. This may depend on a circadian response of D1 receptors. Present findings will provide a better insight of factors eliciting BE and other compulsive disorders.

Title: Mechanisms of dopamine D2 receptor-mediated modulation of excitability in type A pyramidal cells in prefrontal cortex

Authors: *S. E. ROBINSON[1], V. S. SOHAL[2];
[1]Neurosci., [2]Psychiatry, Univ. of California - San Francisco, San Francisco, CA

Abstract: The prefrontal cortex (PFC) mediates many executive functions including working memory, behavioral flexibility, decision making, and social cognition. Dopamine plays a critical role in modulating these PFC-dependent functions. Abnormal dopaminergic modulation of the PFC is believed to contribute to cognitive deficits observed in many psychiatric disorders including schizophrenia. Since all major antipsychotics block dopamine D2 receptors (D2Rs), and D2Rs play a major role in tasks that are disrupted in schizophrenia, a major hypothesis is that abnormal D2R activation contributes to prefrontal dysfunction in schizophrenia. Mechanisms by which dopamine D1 receptors (D1Rs) modulate excitability in the PFC have been extensively studied. Less is known about the mechanisms by which D2Rs modulate pyramidal neurons in the PFC. Canonically, dopamine receptors are thought to mediate downstream signaling in response to dopamine via G protein-coupled receptors (GPCRs), with D1Rs activating G_s and D2Rs activating G_i, which exert opposing effects on the cAMP signaling pathway. Recent studies have classified separate populations of PFC pyramidal neurons with distinct morphology, physiological properties and dopamine receptor expression. Previous work from our lab showed that D2Rs are selectively expressed in a subpopulation of layer V pyramidal neurons (type A neurons) which have thick apical tufts, prominent h-current, and subcortical projections. Within this neuron population, synaptic activity can unmask an afterdepolarization (ADP) mediated by D2Rs, NMDARs, and L-type Ca^{2+} channels. Thus, D2Rs elicit an ADP that powerfully modulates activity in specific prefrontal neurons. We used a combination of optogenetic techniques, pharmacology, and patch-clamp recordings from D2R expressing neurons to test the role of D2R signaling underlying this ADP. Here we will present ongoing work investigating the role of G-protein and G protein-independent signaling mediating this D2R-dependent effect. We also investigated the dysfunction of D2R modulation in transgenic mouse models of psychiatric disorders. We will present results suggesting the impairment of this D2R-dependent ADP in mouse models of schizophrenia.

Abstract: As cognitive abilities decline in normal aging, the ability to learn about probabilistic rewards and to make optimal decisions is impaired. Previous research has shown reduced processing of reward information in the striatum and prefrontal cortex (PFC) among older persons. Although there is evidence that dopamine (DA) modulates some of these effects, it remains unknown whether age-related DA decline affects neural processing in the striatum, PFC, or both. We wanted to assess neural processing of reward information in the striatum and PFC as well as dopaminergic neuromodulation on the same participants. To this end, we measured D1 receptor density across the whole brain using PET in 30 younger and 30 older adults. We also measured BOLD responses with fMRI while the same participants performed a two-armed bandit task. We confirmed that older adults performed the task less well than younger adults. We also found that reward prediction errors in the nucleus accumbens were incomplete in both age groups, because the expected value component at the time of the outcome was absent on a group level. On an individual level however, the strength of the expected-value signal was related to density of D1 receptors in the orbitofrontal cortex independent of age. By contrast, the strength of the expected-value signal at the time of choice in the ventromedial prefrontal cortex (vmPFC) mediated the observed age effects on choice performance. Both age and D1 receptor density predicted the strength of this expected-value signal in the vmPFC, but their effects could not be dissociated. This pattern suggests that age-related DA decline is associated with reduced value signaling in the vmPFC. Finally, we identified a frontoparietal mechanism related to shifting away from the chosen option, which was not modulated by age or D1 receptor density, but predicted task performance independent of the value signal in the vmPFC. These results demonstrate that declining value learning in old age depends on impaired neuronal processing in vmPFC possibly related to DA decline.

Title: KChIP4: a biophysical amplifier of inhibition in mesolimbic dopamine neurons

Authors: *K. M. COSTA[1], A.-M. KASHIOTIS[1], G. SCHNEIDER[2], M. SUBRAMANIAM[1], J. ROEPER[1];
[1]Inst. for Neurophysiol., [2]2 Dept. of Computer Sci. and Mathematics, Goethe Univ., Frankfurt am Main, Germany

Abstract: Fast-inactivating A-type currents in substantia nigra (SN) dopamine (DA) midbrain neurons are mediated by Kv4.3-containing potassium (K) channels, which control pacemaker frequency *in vivo* and *in vitro* (Subramaniam et al. 2014). The A-type K-channels of neighboring DA neurons in the ventral tegmental area (VTA) are more diverse, with time constants of inactivation varying across one order of magnitude (tau_i of 20-200 ms). We recently showed that knockout of the K channel interacting protein 4 (KChIP4) was sufficient to remove slow inactivating A-type currents in VTA DA neurons but only marginally affects A-type kinetics in SN DA neurons. In contrast to our previous finding of altered *in vivo* firing frequencies in response to reduced Kv4 channel function in SN DA neurons (Subramaniam et al. 2014), neither SN nor VTA DA neurons showed altered firing frequencies in KChIP4 KO mice compared to wildtype. There was also no difference in bursting activity, ISI variability or firing pattern proportion between the studied neuronal populations. All recorded neurons were juxtacellularly labeled to confirm their anatomical positions and neurochemical identities via post-hoc immunohistochemistry. However, compared to wildtype, VTA DA neurons from KChIP4 KO mice showed a near seven-fold reduction in the number and a three-fold reduction in the duration of spontaneous firing pauses in VTA DA neurons, with no genotype difference between SN DA neurons. This effect was selective for firing pauses that were not preceded by bursts (periods with initial ISI < 80 ms and final ISI > 160 ms), suggesting these pauses were probably mediated by GABAergic synapses and not depolarization block or calcium-activated K channels. To better define a cell-autonomous role of KChIP4 as an amplifier of synaptic inhibition in VTA DA neurons, we generated a conditional and DA-cell selective mouse model, where exon 3 of the KCNIP4 gene, which codes for the K channel inactivation suppressor (KIS) domain responsible for slow inactivation, is selectively deleted in DA neurons by the use of a DAT-cre line. We are currently characterizing the behavioral phenotype and neurophysiology of VTA DA neurons in

this KChIP4-exon3/DAT-cre line. In particular, we test our key hypothesis that loss of amplified inhibition in VTA DA neurons might selectively impair learning from negative prediction errors during, for example, extinction of a conditioned response.

Title: Dual presynaptic and postsynaptic mechanisms in the nucleus accumbens core may contribute to the enhancement of cocaine-induced locomotion by D_3R antagonism

Authors: *A. K. PETKO[1], D. F. MANVICH[3], R. A. CLIBURN[4], K. A. STOUT[4], A. H. NEWMAN[5], G. W. MILLER[4], J. A. GOMEZ[2], D. WEINSHENKER[3], C. A. PALADINI[2]; [2]Neurosci. Inst., [1]Univ. of Texas at San Antonio, San Antonio, TX; [3]Dept. of Human Genet., [4]Dept. of Envrn. Health, Rollins Sch. of Publ. Hlth., Emory Univ., Atlanta, GA; [5]Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Dopamine (DA) projections onto medium spiny neurons (MSNs) within the nucleus accumbens (NAc) are critical for reward and reinforcement. Within the NAc, cocaine and other drugs of abuse are believed to exert their abuse-related effects by increasing extracellular DA levels and, consequently, the activation of postsynaptic DA receptors located on MSNs. Although it is well established that the abuse-related effects of cocaine may be attenuated via nonselective antagonism of dopamine D2-like receptors (D2R, D3R, and D4R), the precise mechanistic involvement of each of these subtypes in modulating the behavioral, neurochemical, and electrophysiological effects of cocaine in the NAc remains unclear. The purpose of these studies was to assess and compare the impact of selective D2R or D3R antagonism on the behavioral and neuropharmacological effects of cocaine in mice. First, we demonstrate that pretreatment with the selective D2R antagonist, L-741,626, dose-dependently attenuates cocaine-induced locomotor activity, whereas pretreatment with the selective D3R antagonist, PG01037,

dose-dependently enhances cocaine-induced locomotor activity. Next, using in vitro voltammetric measurements of DA transients within the NAc core, we show that application of either L-741,626 or PG01037 potentiates cocaine-induced increases in DA release, likely via the inhibition of presynaptic D2R or D3R autoreceptors, respectively. Finally, in vitro electrophysiological recordings from D1R-expressing MSNs reveal that bath application of DA increases the firing rate in response to current injection of these neurons ,as expected , since D1R are Gs-coupled, resulting in increased cellular excitability. Administration of the D3R-selective antagonist PG01037 potentiates this effect, presumably via the inhibition of postsynaptic Gi-coupled D3Rs co-expressed in these cells. Combined, our findings demonstrate that selective antagonism of D3Rs functionally enhances multiple effects of cocaine, thus exhibiting a pharmacological profile that is qualitatively opposite to that produced by nonselective D2-like receptor antagonists or the selective D2R antagonist L-741,626 and reveals a distinct role for the D3R subtype.

Title: Mesolimbic opioid-dopamine interaction is disrupted in obesity but recovered by weight loss following bariatric surgery

Authors: *H. K. KARLSSON[1], L. TUOMINEN[2,3], P. SALMINEN[4], P. NUUTILA[1,5], L. NUMMENMAA[1,6,7];
[1]Turku PET Ctr., Turku, Finland; [2]Dept. of Psychiatry, Massachusetts Gen. Hosp., Boston, MA; [3]Harvard Med. Sch., Boston, MA; [4]Dept. of Digestive Surgery, [5]Dept. of Endocrinol., Turku Univ. Hosp., Turku, Finland; [6]Dept. of Neurosci. and Biomed. Engin., Aalto Univ., Aalto, Finland; [7]Dept. of Psychology, Univ. of Turku, Turku, Finland

Abstract: Background: Obesity is a growing burden to human health and economy worldwide. We have previously shown that obesity is associated with μ-opioid receptor (MOR) system downregulation, and that the interaction between MOR and dopamine D_2 receptor (D_2R) systems is disrupted in the ventral striatum among obese subjects. It remains unknown whether the aberrant opioid-dopamine interaction is a cause or a consequence of obesity. Here we addressed this issue by studying subjects undergoing surgical weight loss (bariatric surgery) procedure. **Methods:** We recruited 20 healthy non-obese (mean BMI 22.3 ± 2.7) and 25 morbidly obese women (mean BMI 41.3 ± 4.1) eligible for bariatric surgery. Brain MOR and D_2R availability was measured using positron emission tomography (PET) with [^{11}C]carfentanil and [^{11}C]raclopride, respectively, and either Roux-en-Y Gastric Bypass or Sleeve Gastrectomy was performed to obese subjects as their standard clinical treatment. Four obese subjects discontinued the study, and 21 subjects (mean BMI 31.9 ± 4.5) participated in postoperative PET scanning six months after the surgical procedure. **Results:** MOR and D_2R availabilities were associated in the ventral striatum (r = .62) and dorsal caudate (r = .61) in the control subjects. Preoperatively, the obese subjects had disrupted association in the ventral striatum (r = .12) but unaltered association in dorsal caudate (r = .43). The association between MOR and D_2R availabilities in the ventral striatum was recovered (r = .62) among obese subjects following the surgery-induced weight loss (mean 25.0 ± 8.2 kg). **Conclusions:** Bariatric surgery and concomitant weight loss recovers the interaction between MOR and D_2R in the ventral striatum in the morbidly obese. Consequently, the dysfunctional opioid-dopamine interaction in the ventral striatum is likely associated with an obese phenotype and may mediate excessive energy uptake. Striatal opioid-dopamine interaction provides a feasible target for pharmacological and behavioural interventions for treating obesity.

Title: Astrocytic control of dopaminergic neurons

Authors: *J. A. GOMEZ[1], C. A. PALADINI[2];
[1]The Univ. of Texas At San Antonio, San Antonio, TX; [2]The Univ. of Texas at San Antonio, San Antonio, TX

Abstract: Bursts of action potentials by midbrain dopamine (DA) neurons are critical for encoding reward. Using slice physiology, we evoked in vivo-like bursts using electrical stimulation. We found that summation of NMDA receptor (NMDAR)-mediated EPSCs are necessary in generating burst firing. Increasing the extracellular concentration of the obligatory NMDAR co-agonist, glycine, led to an increase in the evoked burst firing frequency without changing the spontaneous activity of dopaminergic neurons. The increase in firing was accompanied by an increase in the NMDAR-mediated current measured. Previously, astrocyte depolarization has been shown to release glycine in different brain regions (e.g. substantia nigra, amygdala, retinal ganglion cells). Thus, we hypothesized that glycine release from astrocytes regulates burst firing of midbrain dopaminergic neurons. We tested our hypothesis by expressing channelrhodopsin, a light activated depolarizing channel, specifically in astrocytes. We found that depolarization of astrocytes caused an increase in the evoked firing frequency without altering the dopaminergic neurons spontaneous activity. Together, our results suggest that astrocytes' ability to control the extracellular glycine concentration is necessary in regulating dopaminergic burst firing.

Title: Endocannabinoid synthesis by dopamine neurons controls cue directed reinforcement

Authors: *D. P. COVEY, H. M. DANTRASSY, J. F. CHEER;
Univ. of Maryland, Baltimore, MD

Abstract: Predictive cues guide reward pursuit and are thus key to survival. Overvaluation of reward-predicting cues, however, underlies detrimental motivational drive contributing to, for example, drug abuse and obesity. Mounting clinical and preclinical work demonstrates that pharmacological manipulations of cannabinoid type 1 (CB1) receptors potently alter cue-directed reinforcement and represent a treatment target for motivational disorders. While CB1 receptor manipulations are thought to alter cue-evoked reward pursuit through modulation of mesolimbic dopamine (DA) projections from the ventral tegmental area (VTA) to nucleus accumbens (NAc), the precise mechanisms by which endocannabinoids (eCBs) shape DA function and cue-evoked reward pursuit are not clear. To assess how mobilization of the eCB 2-arachidonoylglycerol (2-AG) by DA neurons controls DA's role in reinforcement, we selectively disrupted 2-AG synthesis by the diacylglycerol lipase alpha (DGLα) enzyme specifically in DA neurons using Cre-Lox recombination. Mice were then trained to lever press for sucrose or optogenetic intracranial self-stimulation (ICSS) of VTA DA neurons. DGLα deletion suppressed cue-directed reward pursuit, but not primary reinforcement, indicating that DAergic encoding of reward predictive cues relies on 2-AG mobilization by VTA DA neurons. This work unambiguously shows that 2-AG mobilization by DA neurons is fundamental to reward pursuit.

Title: Does children behave the way adults do when it comes to stress?

Authors: *H. BUDDE[1], F. KOUTSANDRÉOU[2], M. WEGNER[3];
[1]Med. Sch. Hamburg, 20457 Hamburg, Germany; [2]Human Sci., Med. Sch. Hamburg, Hamburg, Germany; [3]Inst. of Sport Science, Univ. of Bern, Bern, Switzerland

Abstract: The influence of an active lifestyle on stress reactions and their underlying physiological systems seems to be a potential biochemical mechanism for some of the related health benefits in adults. Previous findings with adults are in line with the "cross-stressor adaptation hypothesis" (Sothmann et al., 1996) which suggests that physically trained individuals show lower cortisol (C) responses to physiological but also to other stressors (e.g.,

psychological). However, little research was dedicated to children and adolescents, which also implies that the underlying neurobiological mechanisms in this young age group need further investigation. Preliminary findings from cross-sectional studies showed that children with a physically more active lifestyle tend to have lower C reactivity to psychosocial stress and lower general C levels. There has been research with adults and some with participants under the age of ten. By investigating C reactivity and activity of children as well as adolescents, the current study aims to fill this gap.
For the first study presented in the talk primary (n = 53) and high school students (n = 121) were randomly assigned to a physical stress task (of different standardized intensities exercising for 12-15) or a control task. Participants' PAS was assessed prior to the intervention using a questionnaire. The salivary C concentration was measured prior and immediately after the interventions. In the second study, the effects of a 10-week afterschool exercise program with 71 participants aged 9-10 years were examined. They were randomly assigned to a control group (CON, n = 21) or an exercise group (EX, n = 50), in which participants were active three times a week for 45 minutes and at a mean intensity of 55-70% of HR_{max}. In the CON students participated in assisted homework sessions. The salivary C concentration was measured prior and after the exercise program.
Our results show lower baseline C levels for physically active high school students but no effect of PAS on the C reactivity in either sample. After the 10-week exercise program participants in the EX increased their fitness compared to the CON. However, results of a stepwise hierarchical regression analysis showed no effects on childrens' C levels depending on fitness gains in response to the exercise program. The findings suggest age-dependent basal C levels with reduced endocrine stress activity and reaction in children and young adolescents. This may be attributed to a yet developing HPA axis in childhood, which seems to mature to its final adult function not before late adolescence.

Title: Hearing impairment, physical stress, and the risk of cardiovascular diseases - An attempt to quantify potential stress markers in hearing impaired workers

Authors: J. LUKAJEWSKI[1], R. HUONKER[1], P. JAUER[1], E. EMMERICH[2], *A. LEHMENKUHLER[3], F. RICHTER[2];
[1]Biomagnetic Ctr., [2]Inst. of Physiol. I, Jena Univ. Hosp., Jena, Germany; [3]Pain Inst., Dusseldorf, Germany

Abstract: Hearing impairment and stress responses are closely linked. Hearing impaired people complain of high mental load during simple hearing tasks that is aggravated during auditory recognition tasks. Especially speech comprehension in noise is disturbed that makes social interactions difficult not only in daily life but also at work. In the past we were able to show that hearing impairment caused higher acoustic demands resulting in higher brain activity states during listening tasks. In addition, in these young probands we observed continuously increased stress levels indicated by reduced heart frequency variability and increased cortisol levels in saliva at rest prior to the listening task. Here we wanted to test whether similar changes could be observed in hearing impaired workers in light industry (food and beverage production). In two groups of age-matched workers (one group normal hearing, 20 participants; one group with moderate hearing impairments (average 45 dB SPL) in the frequency range of 3-4 kHz, 20 participants) we recorded the magnetoencephalogram (MEG) and auditory evoked magnetic fields in order to analyze the distribution of the sources. We recorded the electrocardiogram, arterial oxygen saturation and breathing frequency. From the electrocardiogram we calculated the square root of the mean squared differences of successive heart beat intervals (rmssd) as a parameter of heart rate variability. As a marker for psychical stress we measured the concentration of cortisol in the saliva prior to and after the experiments. Auditory stimuli were tone pips with different pitches (65 dB SPL). In a “one back task” the subjects had to decide whether the next to last pip had a higher or lower frequency than the last pip, and correct responses were rewarded. The tone pips presented were overlaid by random noise. Two different stimulus conditions, at a constant pitch difference or with pitch difference adjusted to the actual error rate, were presented. The hearing impaired workers reported being stressed at rest and during the listening task. Heart rate and breathing frequency as well as the heart rate variability indicated an increased rate of physical stress that was accompanied by higher contents of cortisol in the saliva. The higher mental load has to be considered in occupational medical care particularly with regard to hearing impairment since it is reflected by a worsening of cardiac reactivity or continuously increased parameters of cardiorespiratory functioning. The long term alterations to the cardiovascular system need to be taken into account with regard to prophylaxis of injuries especially caused by noise induced hearing loss.

Title: Effects of genetics and stress on amygdalar activation and associated functional connectivity using fmri

Authors: *N. NAIR[1], J. HEGARTY[3], K. LANE[2], B. FERGUSON[2], P. HECHT[4], S. CHRIST[2], M. TILLEY[5], S. KANNE[2], D. BEVERSDORF[1];
[1]Dept. of Radiology, [2]Univ. of Missouri, Columbia, MO; [3]Stanford Autism Ctr., Palo Alto, CA; [4]USC, Los Angeles, CA; [5]Central Methodist Univ., Columbia, MO

Abstract: Psychological stress has a significant impact on health. Our previous work has investigated the effects of stress on cognitive performance and has recently revealed a genetic marker for greater cognitive impairment due to stress, the promoter region of the serotonin transporter gene. The presence of at least one copy of the short (S) allele (lacking a 44 base pair repeat in the promoter region of the serotonin transporter gene (5-HTT) as compared to the long (L) allele) influences 5-HTT expression such that individuals with the L/S or S/S genotype (68% of the population) express lower levels of 5-HTT than those with L/L genotype. The amygdala is known to be activated to a significantly greater degree in subjects with the S-allele than those in those without the S-allele in response to emotional stimuli. To determine the effects of superimposed stressors, we examined how activation and functional connectivity associated with the amygdala are affected by the presentation of emotional stimuli presented in the presence of a social evaluative stressor in individuals with and without at least one copy of the S-allele. The Montreal Imaging Stress Test (MIST), based on the Trier Social Stress Test (TSST) was used to induce stress. During the stressor (and the no stress control task), the subject was interrupted with three 48-second epochs during which pictures of faces with either an angry, fearful or neutral expression were shown to the subject. The task epochs alternated with 30 second MIST (or in the no-stress condition, control task) epochs. Subjects performed the stress study and the non-stress study on separate days, with half of the subjects in each group performing the stress study first and the other half performing the non-stress study first. Functional magnetic resonance imaging data from 35 subjects (17 subjects with at least one copy of the S-allele and 18 subjects homozygous for the L-allele) were analyzed using the FSL software (FMRIB Software Library, Oxford, UK). The degree of activation of the amygdala was compared to participants with and without the presence at least one copy of the S-allele. Preliminary results

indicate greater activation of the amygdala in subjects with at least one copy of the S-allele as opposed to those without when presented with emotional stimuli when under stress.

Title: The neurobiology of fear and anxiety: circuits engaged by certain and uncertain threat

Authors: *C. M. KAPLAN, M. E. BRINKMAN, L. PESSOA, J. F. SMITH, A. J. SHACKMAN;
Psychology, Univ. of Maryland, College Park, MD

Abstract: When extreme, anxiety—a sustained state of heightened distress or arousal in response to uncertain threat—can become debilitating. A growing body of psychophysiological research demonstrates that exaggerated responses to uncertain threat contribute to the development and maintenance of pathological anxiety, yet the underlying neural circuitry has received scant attention. Here, we leveraged a novel cued threat task and multiband fMRI (3T) to identify regions sensitive to temporally certain and uncertain threat in 32 healthy young adults. Building on mechanistic work in rodents and psychophysiological research in humans, our task constitutes a 2 × 2 factorial design (Certain/Uncertain × Threat/Safe). On each trial, a digital clock was presented that either counted down seconds from 18 to 0 (Certain) or displayed a series of unordered integers for a pseudo-randomized duration (Uncertain: 8-32s, M=18s). Trials terminated with the delivery of either an aversive stimulus (Threat: electric shock, unpleasant image, and aversive sound) or a neutral stimulus (Safe: grey screen with white fixation). Images were processed and analyzed using standard techniques. To maximize resolution, images were spatially normalized to a standard template using high-fidelity diffeomorphic techniques. Analyses focused on the perceptually identical periods of certain or uncertain anticipation prior to stimulus delivery. Results were thresholded at FDR q<.05 (whole-brain corrected) in SPM12. Subjects reported increased anxiety and showed elevated arousal (electrodermal activity) in the threat conditions (ps<.001), confirming the efficacy of the TripleThreat paradigm. Uncertain threat elicited more anxiety and arousal than certain threat (ps<.02), consistent with prior work.

Imaging analyses revealed sustained activation in the bed nucleus of the stria terminalis (BST) during uncertain threat and phasic responses in the dorsal amygdala to certain threat. We also identified a novel set of cortical regions, including mid-cingulate cortex (MCC) and anterior insula (AI), that are recruited by both kinds of threat. These results underscore the value of the TripleThreat task, provide new insights into the neural systems supporting fear and anxiety in humans, and set the stage for developing improved interventions for pathological fear and anxiety.

Title: Neural correlates of dental fear and trait anxiety in the cerebral response to dental sounds

Authors: *H. KARIBE[1], M. KOEDA[2], A. TATENO[2], Y. KATO[1], Y. OKUBO[2];
[1]Nippon Dent. Univ., Tokyo, Japan; [2]Nippon Med. Sch., Tokyo, Japan

Abstract: Background: The sounds of dental treatment frequently evoke anxiety in patients with dental fear. Some previous studies have further reported that the level of dental fear correlates with the level of trait anxiety. However, no studies to date have investigated the relationship between dental fear and trait anxiety in terms of cerebral activation in participants listening to sounds associated with dental treatment. The present study utilized functional magnetic resonance imaging (fMRI) to assess the relationships between cerebral activation in response to auditory stimuli and levels of dental fear and trait anxiety. Methods: Thirty-four right-handed individuals (21 women, 13 men; age, 19-49 years; average age, 31.2 ± 9.1 years) who had reported a history of dental treatment were selected. The Dental Fear Survey (DFS) and the State-Trait Anxiety Inventory-Trait (STAI-T) were used to assess self-reported levels of dental fear and trait anxiety, respectively. Participants were categorized into two groups according to threshold score on the DFS: a dental fear (DF) group (n = 12; overall DFS score ≥ 52) and a control (C) group (n = 22; overall DFS score < 52). Single experimental sessions contained both dental sounds and neutral stimuli. Dental sound stimuli consisted of six sounds associated with dental treatment, including those of dental drilling and vacuum suction. Cerebral activation

during stimulus presentation was evaluated by measuring blood-oxygenation level dependent (BOLD) signals using contrast fMRI. Results: A significantly stronger activation was observed in the left posterior superior temporal gyrus and bilateral precentral gyri while listening to dental sounds in the DF group compared to the C group (2-sample *t*-test, $p < 0.001$, uncorrected). Similarly, activation in the left posterior superior temporal gyrus and bilateral precentral gyri positively correlated with DFS scores in all participants (simple regression analysis, $p < 0.001$ uncorrected). In contrast, activation in the right middle temporal gyrus, the left inferior frontal gyrus, and the right insula positively correlated with STAI-T scores in all participants (simple regression analysis, $p < 0.001$ uncorrected). Conclusions: The findings of the present study suggest that the distribution of neural correlation between dental fear's scores and activation by listening to dental sounds differs from that between trait anxiety and activation by dental sounds. This difference in activation may indicate some differential level of processing for both types of anxious behaviors.

Title: Anatomical and functional dissection of the thalamo-amygdala circuitry underlying associative learning

Authors: *F. MATYAS[1], K. KOCSIS[1,2], B. BARSY[1], A. BABICZKY[1];
[1]Res. Ctr. For Natural Sci., Budapest, Hungary; [2]Pázmány Péter Catholic Univ., Budapest, Hungary

Abstract: Associative learning is indispensable to elaborate adaptive behaviour. Lateral thalamic nuclei connected to the lateral amygdala (LA) are known to control cue-dependent emotional processes. Here we dissected this thalamo-amygdala pathway and investigated its contribution to associative behavioral paradigms applying anatomical, behavioral, electrophysiological and optogenetic techniques.
The majority of the thalamic cells retrogradely labelled from the LA were located in the the lateral posterior thalamic nuclei (LP), the suprageniculate (SG) and the posterior intralaminar

(PIL). Similarly to the LA, the amygdalostriatal region (AStr) receives thalamic inputs exclusively from these areas. Both the LA and AStr projecting thalamic cells coexpressed the calcium-binding protein calretinin (CR). Viral injection of LP/SG/PIL in CR-Cre mice revealed strong axonal labelling in LA and also in the neighboring AStr demonstrating that CR can be used as a marker to selectively probe these pathways. CR-positive thalamic cells also projected to the temporal associative cortex, while the encompassed CR-negative auditory thalamic relay cells in the medial geniculate nucleus were primarily connected to the primary auditory cortex. This pattern suggests that these two thalamic populations carry distinct types of information regarding environmental (auditory/visual) cues. Furthermore, we are currently studying the electrophysiological effects of various CS+ and CS- stimuli on CR+ (and CR-) thalamic cells to find out in what extent these cells carry US associated sensory information to the LA. Our data show that the thalamo-amygdala circuit can be selectively investigated using the CR-Cre animal model, which provides a unique approach to explore the exact role as well as the underlying mechanisms of this pathway in emotional processes and associative memory formation.

Title: Neural mechanisms of human temporal fear conditioning

Authors: *N. G. HARNETT[1], J. R. SHUMEN[2], P. A. WAGLE[2], K. H. WOOD[2], M. D. WHEELOCK[2], J. H. BANOS[3], D. C. KNIGHT[2];

Abstract: Learning the temporal relationship between a warning cue (conditioned stimulus; CS) and aversive threat (unconditioned stimulus; UCS) is an important aspect of Pavlovian conditioning. Prior functional magnetic resonance imaging (fMRI) research has identified brain regions that support Pavlovian conditioning including the dorsolateral prefrontal cortex (PFC), dorsomedial PFC, inferior parietal lobule (IPL), insula, amygdala, and hippocampus. However, it

remains unclear whether these regions support time-related processes important for this type of associative temporal learning. Elucidating the neural substrates of temporal conditioning is important for a complete understanding of the associative learning process. Therefore, the present study used a temporal Pavlovian conditioning procedure to investigate brain activity that mediates the formation of temporal associations. Twenty-three healthy volunteers completed temporal conditioning and a control procedure that does not support conditioning during fMRI. Specifically, during the temporal conditioning procedure, the UCS was presented at fixed intervals (ITI: 20 s) while in the control condition the UCS was presented at random intervals (Average ITI: 20s, ITI Range: 6-34 s). We observed greater skin conductance responses and expectancy of the UCS during fixed relative to random interval trials. These findings demonstrate fixed trials support temporal conditioning, while random trials do not. During fixed trials (compared to random trials), greater conditioned fMRI signal responses were observed within amygdala, hippocampus, dorsolateral prefrontal cortex, inferior and middle temporal cortex, and inferior parietal lobule. These findings are consistent with the broader literature suggesting these brain regions support fear conditioning. Further, the present findings indicate these regions support temporal information processes that are important for this type of associative learning. The current findings suggest these brain regions constitute a neural circuit that encodes the temporal information that is important for Pavlovian fear conditioning.

Title: Impact of a stress stimulus and images with restorative potential in the amygdala's resting state functional connectivity.

Authors: *D. VÁZQUEZ CARRILLO[1], J. MARTÍNEZ-SOTO[2], F. A. BARRIOS[1], L. GONZALEZ-SANTOS[1], E. PASAYE[1], S. ALCAUTER[1];
[1]Inst. de Neurobiología, Univ. Nacional Autónoma De México (UNAM), Queretaro, Mexico; [2]Univ. de Guanajuato, Guanajuato, Mexico

Abstract: Functional connectivity (FC) is modulated by stressor events. Once the stressor disappears, a restorative process returns the homeostatic state. Images with natural environments have the ability to enhance the restorative process, while urban environments have no properties

to facilitate such process. Amygdala plays a central role in both processes, being one of the first structures to respond to a stressor and also participates in the restorative process interacting with other brain regions (Quaedflieg, 2015). Resting state fMRI images were acquired in a 3T MRI scanner for 40 healthy men during three states: before the stressor, after the stressor and after restorative stimuli. The stressor was a video with violent content, while the restorative stimuli consisted of pictures of natural ambience (high restorative potential, HRP) or pictures with urban content (low restorative potential, LRP). Stress was evaluated with the "Stress and Activation Adjective Checklist" (King, 1983). Standard preprocessing and imaging analyses were performed with FSL. The amygdalae were used as seeds to obtain the corresponding FC maps. Voxel-wise paired t-tests were performed to identify the differences between basal and stress states of the sample and between the stress and restorative states for each group. Stress levels were higher during the stress state for the entire sample ($T(39)=4.42$, $p<0.05$). After restorative stimuli, the HRP group showed significant decrement of stress levels ($T(19)=3.40$, $p<0.05$), while the LRP group showed no significant differences between both states ($T(19)=0.44$, $p>0.05$). During stress state, increments of FC of the amygdalae with pre and post-central gyri, occipital and parietal cortices were observed; the same state showed decreased FC of the amygdalae with the anterior cingulate and precuneus. The HRP group showed increased FC with para-hippocampal gyrus and decreased FC with occipital cortex, pre and post-central gyri. The LRP group showed increased FC with superior frontal gyrus and posterior cingulate cortex, and decreased FC with the orbitofrontal cortex and inferior frontal gyrus. Significance in FC changes was defined at $p<0.05$, uncorrected. Stress levels showed significant increase after video presentation for the whole sample, while distinct restorative trajectories were evident after presentation of stimuli with low and high restorative potential. The scenes with natural ambience significantly reduced stress levels, while images with urban content showed no such effect. Accordingly, FC of the amygdalae with occipital, pre- and post-central cortices showed different trajectories for the restorative stimuli.

Title: Mesio-temporal theta oscillations in a human anxiety task

Authors: ***A. TZOVARA**[1,2,3], T. FEDELE[4], T. GRUNWALD[5], P. HILFIKER[5], N. KRAYENBÜHL[4], J. SARNTHEIN[4], D. R. BACH[1,2,3];

Zurich, Zurich, Switzerland; [5]Swiss Epilepsy Ctr., Zurich, Switzerland

Abstract: Theta oscillations in mesiotemporal structures including the hippocampus and amygdala have been proposed as a neural signature of anxiety models in rodents, which typically rely on conflicts between approach and avoidance. Recent work has capitalised on magnetoencephalography (MEG) to show that human hippocampal theta oscillations during approach/avoidance conflict relate to learned threat probabilities. Here, we extend these findings by recording local field potentials directly from subcortical structures in humans, using intracranial electroencephalography (iEEG).
We recorded iEEG from three patients with mesiotemporal epilepsy during pre-surgical monitoring. Patients completed a "scoop-and-run" computer game emulating operant conflict. They collected monetary tokens under threat of virtual predation. Probability of threat had to be learned by experience while monetary loss was explicitly indicated to participants. At trial start, the player was presented with the predator colour and the possible loss. After a random interval, a monetary token appeared to create behavioural conflict. Power spectra for theta oscillations (1-8 Hz) were extracted using welch transform over 1 s windows and were statistically evaluated at the single-patient level, using independent sample t-tests. Correction for multiple comparisons was performed by non-parameteric cluster-based permutations.
All three patients showed a significant increase in the power of theta oscillations during 1 s period following the token appearance, compared to a baseline period ($p<0.05$). Two out of three patients had an additional increase in theta power during 1 s period following the trial start. Only one of the three patients was able to learn the threat probabilities and also showed higher theta power for higher threat level at token appearance. Strikingly, in different contacts, we also observed higher theta power for higher potential loss in the same patient both at trial start and token appearance. The latter effect was partly replicated in the other two patients.
In summary, our findings confirm that approach-avoidance conflict increases mesiotemporal theta power in humans. They extend previous MEG results, by suggesting that mesiotemporal theta oscillations relate to expected loss, whether it is explicitly signalled or successfully learned.

Title: Striatal beta-band oscillations associated with long-lasting pessimistic mood induced by intrastriatal microstimulation

Authors: *K.-I. AMEMORI, S. AMEMORI, D. J. GIBSON, A. M. GRAYBIEL; McGovern Inst. for Brain Res., MIT, Cambridge, MA

Abstract: Long-lasting pessimistic moods that are not restored by a transient emotional response are a cardinal feature of neurologic symptoms in anxiety disorder and depression. Though it is known that the primate striatum is a node in circuits controlling optimistic and pessimistic states, the mechanisms underlying such long-lasting pessimism are not understood. To approach this issue, we applied a combination of striatal microstimulation and recording of local field potentials (LFPs) as two macaque monkeys performed an approach-avoidance decision-making task (Amemori and Graybiel, 2012). We performed 124 stimulation experiments consisting of blocks of stimulation-off trials, stimulation-on trials and follow-up trials without stimulation. In 28 sessions, we found that the intrastriatal microstimulation (1-s trains, biphasic pulses, 70-100 μA at 200 Hz, during cue period) induced pessimistic choices (defined as > 5% increase in avoidance choices). Strikingly, in 16 sessions (~12%), the induced pessimistic state lasted even in the follow-up trials in which the stimulation was no longer applied. To characterize a neural biomarker related to such long-lasting pessimistic states, we focused on analyzing striatal beta oscillatory activity before (stimulation-off trials) and after (follow-up trials) the stimulation-on trials. For each trial block, we calculated a tuning index (beta-range power spectrum for avoidance choices minus that for approach choices) for the precue period (2-s duration before cue onset) and cue period (1.5-s duration for decision-making). Among 89 channels recorded in the 28 effective sessions, we selected channels exhibiting beta tunings significantly greater (avoidance-tuned) or lesser (approach-tuned) than zero in the beta range ($P < 0.05$). Then, we classified them into four categories: precue avoidance (n=23), precue approach (n=23), cue avoidance (n=40) and cue approach (n=59). Importantly, the group mean of beta tuning toward avoidance increased for the precue avoidance and cue avoidance groups during follow-up trials relative to stimulation-off trials; beta tuning toward approach of the cue approach group

decreased ($P < 0.05$). These tuning changes disappeared in the next sessions along with behavioral recovery. No significant change in the mean of tuning indices was observed in 'non-effective' sessions in which microstimulation did not induce changes in decision-making. These findings suggest that striatal beta oscillations could be crucially involved in, or reflect, regulation of sustained pessimistic and optimistic moods that persistently influence conflict decision-making and value judgments.

Title: Unconditioned fear: continued evaluation of the k-turn in C57 and Balbc mice

Authors: *K. J. KUJAWA, A. M. BABCOCK;
Psychology, Montana State Univ., Bozeman, MT

Abstract: Although unconditioned fear is not a new concept, it can be difficult to observe it due to strain differences in mice. Because the current behaviors used to evaluate fear are also subject to strain differences, it was necessary to investigate alternate behaviors that could be indicative of a fear state. In addition to stretch-attends, defensive bury, and freezing behaviors the present study also investigated a novel behavior, known as a K-Turn. This new behavior has been shown to increase in C57 male mice in response to predator odor exposure, similarly to other fear-linked behaviors. In the present study, previous data in C57 mice is expanded upon with the addition of female C57 and male and female Balbc mice. The unconditioned fear paradigm in the present study involved repeated exposure to a cage which contained a petri dish at one end of the cage and bedding covering the floor of the cage. On days 1-4 the petri dish contained a plain cloth while days 5-7 contained a cloth covered in either a non-predator (cinnamon) or a predator odor (cat). The present study highlights the need for greater defining of discrete behaviors and chains of behaviors in order to expand on the knowledge of behaviors in response to fear stimuli. In doing so, the present research provides additional measurements that may be helpful in the assessment of unconditioned fear behaviors.

Title: The acetylcholinesterase inhibitor pyridostigmine bromide interacts with stress to alter fear conditioning in a model of Gulf War Illness

Authors: *V. A. MACHT, J. L. WOODRUFF, C. A. GRILLO, M. A. WILSON, L. P. REAGAN;
Univ. of South Carolina, Columbia, SC

Abstract: Gulf War Illness describes clusters of medically unexplained symptoms reported by soldiers returning from the 1990-1991 Gulf War. These symptoms include chronic fatigue, muscle pains, headaches, and impairments in working and long-term memory. Unique to this war, soldiers were chronically administered the reversible acetylcholinesterase (AChE) inhibitor pyridostigmine bromide (PB) prior to and during deployment to protect against the potentially toxic effects of nerve gas exposure. One possibility which has gathered recent support is the idea that stress of military deployment interacted with PB to contribute to ontogeny of memory problems reported by soldiers with GWI. In order to test this hypothesis, the current study examined the effects of PB pre-treatment alone and in combination with repeated restraint stress. Adult male Sprague Dawley rats were given 14 days of 1.3 mg/kg/day PB or vehicle treatment by gavage. Beginning on day 5 of this PB treatment paradigm, rats were randomly assigned to either restraint stress or non-stressed conditions (i.e. daily handling). Restraint stress was performed for 6 hours/day approximately 30 minutes following PB treatment for 10 consecutive days. AChE was measured on the last day of treatment and then either at an early time point (i.e. 10 days post-treatment) or a delayed time point (i.e. 3 months post-treatment). AChE activity was reduced by approximately 50% in PB-treated rats on the last day of treatment, but normalized across groups 10 days post-treatment. Three months later, AChE activity was selectively elevated in PB-stressed rats relative all other groups, suggesting that there is a persistent interaction between PB and stress on peripheral AChE activity. Rats were also

subjected to a fear conditioning paradigm at either early or delayed time points. In the early test group, rats exposed to both PB and stress selectively exhibited decreases in context-associated freezing behavior, indicating deficits in contextual fear-learning. In the delayed test group, rats exposed to stress and vehicle exhibited increases in freezing behavior relative to non-stressed controls, and PB blocked this stress effect in context-associated fear conditioning. These data support the idea that stressful events combined with PB adversely impact specific aspects of fear learning in our model of GWI and suggest that examining both immediate and delayed interactions of PB and stress are critical to understanding alterations in fear learning and GWI pathology.

Title: Multiple stress response under novel chasing stress using a predator-like robot

Authors: *J.-H. LEE, A.-R. CHOI, S. KIM, J.-S. CHOI;
Korea Univ., Seoul, Korea, Republic of

Abstract: Popular stress paradigms often employ physical stimulation such as restraint or electric shock. Others employ natural predators or predator odors. We developed a novel stress model in rats using a high-speed chasing robot which emulates predatory threat.
Rats received repeated stress trials which consisted of being chased by a fast-approaching robot in an inescapable donut-shaped maze for 2.5 s. To test the validity of the model as a stress paradigm, we measured physiological and behavioral responses: plasma corticosterone (CORT) level; emotional memory of chasing stress; general anxiety level; sensitized fear response.
In Exp. 1, the plasma CORT level was measured following one of the three behavioral treatments: chasing stress (60 trials), restraint stress (30 min) or control (mere exposure to the stationary robot for 30 min). During chasing stress, the rats emitted massive amount of ultrasonic vocalization (USV) which indicates distress. The post-treatment CORT levels of all groups

significantly increased compared to the pre-treatment baseline. In addition, the post-chasing stress and post-restraint stress CORT levels significantly increased compared to the control. There was no difference between post-chasing stress and post-restraint stress groups indicating that repeated chasing produced a significant level of physiological response comparable to restraint stress.
In Exp. 2, rats received 20 trials (15 - 20 s between trials) of chasing stress per day for 3 days. Chasing was forewarned by a 5-s, 2-kHz, coterminating tone. Another group of rats received the tone only. Three weeks later their freezing and USV to the previously-chased context and the tone in the same context were measured. Rats were also tested in the elevated plus maze (EPM) and subjected to Pavlovian threat conditioning with 3 pairings of the tone conditioned stimulus (CS, 20 s, 4 kHz, 75 dB) and the footshock unconditioned stimulus (US, 1 s, 0.6 mA). Following conditioning, their freezing and USV to the conditioning context and CS were measured. Rats that had experienced chasing stress showed a significantly higher level of freezing and USV to the previously-chased context as well as the 2-kHz tone, compared to the control group. In addition, they also showed a significantly higher level of freezing and USV during Pavlovian threat conditioning. On the other hand, there was no significant difference in time spent in the open arm zones of EPM between the groups.
To sum, chasing by a high-speed robot effectively produced a constellation of hormonal, behavioral and emotional stress responses which confirms the validity of the model and suggests its further use as a model of traumatic experience.

Iberoamericana, Ciudad de México, Mexico; [5]Sociedad Iberoamericana de Neurociencia Aplicada, A.C., Ciudad de México, Mexico

Abstract: Post-Traumatic Stress Disorder (PTSD) is a psychiatric diagnosis associated with traumatic life experiences that trigger chronic and debilitating symptomatology. Although differential traumatic stress-coping mechanism have been identified in men and women, animal models of PTSD have mostly focused on male experimental subjects. Also, a growing concern has emerged on the ecological validity of PTSD animal models, which has been answered with models characterized ethologically relevant stressors. The predator scent stress (PSS) is one of such models that has been subject to controversy regarding the origin of the compound used as the stressor and the duration of the exposure. This current study is interested in evaluating the effects of different durations of exposure to the scent of urine from a natural predator, the bob cat. Female Wistar adult rats were assigned (n=6 per group) to 3 min., 10 min., or 20 min. of exposure. The open field test (OFT) was implemented one day after exposure. All experimental groups showed greater frequency and duration of immobility, in which the 3 min. All experimental conditions and the control group did not vary significantly on the time spent in the periphery, but the 10 min. exposure group did demonstrate a lower time spent in the center of the arena. The 10 min. exposure group showed less crosses into the periphery and central area compared to the other groups. Furthermore, 10 min. exposure also elicited a greater frequency of grooming behavior, which has been associated as a stress-coping behavior. The data presented suggests that the 10 min. exposure to predator scent might have a greater impact on the expression of anxiety-like behavior. Expanding scientific knowledge about the particularities of trauma models in animals is an important means to fine-tune propositions geared toward understanding the biological bases of traumatic stress and possible treatments.

Abstract: Stress has been associated to various pathophysiologic states that cut across the traditional boundaries of medical disciplines. These include a range of psychiatric, endocrine, and inflammatory disorders and/or susceptibility to such disorders. The Chronic Unpredictable Stress (CUS) procedure exposes animals to a variety of different and randomized stressors over a period of days. The unpredictability of the stress prevents adaptation and/or habituation. Previous research has reported a reduction in the exploration of novel environments and increase immobility in the Forced Swim Test (FST). The aim of this study was to compare the short-term and long-term effects of CUS. Male Wistar rats were used (n=10) and had an approximate age of three months at the beginning of the experiment. Animals were exposed to a Chronic Unpredictable Stress Battery (CUSB) for a duration of ten days. The stressors that made up the battery consisted of 1) placing animals in movement restrictors for twenty minutes three times per day, 2) swimming in cold water for five minutes (16°C), 3) overnight light exposure (12 hours), 4) placing the rats for twelve hours (overnight) in their home cages with wet bedding, 5) placing the rats for three hours in their home cage that is tilted at 45°C, and 6) overnight water deprivation (12 hours). The exposure to each stressor was randomized according to the CUSB protocol. The behavioral assessments were performed before, immediately after (short-term effects), and after a recovery window of three months (long-term effects). In the FST, there was a decrease in the time spent climbing, which is maintained in the long-term assessment. On the other hand, there was an increment in the time spent immobile immediately after stress exposure; nevertheless this behavior was not maintained in the long-term. In the Saccharin Preference Test (SPT) the experimental subjects showed a reduction in the total fluid intake that persisted in the long-term. This pattern was also reflected in saccharin consumption compared with first behavioral assessment. Finally, it was observed in the Open Field Test (OFT) that experimental subjects spent more time in periphery, which is an index of anxiety-like behavior.

Title: A modification of the platform-mediated avoidance task to study food-avoidance conflict.

Authors: *H. BRAVO-RIVERA[1], P. A. RUBIO-ARZOLA[2], G. J. QUIRK[2];
[1]Univ. of Puerto Rico Lab. of Fear Learning, San Juan, PR; [2]Psychiatry, Univ. of Puerto Rico Sch. of Med., San Juan, PR

Abstract: Previous work from our group has shown that rats learn to avoid foot-shocks by stepping onto a platform when they are exposed to a 30s tone that co-terminates with a 2s shock (Bravo-Rivera C et al., 2014). In this platform-mediated avoidance task, rats continually press a lever to receive a sucrose pellet delivered on a variable interval schedule. Avoidance comes at a cost because the lever cannot be reached from the platform. This cost is minimal, however, because food is also available during the inter-tone intervals. In our modified task, we increased the food-avoidance conflict by limiting food availability to the tone period only. Food availability was signaled by a light co-occurring with the 30s tone. After 16 training sessions, most rats (44/60, 73%) learned to divided their time between pressing for food (avg 24% of time) and avoiding (avg 51% of time). Moreover, we observed two additional subgroups: an avoidance preferring group (6/60, 10%) showing virtually no pressing for food (<5% time) coupled with excessive avoidance (avg 96%), and a food-preferring group (10/60, 17%) that spent excessive time pressing (>50%) coupled with minimal avoidance (avg 28%). Thus, increasing the conflict in the platform-mediated avoidance task reveals three subgroups showing different motivational drives. We are analyzing neural activity with cFos to reveal structures that could mediate these behavioral strategies.

Title: Effects of chronic social defeat stress on mice that lack zinc transporter 3 (ZnT3) and synaptically-releasable zinc

Authors: *B. B. MCALLISTER, R. H. DYCK;
Psychology, Univ. of Calgary, Calgary, AB, Canada

Abstract: Zinc ions are found within synaptic vesicles in a subset of the glutamatergic neurons in the forebrain. Through activity-dependent vesicular exocytosis, this zinc can be released into the synaptic cleft and can exert signaling functions through interactions with numerous receptors. Zinc transporter 3 (ZnT3) is expressed on the membranes of synaptic vesicles and is responsible for maintaining this pool of vesicular zinc. Mice that lack ZnT3 therefore lack the ability to store zinc in vesicles and release it in a neurotransmitter-like fashion. Previous research indicates that ZnT3 knockout (KO) mice generally perform normally in standard behavioural tests, but cognitive deficits are unmasked when they are challenged by advanced age or with more difficult testing. How these mice respond when challenged by stress has not yet been assessed, though zinc-containing neuronal projections are numerous in brain regions that influence stress susceptibility, including the nucleus accumbens, prefrontal cortex, amygdala, and hippocampus. Here, we investigated how chronic stress affects the behaviour of male ZnT3 KO mice, using the repeated social defeat model, which is commonly employed to characterize stress-susceptibility in mice, and is well-established to induce anxiety- and depression-like behaviours. Wild type and ZnT3 KO mice were subjected to 10 days of social defeat stress followed by a battery of behavioural tests, including tests of social interaction, anxiety, and cognition. We found that, relative to stressed wild type mice, stressed ZnT3 KO mice were less avoidant of a novel conspecific. However, we also found that ZnT3 KO mice, but not wild type mice, froze more in a cued fear conditioning test following stress. Anxiety-like behaviour was similar between both genotypes. Thus, there is not a clear increase or decrease in stress susceptibility in ZnT3 KO mice; the interaction between chronic stress and ZnT3 status instead seems to differ between different behavioural domains.

Title: Functional mapping of brain circuits supporting social modulation of pain in mice

Authors: *H. N. TURNER[1], S. SIVASELVACHANDRAN[2], S. ABDALLAH[2], L. J. MARTIN[2], N. M. FOURNIER[1];
[1]Psychology, Trent Univ., Peterborough, ON, Canada; [2]Psychology, Univ. of Toronto Mississauga, Mississauga, ON, Canada

Abstract: Although empathy had been traditionally considered to be a higher level affect/cognitive process expressed exclusively by humans, recent developments have placed this anthropocentric view into question. It is now widely accepted that many species, including rodents, can engage in empathetic behavior. Recent studies have demonstrated that mice have the ability to transmit pain status between paired cage-mates resulting in contagious pain hypersensitivity (hyperalgesia). Interestingly, this transmission of pain status only occurred during interactions where both mice of the dyad are in pain and shared a social history with each other; unfamiliar mouse dyads produced the opposite response inducing marked analgesia. Because the detection of distress or pain in other members of the same species carries information of high survival value, extensive efforts have been directed at elucidating the neurobiological substrates that underlie emotional contagion. To address this, we performed whole-brain mapping by examining expression of the immediate early gene product c-fos across multiple cortical and limbic brain regions in stranger or familiar mice dyads treated with dilute acetic acid. Preliminary analyses found greater Fos+ neurons in the basolateral amygdala of familiar mice compared to isolated or unfamiliar mice consistent with the role of this structure in the appraisal of threat vs. safe cues. In addition, for familiar dyads, higher levels of activation (i.e. increased Fos+ neurons) in the mPFC was associated with lower levels of writhing behaviour consistent with the role of this structure in the suppression of pain behaviour. These findings provide a starting point for mapping the neural circuitry that support emotional contagion in rodents.

Title: Fear expression and safety signals correlate with characteristic patterns of network activity in the limbic system

Authors: *T. E. MADSEN[1], C.-C. HSU[2,1], D. G. RAINNIE[3,1];
[1]Behavioral Neurosci. and Psychiatric Disorders, Yerkes Natl. Primate Res. Ctr., Atlanta, GA;

Abstract: Fear conditioning and extinction are critical emotional learning processes that require complex coordination within the limbic system. Previous studies have shown that interconnections between the basolateral amygdala (BLA), the hippocampus (HPC), and the prelimbic (PL) and infralimbic (IL) subregions of the medial prefrontal cortex (PFC) are critical for fear learning and extinction. In particular, PL and IL are purported to have opposing roles on fear expression. Electrophysiological research in rodents has also revealed synchronous oscillations between the BLA, HPC, and PFC the during fear recall. However, direct comparison of neural signals simultaneously recorded in the PL and IL, along with BLA and HPC, during fear learning and extinction has not yet been done. Here, we performed *in vivo* recording of local field potentials (LFPs) and single-unit activity (spikes) in freely-moving, adult, male, Sprague-Dawley rats during acquisition and extinction of acoustic differential fear conditioning. Prior to fear conditioning, the rats were food-restricted and trained to perform nosepoking for food pellets using an operant conditioning paradigm. Rats were presented with repeated pairings of one tone (CS+) with a mild foot shock (US), pseudorandomly interspersed with another tone (CS-). Nosepoking (NP) behavior and freezing detection provided complimentary measures of fear, as fear tends to suppress reward seeking behavior and locomotor activity. A Behavior Suppression Ratio (BSR) was calculated as (# of NP before tone - # of NP during tone) / (# of NP before tone + # of NP during tone). When fear recall was tested two days later, most rats

demonstrated high levels of freezing and BSR to both CS+ and CS-, but showed a stronger response to CS+. While there was substantial individual variation in rats' ability to discriminate between the two stimuli, on average, the rats extinguished fear to CS- faster than CS+. The power and coherence of delta (2-4 Hz) and mid-gamma (50-60 Hz) oscillations, between BLA and both subregions of the PFC, increased with fear expression and were suppressed in response to CS- during fear extinction training. Conversely, the power of a 7-9 Hz theta oscillation in CA3 was inversely correlated with fear expression. A transient burst of high gamma power (70-130 Hz) was observed in all four regions at the onset of CS-. Further analysis of phase relationships within the network, cross-frequency coupling, single-unit spiking, and Granger Causality will be performed.

Title: Blockage of basolateral amygdala afferent input by *In vitro* 130 Hz stimulation shows frequency- and pathway- specificity.

Authors: *B. O'FLAHERTY[1], D. G. RAINNIE[2];
[2]Psychiatry, [1]Emory Univ., Atlanta, GA

Abstract: Deep brain stimulation (DBS) of the infralimbic cortex (Brodmann Area 25) at 130 HZ is an effective treatment of major depressive disorder (MDD) in patients that are unresponsive to traditional MDD therapies such as SSRIs. However, the therapeutic mechanism of high-frequency stimulation remains unknown. Notably, no one to date has shown how 130 Hz stimulation affects neuronal activity in key limbic areas known to be dysregulated in MDD. For example, the basolateral amygdala (BLA; a key mood area that is hyperactive in MDD patients) receives dense synaptic projections from the infralimbic cortex, and may be a key region influenced by DBS in humans. Previously we showed that 130 Hz stimulation of the external capsule (EC) decreased the amplitude of evoked synaptic activity onto BLA principal neurons.

We hypothesize this effect is both frequency- and pathway-specific. To test this hypothesis, we used in vitro whole-cell patch clamp recordings from BLA principal neurons in coronal slices, in conjunction with extracellular stimulation of the external capsule (EC, representing cortical input) and internal capsule (IC, representing thalamic input). The EC was stimulated at 130 Hz for a period of 6 minutes. Input resistance, spike threshold, spontaneous synaptic activity frequency / amplitude, evoked synaptic activity amplitude, and paired pulse ratio were measured before 130 Hz stimulation, immediately after, and following a 15 minute recovery period. We found 130 Hz stimulation of the EC decreased the amplitude of EC evoked synaptic activity to 9.08% of baseline, but did not change the amplitude of IC evoked synaptic activity. Additionally, we observed an increase in action potential threshold of approximately 3 mV in BLA principal neurons immediately following 130 Hz stimulation of the EC. No change in membrane resistance was seen in BLA principal neurons after stimulation. These effects were not seen when the EC was stimulated at 20 Hz. We interpret the reduced evoked synaptic response as an action potential-dependent blockage of excitatory drive onto BLA principal neurons, possibly coupled with other pre- and post- synaptic mechanisms. As hyperactivity of the BLA has been implicated in MDD, a reduction in synaptic input into the BLA principal neurons could reduce BLA activity and restore normal functioning. Understanding how 130 Hz stimulation affects the BLA is vital for understanding the clinical efficacy of DBS, and to develop more effective and less invasive treatments for treatment-resistant MDD.

Title: Development of fear learning in rats prenatally exposed to valproic acid

Authors: *C. E. BARRETT[1,2], K. GORDON[1,2], T. HENNESSEY[1,2], K. RESSLER[3], D. RAINNIE[1,2];
[1]Dept. of Psych. and Beh. Disorders, Emory Univ., Atlanta, GA; [2]Dept. of Beh. Neurosci. and Psych. Disorders, Yerkes Natl. Primate Res. Ctr., Atlanta, GA; [3]Dept. of Psychiatry, Harvard Univ., Boston, MA

Abstract: The emergence of fear learning in the rat occurs in the second week of life and coincides with the maturation of the amygdala. Precocious amygdala development and heightened levels of anxiety are commonly reported in Autism Spectrum Disorder (ASD). However, little is known about the cellular, molecular, or genetic changes that occur in the amygdala, or how abnormal development impacts socioemotional behavior. Prenatal exposure to valproic acid (VPA) leads to an ASD-like phenotype in both humans and rats, and has become a commonly used tool to model the complexity of ASD symptoms in the laboratory. We previously found that gavage treatment of VPA overcomes embryo resorption problems associated with intraperitoneal administration, while recapitulating the same behavioral phenotype. Male offspring display reduced separation-induced ultrasonic vocalizations, increased latencies to approach maternal bedding, and impaired juvenile social interaction. Here, we examined amygdala gene expression and fear conditioning across development in rats exposed to VPA in utero. Rat dams were gavaged with VPA (500mg/kg) or saline daily between E11-13. RNA sequencing was performed on amygdala micropunches on P10 and 21. Fear conditioning was performed in infant (P8-9) and juvenile (P18-19) animals and consisted of two days of 10 light-shock (0.4mA, 0.5s) pairings with 2 min intertrial intervals. Fear potentiated startle responses to 95dB noise bursts were examined 12 and 30 days after conditioning. After fear conditioning at P8-9, VPA animals (n=12 per sex) displayed greater light-potentiated startle responses than saline animals (n=10 per sex; p=0.037), which was driven by greater fear responses in female VPA animals. In juveniles conditioned at P18-19, VPA males (n=8) displayed greater light-potentiated startle than did saline males (n=8; p=0.013), but no differences were detected in females (n=8 per drug). Thus, VPA exposure may enhance infant fear expression in females, but increase juvenile fear retention in males. In order to find gene targets amendable to pharmacological manipulation in development, genes with significant expression differences were run through the druggable genome (http://dgidb.genome.wustl.edu/). Those confirmed with quantitative PCR in biological replicates will be discussed. An understanding of the differential molecular trajectories in amygdala development between control and ASD-like rats could reveal gene pathways and critical windows for treatment.

Title: Postnatal development of membrane potential oscillations in the basolateral amygdala.

Authors: *S. J. RYAN[1], D. G. RAINNIE[2];
[2]Dept. of Psychiatry, [1]Emory Univ., Atlanta, GA

Abstract: 4-8 Hz membrane potential oscillations (MPOs) in the basolateral amygdala (BLA) play an important role in processing affective sensory input. Notably, the BLA, prefrontal cortex (PFC), and hippocampus show coherent 4-8 Hz oscillations during the acquisition and retrieval of learned fear. Significantly, artificially driving PFC parvalbumin (PV) interneurons at 4 Hz induces coherent delta frequency oscillation in the BLA and PFC, which can elicit fear behavior. We have shown that MPOs in BLA principal neurons are engendered, sustained, and synchronized by an interaction between intrinsic voltage-gated membrane currents and synchronous inhibition from PV interneurons. Both components of this interaction are subject to modulation by neuromodulators, including dopamine, noradrenaline, and acetylcholine. Although each of these neuromodulators are known to play critical roles in BLA-dependent learning and memory; innervation of the BLA by cholinergic, noradrenergic, and dopaminergic fibers develops gradually over the first two postnatal months. Furthermore, the perisomatic PV synapses are first observed around P17 and continue to develop into adulthood. As a result, little is known about the ability of BLA principal neurons to sustain MPOs or the interaction between synchronized inhibition and MPOs in developing BLA principal neurons. We have begun to address this knowledge gap using whole-cell patch clamp recordings from BLA neurons across development to examine the maturation and modulation of MPOs in the BLA.
We will present data showing that 4-8 Hz MPOs can be observed and amplified by isoproterenol, a beta-adrenergic agonist, as early as postnatal day (P)14 and that these MPOs are capable of interacting with artificially injected inhibitory currents. In experiments examining the interaction of MPOs with artificially injected inhibition, 4-8 Hz oscillations were amplified by a significant amount in 78% of neurons; however, MPOs in young animals occur at a lower amplitude than in adults, and demonstrate a weaker interaction with inhibition. Furthermore, the spontaneously occurring synchronized inhibition which is a hallmark of BLA recordings appear much less frequently in recordings from young animals. This data is consistent with the hypothesis that MPOs are a critical mechanism in memory formation in the BLA, and that the developmental course of MPO development parallels that of BLA-dependent memory formation.

Title: Reciprocal effect between like-anxiety behaviors and epileptogenesis in an experimental model

Authors: *A. E. HIDALGO-BALBUENA[1], P. DOMÍNGUEZ-ZUÑIGA[2], A. VALDÉS-CRUZ[2], B. A. GARAY-CORTES[2], M. G. MARTÍNEZ-MONTALVO[2], S. ALMAZÁN-ALVARADO[2], R. FERNÁNDEZ-MAS[2];

[2]Neurociencias, Inst. Nacional De Psiquiatria Ramon De La Fuen, Ciudad De México, Mexico

Abstract: Temporal Lobe Epilepsy (TLE) is a syndrome characterized by focal secondary generalized seizures with prevalence from 50% to 70% among those people diagnosed with epilepsy. Comorbidities with some other neuropsychiatric disorders such as depression and anxiety have been reported. In the comorbidity anxiety-epilepsy, limbic system structures like amygdala and hippocampus participate. Anxiety related to epilepsy is evident in the clinic, but the relationship between the two conditions has many questions. The objective of this study was to analyze the effect of unconditioned anxiety tests (UATs) on the development of epileptogenesis induced by electrical amygdala kindling (EAK) and the effect of EAK on anxiety-like behaviors. Male Wistar rats (300-350 g) were implanted with epidural electrodes in both prefrontal cortices and a tripolar electrode in the left temporal lobe amygdala for EAK. Amygdala was stimulated every 24 h (1 s, 1 ms, 60 Hz, 250-500 μA) until rats presented three consecutive convulsive generalized seizures (CGS). UATs were applied once with 24 h of interval in next order: Open field test (OFT), elevated plus maze (EPM), and light/dark box (L/D). 5 groups with N = 7 were formed: 1) Control UAT, rats only subjected to UATs; 2) UAT + EAK, rats subjected to UATs, 24 h later were implanted and EAK began; 3) EAK + UAT, rats subjected to EAK, 24 h after the 3rd CGS UATs were applied; 4) SHAM + UAT, rats were implanted with any stimulation and UATs were applied; 5) Control EAK, rats that only received kindling. In EAK groups was done the seizure susceptibility test. Furthermore, was performance a correlation between number of stimuli to reach CGS and like-anxiety behaviors. In OFT were observed significant increases in the spent time in central area ($P < 0.001$) and the central area entries ($P < 0.001$) in EAK + UAT *vs* UAT. It was also observed an increase of total movement time in EAK + UAT *vs* UAT + EAK ($P < 0.014$) and number of rearings in SHAM + UAT *vs* control UAT ($P < 0.026$) and UAT + EAK ($P < 0.008$). In EPM, spent time on the close arms

showed a significant increase in UAT + EAK *vs* EAK + UAT ($P < 0.026$). In seizure susceptibility test, there was an increase of necessary current (μA) to evoke spikes in UAT + EAK compared to EAK + UAT ($P < 0.015$) and control EAK ($P < 0.038$). It was exhibited a correlation between number of stimulations to reach CCG and latency to center entries ($r = 0.791$, $P < 0.034$). Our results suggest that EAK interferes with expression of unconditioned anxiety behaviors and, anxious phenotype could interfere with epileptogenesis without affecting the severity of the CGS.

Title: Work related stress assessment in health care workers: objective and subjective indicators

Authors: *S. ZAFFINA, JR, M. VINCI, V. CAMISA, G. DALMASSO, A. ANTICO, A. SANTORO;
Children's Hosp. bambino Gesù, Rome, Italy

Abstract: Job stress was defined as the harmful physical and emotional responses which occurred when the requirements of the job do not match the capabilities, resources, or needs of the worker. The enormous human and economic costs associated with occupational stress suggest that initiatives designed to prevent and/or reduce employee stress should be high on the agenda of workplace health promotion programmes.The assessment of work-related stress, based on the local legislation, is divided into two phases: the first necessary (objective assessment); the other possible, to be activated in the event that the preliminary assessment shows elements of risk of work-related stress and the corrective measures taken in response of the same, prove to be ineffective.In the preliminary assessment reveal objective and verifiable indicators belonging to three distinct categories (sentinel events, working environment and job content factors).For the subjective assessment is adopted the Health & Safety Executive's Management Standards Revised Indicator Tool (MS-RIT), a 35-item self-report instrument designed to investigate employees' exposure to workplace elements that are presumed to cause a stress related outcome. The value of the subjective assessment by department (Δ) is based on the difference between the number of positive, negative and equal (standoff) answers.The evaluation of objective factors, in

a large pediatric Italian hospital, has identified the level of work-related stress as of medium severity.Quarterly and divided by 13 hospital department they were monitored 3 significant objective indices that, in our experience, are work-related stress: sickness absence, transfer requests and requests for extraordinary visit of Occupational Medicine .For the purpose of subjective assessment we were submitted 523 MS-RIT questionnaires.Analysis of objective indicators showed 2 indicators over the threshold in four departments, 1 indicator over the threshold in six departments and a value below the threshold for all three indicators in two departments.
The department of pediatric oncology and hematology was the only one that showed two parameters objective over the threshold (sickness absence and requests for extraordinary visit of Occupational Medicine) and a subjective assessment with apparent critical level (positive Δ).Also the data relating to the sickness absence, unlike other departments under investigation, is not directly related to the company average age (41.42 vs 46.6).
The continuous monitoring of objective parameters correlates with the level of work-related stress if it is matched with the subjective assessment and the workers average age.

Title: The effect of handling conditions on depressive-like behaviors in laboratory mice

Authors: C. LANE, J. TORRES, C. NEELY, *J. M. FLINN;
Psychology, George Mason Univ., Fairfax, VA

Abstract: Laboratory animals are subjected to an enormous amount of stress during experimentation which presents a neuroethical dilemma. This stress may be manifested in the form of aggression, anxiety, and depressive symptoms (Miller & Leah, 2015; Hurst & West, 2010). Researchers and caretakers can utilize different methods of handling that may be detrimental to animals and inadvertently affect behavioral measures. In contrast, affectionate handling can decrease anxiety, reduce stress hormones (Costa et al., 2012), and can be a good alternative to social housing (Cloutier et al., 2012). This study examined the effects of handling

on depressive-like behaviors in C57BL/6J mice. We hypothesized that mice that were affectionately handled would display the least amount of depressive behavior when compared to mice that were aggressively or minimally handled. C57BL/6J male mice (N = 21) were separated into the three conditions: affectionate, aggressive and control. Each mouse underwent 90-second handling sessions for 13 days over the course of three weeks. Affectionate handling consisted of the handler gently petting the head and flanks and permitted the mouse to move between hands. Aggressive handling involved tail suspension four inches in the air. The control condition received no additional handling beyond that of caretakers. At the end of the three-week period, mice were subjected to a 6 minute Forced Swim Test (FST) to determine the efficacy of handling conditions on immobility, a depressive behavior in rodents. Analyses demonstrated a significant effect of handling: the affectionate handling group had the greatest latency period before becoming immobile (114.7±55.3s), and the least time immobile (52.0±21.4s) ($p<0.05$). The aggressive handling condition exhibited the shortest latency before becoming immobile (84.4± 17.1s), and the greatest amount of time immobile (156.0±28.1s). The control condition did not statistically differ from the aggressive handling group in terms of latency (92.9±24.2s) and immobility (128.7±63.7s), $p>0.50$. Data suggest that the gentle handling technique diminished stress-induced depression during FST experimentation. If this standard of care is applied, then it can improve the overall well-being of laboratory animals and affect experimental outcomes among laboratories.

Title: Reducing DAT function results in hypersensitivity to seasonal photoperiod-induced changes in affect

Authors: *Z. A. COPE, D. DULCIS, J. W. YOUNG;
Dept. of Psychiatry, Univ. of California San Diego, La Jolla, CA

Abstract: Bipolar disorder (BD) is a debilitating mental illness characterized by chronic relapse and switching between extreme moods including depression and mania. Mechanisms underlying

unipolar symptoms are well understood, but mechanisms underlying the switch between extremes within the same individual remain unknown. Switches between extreme states have been linked to seasonal variation, with mania in long-active photoperiods and depression in short-active photoperiods (Berk, et al. *Acta Psychiatr Scand.* 2007). Exposing rats to summer-(long-active; LA) or winter-(short-active; SA) like photoperiod lengths resulted in neurotransmitter switching between somatostatin (SST) and the dopamine synthesizing enzyme tyrosine hydroxylase. Each condition was associated with mania- (LA photoperiod), and depression-relevant behavior (SA photoperiod; Dulcis, et al. *Science*, 2013). Mania or depression in summer or winter is observed in subjects affected by seasonal affective disorder, however, and BD patients likely have a genetic susceptibility. Euthymic BD patients exhibit reduced dopamine transporter (DAT) expression (Anand, et al. *Bipolar Disorders*, 2011). Here, we exposed mice with an ~50% reduction in DAT expression (DAT-HY) to SA or LA photoperiods to assess the degree to which these manipulations could induce mania- or depression-relevant behavior. Increased depression-relevant forced-swim immobility was observed in mice housed under SA conditions [$F_{(2,64)}$,=4.3, $p<0.05$], while LA photoperiod resulted in increased mania-relevant open arm exploration [$F_{(2,61)}$=4.7, $p<0.05$], effects exaggerated in DAT HY mice. Further, we performed a multi-dimensional behavioral characterization in these same mice following exposure to altered photoperiods including cross-species relevant measures of reward learning and effortful motivation. Notably, DAY HY mice exhibited enhanced 5C-CPT performance under normal photoperiod conditions, an effect abolished under both SA [$F_{(2,64)}$=5.6, p=0.05] and LA [$F_{(2,64)}$=4.62, $p<0.05$, $F_{(2,64)}$=5.1, $p<0.05$] photoperiods. Increased reward-seeking behavior across two separate tasks was observed in DAT-HY mice resulting from LA photoperiod exposure compared with WT mice ($p<0.05$). However, under SA conditions, HY mice showed a selective impairment in probabilistic reward learning [$F_{(2,64)}$=3.0, p=0.059] and increased punishment sensitivity [$F_{(2,64)}$=3.2, p=0.057], compared to WT mice ($p<0.05$). Hence, a genetic (DAT) and photoperiod (seasonality) interaction may drive switching between states in BD sufferers, and offer a target for minimizing such changes.This study was funded by NIH R01 MH104344

Title: Affective and addictive consequences of adolescent stress in rats selectively bred for differences in emotional reactivity

Authors: *C. AYDIN, K. S. FROHMADER, P. BLANDINO, Jr, H. AKIL;
Mol. and Behavioral Neurosci. Inst., Universty of Michigan, Ann Arbor, MI

Abstract: In humans, certain temperamental characteristics can predict the propensity for mood disorders and substance abuse. One such personality trait, novelty-seeking behavior, is modeled in rats by identifying outbred rats as high (HR) versus low (LR) responders based on their locomotor reactivity to the mild stress of a novel environment. Compared to LRs, HRs display lower anxiety- and depression-like behaviors and higher vulnerability for drug seeking behavior. To ascertain the genetic and developmental underpinnings of these phenotypes, our laboratory has employed a selective breeding strategy to amplify and segregate these naturally occurring differences generating two lines, the bred HR (bHR) and bred LR (bLRs) rats. We have shown that these lines exhibit stable, predictable and profound differences in multiple facets of affective behavior suggesting a pervasive difference in emotionality. The present study investigated how environmental interventions interact with the genetic differences that bHRs and bLRs exhibit to alter affective and addictive behaviors. We employed a chronic variable stress (CVS) regimen in adolescence, and determined the effects of this manipulation on depression-like behavior, and vulnerability to substance abuse. Our results showed that adolescent CVS exposure resulted in affective resilience in bLRs, but vulnerability in bHRs to a stress challenge in adulthood. This phenotype-switch in affective behavior was accompanied by changes in the mRNA levels of genes associated with neuronal maturation and survival, in the hippocampus. Moreover, a phenotype-switch was also observed in cocaine sensitization in CVS-exposed bLRs and bHRs, in that, CVS-experienced bHRs showed a reduction in sensitization, while bLRs displayed a sensitized response to cocaine. Molecular analyses showed that the CVS-related differences in cocaine sensitization might be mediated by dopaminergic signaling in the nucleus accumbens and the hippocampus. Overall, these findings indicate that the effects of CVS on animals with differential stress reactivity depends highly on the age of stress exposure, and confirm that environmental challenges encountered in adolescence interact with genetic background to alter affective and addictive behaviors later in life. Understanding the neurobiological underpinnings of individual differences in resilience vs vulnerability to affective and addictive behaviors is crucial for developing personalized treatment strategies.

Title: Mechanisms linking depression associated with obesity through serotonergic modulation in experimental mice

Authors: *Y. KURHE[1], R. MAHESH[1], T. DEVADOSS[2];
[1]Birla Inst. of Technol. & Science, Pilani, Pilani, India; [2]Pharmaceut. Chem., Intl. Med. Univ. (IMU), Kaula Lampur, Malaysia

Abstract: One of the key psychological risk factor of obesity is depression, where more than 50% of obese population is twice susceptible to depression than non-obese individuals. Several pre-clinical studies has revealed the antidepressant potential of 5-HT_3 receptor antagonists through serotonergic neuromodulation. Hence, the present study was designed to investigate the effect of a novel 5-HT_3 receptor antagonist (4-phenylpiperazin-1-yl) (quinoxalin-2-yl) methanone **(4a)** on various pathological factors involved in co-morbid depression with obesity using behavioral, biochemical and molecular assays in experimental mice.
Swiss albino mice were fed with high fat diet (HFD) for 14 weeks to induce obesity and subsequently followed by a dosing regimen with **4a** (2 and 4 mg/kg, p.o.)/standard escitalopram (ESC) (10 mg/kg, p.o.)/vehicle (0.25 % sodium carboxyl cellulose 10 ml/kg, p.o.) for 28 days. HFD fed animals were subjected to behavioral assays such as forced swim test (FST), sucrose preference test (SPT), elevated plus maze (EPM) and light-dark test (LDT) biochemical assays including brain hippocampus malonaldehyde (MDA), reduced glutathione (GSH) concentrations, oral glucose tolerance test (OGTT), plasma insulin, and corticosterone (CORT), and molecular assays including hippocampal 5-HT, cyclic adenosine monophosphate (cAMP) and brain derived neurotrophic factor (BDNF) concentrations and hippocampus dentate gyrus histological assay. HFD mice showed significantly increased body compared to normal pellet diet (NPD) control group. HFD animals exhibited severe depressive phenotypes with significantly, reduced sucrose consumption in SPT, increased immobility time in FST, decreased % open arm entries and time in EPM, reduced transitions and time in light chamber in LDT, impaired glucose tolerance in OGTT, abnormally raised MDA and decreased GSH, elevated CORT & poor insulin sensitivity reduced hippocampal BDNF, cAMP, 5-HT concentrations and hippocampal dentate gyrus neurodegeneration as compared to NPD control group. Chronic treatment with 5-HT_3 receptor antagonist **4a** significantly improved the sucrose consumption in SPT, reduced the immobility time in FST, improved EMP paradigms, showed poor sensitivity for glucose, improved insulin sensitivity, increased hippocampal 5-HT, cAMP, and BDNF concentrations and reversed hippocampal neuronal degeneration in HFD fed obese mice compared to HFD control group.

Repetitive treatment with **4a** ameliorates the depressive phenotypes in HFD fed obese mice by reversing behavioral, biochemical and molecular alterations through modulating serotonergic neurotransmissions.

Title: The effects of dietary linoleic and alpha-linolenic acid on brain lipid metabolism and depression-like behavior in male rats

Authors: *M. FERNANDES, D. MUTCH, F. LERI;
Univ. of Guelph, Guelph, ON, Canada

Abstract: *Introduction*: An imbalanced ratio of dietary Omega-6 (n-6) / Omega-3 (n-3) polyunsaturated fatty acids (PUFAs) contributes to onset and severity of depression-related disorders; however, the underlying neurobiological mechanisms remain unclear. We hypothesize that PUFA-derived metabolites, such as endocannabinoids and oxylipins, could serve as a molecular mechanism linking dietary PUFAs and depression-like behavior.
Methods: Male rats (11 weeks old) were fed either a control (AIN-93G), n-3 α-linolenic acid (flaxseed) or n-6 linoleic acid (safflower)-supplemented diet for a month. Brains were collected for the analysis of phospholipid composition, as well as endocannabinoid and eicosanoid profiles, in the pre-frontal cortex, hippocampus and hypothalamus. Different cohorts of animals in the same dietary conditions were tested for behavioral despair and anhedonia using the forced-swim and fructose/sucrose self-administration tests, respectively.
Results: PUFA composition of brain regions reflected the diet, i.e., higher concentrations of n-3 PUFAs in total phospholipids of α-linolenic acid-fed rats, and higher concentrations of n-6 PUFAs in phospholipids of linoleic acid-fed rats. Moreover, dietary α-linolenic acid increased levels of several n-3-derived eicosanoids and endocannabinoids in the brain, while no significant changes were seen with linoleic acid. Finally, depression-like behavior was only observed in rats fed linoleic acid, as reflected by increased immobility in the forced-swim test and reduced sweet

solution consumption in rats with free access to a fructose/sucrose solution.
Conclusion: Linoleic and α-linolenic acid modulates brain phospholipid composition and PUFA metabolites, and these effects coincided with depressive-like behaviors in rats. These data provide valuable new insights regarding the differential roles of dietary fats and their potential links with depression.

Title: Carbetocin stimulates release of TRH and TRH-like peptides throughout the male rat brain and peripheral tissues

Authors: *A. E. PEKARY, A. SATTIN;
Res., VA Greater Los Angeles Hlthcare Syst, Los Angeles, CA

Abstract: Oxytocin (OXT) analogs and mimetics have exciting potential as therapeutics for an array of psychiatric illnesses including major depression, autism, social anxiety disorder, and Prader-Willi syndrome. We have used young adult male Sprague-Dawley rats to assess the role of TRH and TRH-like peptides, with the structure pGlu-X-Pro-NH_2, where "X" can be any amino acid residue, as mediators of the neurobiochemical, metabolic, and reproductive effects of OXT. The levels of these peptides in 12 brain regions involved in mood regulation decreased (due to accelerated release/clearance) 105 times but increased only 16 times following a single ip injection of carbetocin, a long-acting analog of OXT. The corresponding changes in peripheral tissues were: 67 decreases and 1 increase. These changes, listed by brain region in the order of decreasing number of significant decreases (↓) and/or increases (↑), were: hypothalamus (21↓), striatum (17↓, 1↑), medulla oblongata (15↓), anterior cingulate (14↓), entorhinal cortex (12↓), amygdala (9↓,1↑), nucleus accumbens (3↓, 6↑), posterior cingulate (5↓), cerebellum (3↓,2↓), frontal cortex (2↓, 3↑), piriform cortex (3↓,1↑), and hippocampus (1↓,2↑). In peripheral tissues the corresponding changes were: adrenals (20↓), epididymis (16↓), prostate (14↓), testis (13↓),

pancreas (4↓,1↑). We conclude these peptides may be downstream mediators of some of the therapeutic effects of OXT.

Title: Neuronal functions of trace amine-associated receptor 5 (TAAR5)

Authors: *S. ESPINOZA[1], I. SUKHANOV[2], P. ILLIANO[1], A. GERASIMOV[2], T. D. SOTNIKOVA[2], I. FERRER[3], D. LEO[1], R. R. GAINETDINOV[2];
[1]Inst. Italiano Di Tecnologia, Genova, Italy; [2]Inst. of Translational Biomedicine, St. Petersburg, Russian Federation; [3]Inst. of neurophatology, Barcelona, Spain

Abstract: Trace amine-associated receptors (TAARs) are a class of G protein-coupled receptors found in mammals. TAARs family consists of 9 genes in human (including 3 pseudogenes) while 19 and 16 genes (including 2 and 1 pseudogenes) are present in the rat and mouse genome, respectively. While TAAR1 is expressed in several brain regions and its function in the central nervous system is well characterized, all the other TAARs have been described in the olfactory epithelium and believed to serve as a new class of olfactory receptors. However, there is evidence that other TAARs, such as TAAR5, could play a role also in the central nervous system. In our study, we report that TAAR5 is expressed in distinct brain regions. By using a mouse line expressing beta-galactosidase under TAAR5 promoter, we noted TAAR5 expression in amygdala, enthorinal cortex and olfactory bulb. These data were confirmed by the quantification of TAAR5 mRNA using RT-PCR. Interestingly, we also found TAAR5 mRNA in human amygdala, suggesting a conservation of the expression between mouse and human. We then studied the in vitro pharmacology of the receptor and confirmed that 3-methylamine is a full agonist of the receptor. Similarly to TAAR1, TAAR5 poorly desensitized upon agonist stimulation and shows an almost complete lack of beta-arrestin2 recruitment. TAAR5-KO mice are viable and do not show gross abnormalities in several tests. The lack of TAAR5 does not seem to affect the dopaminergic system, as evaluated by the challenge with dopaminergic drugs in behavioral assays. Interestingly, 5-HT1A receptor activity was altered, as demonstrated by 8-OH-DPAT-induced hypothermia. Since serotonin and 5-HT1A receptor are involved in mood

disorders we evaluated TAAR5-KO mice in depression and anxiety-related tasks. In certain behavioral paradigms, we noted that TAAR5-KO mice displayed anti-depressant-like phenotype and showed less anxiety in comparison to controls. In conclusion, TAAR5 is expressed in the mouse and human brain in regions involved in mood and cognition, and TAAR5-KO mice show altered depression and anxiety-related behaviors.

Title: Dental noise exposed mice display depressive-like phenotypes

Authors: *Y. ZHOU[1,2], W. LI[1], Y. DONG[1], X. CHU[1];
[1]Bio-X Institutes,Shanghai Jiao Tong Univ., Shanghai, China; [2]Shanghai Key Lab. of Psychotic Disorders, and Brain Sci. and Technol. Res. Ctr., Shanghai, China

Abstract: Background: Studies have indicated that depressive disorders are observed frequently in dentists. It's suggested that dentists encounter numerous sources of stress in their professional career. We noticed that the noises in dental environments are very unpleasant. The animal modeling studies suggested that stressful noise could produce depressive-like phenotypes in rodent animals. We hypothesize that the dental noise may be one of the primary stressors causing depressive disorders in dentists.Results: We treated C57BL/6 mice with programmatically

played wide-spectrum dental noise for 8 hours/day at 75±10dB SPL level for 30 days, and then tested the behaviors.After exposure to dental noise, animals displayed the depressive-like phenotypes,accompanied by inhibition of neurogenesis in hippocampus. These deficits wereameliorated by orally administered with antidepressant fluoxetine.Conclusions: Our results suggested that dental noise could be one of the primary stressors for the pathogenesis of depressive disorders and the dental noise mouse model could be used in further depression studies.

Title: Investigating a critical period needed for perinatal photoperiod effects on the serotonergic system

Authors: *J. K. SIEMANN[1], N. GREEN[1], H. IWAMOTO[2], D. G. MCMAHON[1];
[1]Biol. Sci., [2]Pharmacol., Vanderbilt Univ., Nashville, TN

Abstract: Globally, it is estimated that over 350 million individuals suffer from depression while 16 million Americans have reported experiencing at least one depressive episode. In addition, studies have shown seasonally varying risks for mood disorders with higher rates occurring during the fall or winter months when daylight is lowest in the year. The serotonergic system is known to be impacted by the duration of light exposure (i.e. photoperiod) and has been implicated in mood disorders, providing a promising new area of research. Thus, evaluating the mechanisms underlying the interaction between photoperiod and this system may provide understanding that is critical for developing insights into the etiology and novel treatment options. Recently, our lab has shown that mice exposed during development to long summer-like photoperiods of 16 hours of light and 8 hours of darkness each day (LD 16:8) demonstrate a greater neuronal firing rate of dorsal raphe serotonin neurons in isolated brain slices and higher levels of monoamines (i.e. serotonin and norepinephrine) in the midbrain along with more

anxiolytic and anti-depressive behavioral effects compared to animals exposed to short winter-like LD 8:16 photoperiods or equinox LD 12:12 photoperiods. Based on these prior findings that used a developmental photoperiod from E0 to P30, we have now focused on when these photoperiod changes occur in development (i.e. the critical period), resulting in lasting changes in the serotonergic system. Specifically, we found that when animals were exposed only prenatally (E0-P0) to long photoperiods and then switched to a short photoperiod at birth, the average firing rate of dorsal raphe serotonin neurons measured in adulthood (P50-P90; 1.18 ± 0.076 Hz) resembled the firing rate for animals which continued to develop under a long photoperiod (1.24 ± 0.084 Hz). Interestingly, raphe neurons from animals that were prenatally exposed to a short photoperiod and then switched to a long photoperiod at birth, displayed an intermediate firing rate (0.99 ± 0.083 Hz) compared to those that were continuously exposed to either a long (1.24 ± 0.084 Hz) or short photoperiod (0.69 ± 0.024 Hz) throughout development. These findings demonstrate that photoperiodic programing of serotonin neurons can occur in utero, long photoperiods may be serving as an active agent and affecting the serotonergic system perinatally, and exposure to short photoperiods in utero may extend the critical period into the perinatal period. By evaluating a developmental critical period for the effects of photoperiod on the serotonin system, this may provide novel insights into therapeutic treatments for mood related disorders.

Title: Photoperiod-induced neurotransmitter plasticity relevant to bipolar disorder

Authors: *B. ROMOLI, E. SCHRURS, Z. COPE, J. W. YOUNG, D. DULCIS;
Psychiatry, UC San Diego, LA Jolla, CA

Abstract: Bipolar disorder is a neuropsychiatric condition associated with altered function of specific neurotransmitters, including serotonin and dopamine. Although it is generally believed that neurotransmitters expressed by differentiated neurons are fixed, our findings demonstrate that photoperiod regulates the number of dopamine- and somatostatin (SST)-expressing neurons in the adult mouse hypothalamus. We have investigated this novel form of neuroplasticity in

dopaminergic neurons of the paraventricular nucleus (PVN) following two weeks of exposure to a short-active (19L:5D), balanced (12L:12D), or long-active (5L:19D) photoperiod. Firstly, we measured the effect of photoperiod on neurotransmitter expression observed in wild-type animals. Next, we compared the light-induced response displayed by dopamine transporter (DAT) hypomorphic (HY) mice, an animal model for bipolar disorder characterized by 50% reduction in DAT and depressive-like symptoms. Following photoperiod manipulation and behavioral testing, brain tissue was processed for immuno-histochemistry with the dopaminergic marker tyrosine hydroxylase (TH) and SST. Stereological quantification of stained neurons was carried out for all photoperiods. We found that the total number of PVN TH+ neurons of wild-type mice was decreased following two weeks of short-active photoperiod and it is increased after two-week exposure to long-active photoperiod, compared to controls. Conversely, SST expression was higher following the short-active photoperiod and lower after exposure to long-active photoperiod, compared to controls. One-week exposure to altered photoperiod was insufficient to induce changes in neurotransmitter expression. Importantly, our data shows that DAT-HY mice respond to photoperiod manipulations and displayed changes in stress responses. Lower levels of SST and higher levels of TH correlate with reduced stress response in behavioral paradigms, such as elevated plus maze and forced swimming tests in rats. Therefore, these findings may indicate that the ability to cope with stress is increased following long-active photoperiod exposure. To this aim, we are currently testing photoperiod-dependent changes in stress hormone, corticotrophin releasing factor. Induction of neurotransmitter plasticity by alterations in ambient illumination raises the possibility of activating other sensory modalities to regulate transmitter expression in specific brain nuclei otherwise accessible only by invasive procedures. Activity-dependent induction of neurotransmitters in circuits in the adult brain could have clinical benefit for treatment of bipolar disorder.

Title: Learning and memory impairment associated with learned helplessness depression-like behavior

Authors: *M. PARDO, E. BUREL, R. JOPE;
Departments of Psychiatry and Biochem., Univ. of Miami, Miami, FL

Abstract: Depression is a complex psychiatric disease caused by genetic and environmental factors that is induced in part by abnormal responses to stress. Depression is primarily characterized by alterations in mood, but this is commonly accompanied by impairments in learning and memory, which significantly contributes to disability. We used the learned helplessness paradigm to differentiate (1) cognitive impairments induced by stress alone in resilient mice that did not develop learned helplessness and (2) cognitive impairments caused by stress-induced depression-like behavior in mice that did develop learned helplessness. In the learned helplessness paradigm, mice are exposed to inescapable foot shocks one day followed by escapable foot shocks the following day. Mice were divided into resilient and "depressed" cohorts based on their failures to escape the foot shocks on day 2. About 30% of wild-type mice displayed resilience to stress-induced "depression". Two memory tasks were measured the day after characterization of mice as resilient or "depressed, novel object recognition and temporal order recognition. Novel object recognition was impaired in all stressed mice but temporal order recognition was only impaired in the depressed cohort of mice, indicating a mood-dependent impairment in cognition. The involvement of glycogen synthase kinase-3β (GSK3β) and Toll-like receptor 4 (TLR4) were studied because they mediate some components of the stress response, mood, and cognition. The inhibitory serine- phosphorylation of GSK3β was significantly decreased in the "depressed" mice compared to the resilient mice, indicating activation of GSK3 during learned helplessness. Treatment of learned helpless mice with the GSK3 inhibitor TDZD-8 resulted in two cohorts of mice, those that remained "depressed" and those that recovered. After TDZD-8 treatment, the mice that remained "depressed" also retained impaired novel object recognition, whereas the mice that recovered from learned helplessness after TDZD-8 treatment also recovered from the impaired novel object recognition. Furthermore, 90% of TLR4 knockout (KO) mice were resistant to learned helplessness and TLR4 KO mice displayed less stress-induced cognitive impairments than wild-type mice. These results demonstrate that "depression" resulting from stress exacerbates stress-induced deficits in learning and memory in mice and that stress-induced mood and memory impairments are modulated by GSK3 and TLR4.

Title: A double hit stress rodent model of major depressive disorder

Authors: *L. J. HERNANDEZ[1], K. C. BURGESS[1], J. D. WHERRY[1], A. SZEBENI[2], K. SZEBENI[2], G. A. ORDWAY[2], R. W. BROWN[2];
[1]Psychology, [2]Biomed. Sci., East Tennessee State Univ., Johnson City, TN

Abstract: Social defeat is an ethologically relevant stressor that utilizes the natural establishment of social rank in male rodents and has been shown to be relevant to major depressive disorder (MDD) and post-traumatic stress disorder (PTSD). In the present study, we wished to establish a social defeat stress model in combination with the chronic unpredictable stress model, which is considered a mild stressor to the rodent. In this way, we create a "double hit" model that may more accurately mimic severe stress that is common in both MDD and PTSD. In the present study, residents established dominance over the intruder for 10 consecutive days. In addition, social defeat stress was followed by another stressor given at random times during each day, i.e. chronic unpredictable stress. These unpredictable stressors included 30 min restraint, 1 h shaking/crowding, a cold water swim, a warm water swim or a tipped cage for 24 h. In one cohort of animals, brain tissue was taken 24 h after the last stressor for DNA. In a second cohort, animals were tested on a sucrose preference test in which two bottles containing 0.8% sucrose was placed on their cages for 3 consecutive days (days 8-10 of social defeat stress), and the total amount of sucrose was calculated relative to total volume consumed. Brain tissue analyses revealed significantly elevated DNA oxidation in white matter comparing stressed animals to non-stressed controls, consistent with what has been found in post-mortem white matter from MDD subjects. Further, animals given the social defeat + chronic unpredictable stress demonstrated a deficit in sucrose preference, a natural reward, revealing that these animals were anhedonic as compared to controls. Stressed animals also demonstrated fear of the intruder in a social interaction test performed one day after the social defeat/chronic unpredictable stress was complete. Therefore, it appears that social defeat plus chronic unpredictable stress produces a phenotype relevant to clinical data in humans.

Title: The effects of intermittent swim stress on morphine conditioned place preference

Authors: *R. C. DRUGAN, J. WATTS, N. P. STAFFORD;
Dept Psychology, Univ. of New Hampshire, Durham, NH

Abstract: Previous work has demonstrated a stress potentiation of conditioned place preference (CPP) using inescapable shock as the stressor. In the current study, we sought to test the generality of this effect by examining the effects of intermittent cold water swim stress (ISS) on morphine CPP. Two experiments were conducted. In experiment 1, rats were exposed to handling habituation for 2 days, Day 1 pre-exposed to the chamber, Day 2 ISS, Days 3+4 conditioning, and Day 5 CPP test. Experiment 2 was conducted because we were concerned that ISS might have affected conditioning, and as such conditioning occurred prior to ISS administration. Therefore, subjects experienced conditioning on Days 2+3 followed by ISS exposure on Day 4, and Day 5 CPP test. The results indicated a significant CPP effect in both experiments. However, ISS treatment did not potentiate CPP in comparison to controls in either experiment. Overall, these experiments suggest ISS does not enhance the rewarding properties of opiates. Future work will determine if ISS induces analgesia. If so, the role of endogenous opioids will be examined.

Title: Establishment of repeated social defeat stress model in female mice

Authors: ***S. J. RUSSO**[1], A. TAKAHASHI[1,2], H. ZHANG[1], S. ZHANG[1], Y. GROSSMAN[1], H. ALEYASIN[1], M. E. FLANIGAN[1], C. PENA[1], M. L. PFAU[1], G. E. HODES[1], C. MENARD[1], E. J. NESTLER[1], M.-H. HAN[1];
[1]Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Univ. of Tsukuba, Tsukuba, Ibaraki, Japan

Abstract: Despite higher lifetime prevalence rates of depression and anxiety disorders in women, the majority of basic rodent studies into the mechanisms of depression have been conducted exclusively in males. Repeated social defeat stress is an animal model of depression with ethological significance and face validity. Traditionally, this model exploits a strong innate territorial aggression in male rodents towards other males. In this model, male C57BL/6 mice experience daily physical defeat by a larger dominant CD-1 male mouse (aggressor), along with continuous psychological stress for 10 days. This procedure causes social avoidance along with several depressive- and anxiety-like phenotypes such as reduced sucrose preference (anhedonia), weight and metabolic syndrome, immobility in the forced swim test (behavioral despair), and reduced exploratory behavior. While other species, such as the California mouse (*Peromyscus californicus*), exhibit female territorial aggression towards other females, commonly used inbred female C57BL/6 mice (*Mus musuclus*) do not exhibit sufficient aggression in males or females except under very specific conditions such as maternal aggression. To establish a high throughput female social defeat model, we injected an AAV vector encoding the activating DREADD Syn-hM3Dq-Citrate into bilateral ventromedial hypothalamus, ventrolateral area (VMHvl) of CD-1 male mice. The VMHvl mediates attack behaviors in male mice and has been shown to initiate defeat behavior towards females. Indeed, after 3 weeks to allow for maximal expression of the DREADD, we injected CNO (1mg/kg) in aggressor males to activate VMHvl neurons and induce aggressive behavior toward female C57BL/6 mice. We found that repeated social defeat in females produced depressive-like behaviors such as social avoidance, reduced sucrose preference, and increased immobility in the forced swim test similar to males. These important results confirm the feasibility of social defeat as a model of depression in females, increasing the utility of this model in defining biological targets for depression treatment.

[3]Integrative Physiol., Univ. of Colorado at Boulder, Boulder, CO

Abstract: Exposure to inescapable intermittent swim stress (ISS) reliably produces aspects of learned helplessness (instrumental learning deficits) and behavioral despair (immobility), however, the effects of controllability on ISS are varied and less understood. One possible reason may be differential water exposure between the uncontrollable ISS and controllable ISS paradigms. In the inescapable ISS paradigm, rats are exposed to a series of 5s swims, whereas controllable escape acquisition trials typically require a minimum 2s swim but can reach a maximum of 60s, and this prolonged water exposure in poorer learners may mask the controllability effects. Therefore, the current experiments were conducted in order to compare the effects of ISS controllability and inescapable ISS on subsequent behavioral despair in a forced swim test (FST).
Experiment 1 was conducted as a behavioral assessment of 60 trials escapable (E), yoked-inescapable (Y), and inescapable (I) ISS on immobility in the FST 24hr post-stress. Results indicated overall increased FST immobility following ISS, regardless of E, Y, or I-ISS treatment. Experiment 2 was conducted to elucidate the biological mechanisms underlying 60 trial ISS-induced immobility. The I-ISS condition was selected due to equivalent stress exposure (5s swims) across trials. Following the FST, blood was collected for corticosterone (CORT) and brains were extracted for c-Fos analysis in serotonergic (5HT) dorsal raphé neurons. ISS-induced immobility was replicated, there was no effect on CORT or 5HT activity.
These results are the first to directly compare escape-yoke ISS with inescapable ISS, as well as assess these effects in a 60 trial paradigm. Null controllability effects and stress effects per se may be due to total water exposure in E/Y-ISS subjects that is equivalent to the I-ISS condition. The CORT and 5HT data suggest I-ISS behavioral despair may be driven by other physiological mechanisms. Overall, ISS-induced behavioral despair may not be sensitive to controllability at 60 trials, and individual differences in immobility contributing to null effects should be explored.

Furthermore, CORT and 5HT activity should be examined immediately following ISS to determine a time course of ISS-induced physiological changes.

Title: The effects of paw lateralization and time of testing on behavioral despair in wistar rats

Authors: *D. G. YILMAZ[1], G. DEDEOGLU[2], N. ATESYAKAR[3], D. ALASHAN[2], C. BUYUKYABAT[2], E. ADIBELLI[2], S. TIRYAKI[2], R. CANBEYLI[2];

Abstract: Despite the vast literature on vulnerability to depression and cognitive impairment in the depressive state, there is a paucity of research on factors that may provide protection against induction of depression in an animal model. The present study investigated the potential protective effects of cognitive competence and pawedness (handedness) to depressogenic treatment in rats. Additionally, performances in the RAM and FST treatments in the early morning were compared to those in the afternoon to evaluate potentially differential effect of testing time during the day.
Adult male Wistar rats (n=19) kept on a 12h light:12h dark lighting schedule (lights on at 07:00 AM) were trained in a radial arm maze (RAM) and subsequently subjected to two forced swim tests (FSTs). On the first day of the RAM task, all eight arms of the maze were baited with sweetened rice cereal and each animal was allowed to explore the maze for 10 min. On subsequent days, only the same four arms were baited (one trial/day) and the trial was ended either when the animal ate the food in all baited arms or 10 min had expired. Time to finish the trial as well as errors in re-entering the baited arms and visiting the non-baited arms were recorded. A week later, animals were administered two FSTs separated by 24 hr (of 15 min and 5 min durations, respectively). Increased immobility in the second FST compared to the initial 5 min of the first FST is a sign of behavioral despair. Finally paw preference was determined in four tests (50 trials/day) by a task where food-deprived rats could obtain food from a tube narrow enough to be accessible only by a single paw. Results indicated no significant differential effect of competence in the RAM task on protection against behavioral despair. Rats subjected to forced swimming in the late afternoon displayed significantly more behavioral despair (t-test

between FSTs, p=0.039) than those treated early in the morning (p>0.05). Paw preference did not significantly affect overall RAM performance but left- but not right-pawed rats displayed significant behavioral despair as shown by durations of immobility, respectively, in the first and second FSTs for the left-pawed rats (n=7; 54.3 ± 5.9, 73.6 ± 6.5; p<0.05) and right-pawed rats (n=9; 58.6 ± 4.2, 64.4 ± 8.2; p>0.05). Paw preference did not significantly affect performance in the RAM task. Since paw preference in rats is related to lateralization of hemispheric function including differential expression of several mood related neurotransmitters, our results may provide the basis for further investigation of the influence of hemispheric lateralization and its interaction with circadian rhythms on depression.

Title: Use of physical or psychological stressors to induce anhedonia in the unpredictable chronic mild stress model of depression

Authors: *K. S. HOMEM[1], A. T. RAMOS[2], C. M. DOMINGUEZ[3], M. M. SOARES[3], C. SCAVONE[2], L. R. P. TRONCONE[3];
[1]Univ. of São Paulo - IPUSP, Sao Paulo, Brazil; [2]ICB, Univ. of São Paulo, São Paulo, Brazil; [3]Lab. of Pharmacol., Inst. Butantan, São Paulo, Brazil

Abstract: Major Depressive Disorder is an incapacitating disease with a high prevalence. Several hypotheses have been proposed in order to investigate its etiology. One of them involves stress. Imbalances of the hypothalamus-pituitary-adrenal axis - HPA - are present in up to 70% of patients with depression. While searching for a better animal model to study the impact of stress on depression, we came across the Unpredictable Chronic Mild Stress model - UCMS. Previous studies developed in this lab described relevant differences among types of stressors and HPA axis response. While all stressors induce remarkable ACTH secretion, such secretion

can be inhibited by vasopressin 1b - V1b - antagonists when physical stressors like ether vapor inhalation are applied. On the other hand, ACTH secretion was blocked by CRH1 antagonists when psychological stressors are in play, such us restraint. Mixed stressor such as forced swimming only had its effects blocked by concomitant use of both antagonists. In this study, we proposed to investigate whether physical or psychological stressors can induce anhedonia in the UCMS protocol. We used Wistar rats and physical stressors used were cold exposure, ether vapors inhalation, wet bedding, water in the cage, empty cage, light-dark cycle disruption, water and food deprivation. As psychological stressors we used restraint for 1 hour, naïve intruder placed in the experimental animal's cage, experimental animal placed inside a naïve animal's cage, crowded housing, restricted access to food, empty water bottles. The sucrose preference test was applied weekly for 1 hour. Animals were weighted and total liquid intake and sucrose intake were measured. None of the types of stressors were able to decrease sucrose preference. However, we noticed that psychological stressors had a greater impact over weight gain than physical stressors, with psychological stress groups gained roughly 20% less weight. Sucrose preference and intake tended to increase over time - sucrose preference ranged between 50-90% and sucrose intake between 5-30g. There was no significant difference between all the groups regarding sucrose preference and intake. Our partial conclusions are: a. perhaps our protocol should increase the frequency of stressful events to achieve significant anhedonia; b. perhaps the 2 types of stressors need to be present so anhedonia can develop.

Abstract: Major depressive disorder is an illness that in recent years has increased in young people between 15 and 24 years of age; It is a major health concern since a large percentage of patients become suicidal. The various mechanisms involved in this disorder include oxidative/nitrosative stress, imbalance of the hypothalamus-pituitary-adrenal axis, and deregulation of some neurotransmitters, such is the case of serotonin. Pharmacological therapies of choice, to treat this condition, have not been sufficiently effective by suggesting that there is deregulation in this disorder in serotonin receptors. The objective of this work is to study serotonin 1A (5-HT1A) receptor involvement in the area of hippocampus, using the model of olfactory bulbectomy in a rat (OBX) as a model for major depression. The model was characterized behaviorally finding comparable signs with depression in humans. These behavioral changes occur early and persist until 45 days after surgery. It was confirmed with Nissl staining that the characteristics of the citoarchitecture of the hippocampus were not a determinant factor in the levels of the receptor. In the evaluation of the messenger RNA of the receiver, significant statistical differences were not found, however the main metabolite over which the receptor effects: cyclic AMP; was found to have decreased in rats OBX, treated with vehicle (OBX+V) or fluoxetine (OBX+F); This decrease is associated with the increment of the receptor found in area CA1 of the hippocampus because by analyzing the factor Akt, which is part of the signaling cascade after the activation of the receptor, is increased in the same area. This work opens up a new view on the participation of the 5-HT1A receptor in major depressive disorder.

Title: Multi-dimensional characterization of pre-clinical models of neuropsychiatric disorders: exploring new therapeutical approaches in depression and schizophrenia

Authors: A. MATEUS-PINHEIRO[1,2], P. PATRICIO[1,2], J. BESSA[1,2], N. SOUSA[1,2], *L. PINTO[1,2];
[1]Life and Hlth. Sci. Res. Inst. - Sch. of Hlth. Sci. - UM, Braga, Portugal; [2]BnML - Behavioral and Mol. Lab., Braga, Portugal

Abstract: Neuropsychiatric disorders are the source of a substantial proportion of world's disease burden, contributing as an important source of both morbidity and mortality, with increasing expression in developed countries.
In particular, major depressive disorder is estimated to affect 350 million people worldwide, and available treatments are ineffective in more than 30% of diagnosed patients. Here we present data from a longitudinal characterization of the unpredictable chronic mild stress (uCMS) animal model of depression. We have submitted young-adult rats to 6 weeks of uCMS and treated subsets of animals with antidepressants belonging to different pharmacological classes. Our longitudinal characterization provides insight in how these drugs impact on pathophysiological mechanisms of the depressive disorder, namely on cortico-limbic structural and functional neuroplasticity. The neuroplastic adaptations of the adult brain are studied in articulation with a multi-dimensional behavioral analysis, focusing hallmarks of depressive disorder, such as behavioral despair and anhedonic behavior, using innovative methods such as the *Sweet-Drive Test*, in which food preference and 50 KHz ultrasound vocalizations are simultaneously monitored as surrogate markers of anhedonia.
Schizophrenia, estimated to affect 24 million people worldwide, is also a disorder whose neuropathological basis is yet to be fully comprehended. In light of the importance of exploring new therapeutical alternatives for the treatment of schizophrenia, we present data concerning an animal model of schizophrenia, that we used for that purpose - the rat methylazoxymethanol acetate (MAM) administration model. In this developmental disruption model, MAM is administered to pregnant dams at E17 and the offspring from MAM-treated dams have been reported to exhibit neuropathological deficits in brain circuitry that is implicated in schizophrenia. We show the impact of different pharmacological classes of antipsychotics in different cognitive and social-interaction behavioral domains.
Altogether, these models have proved to be invaluable tools to test novel therapeutic options for neuropsychiatric disorders.

Italiano di Tecnologia, Genova, Italy

Abstract: The hippocampus is critically involved in higher-thinking processes, such as learning, memory, cognition, emotion and motivation. Accordingly, bidirectional alterations of hippocampal activity are strongly associated with several neuropsychiatric disorders. For instance, both postmortem/imaging studies in depressed patients and experiments on animal models suggest that hippocampal hypoactivity is a core feature of depression. Conversely, increased neurogenesis and hippocampal hyperexcitability has recently been associated to bipolar disorder, according to studies performed both on bipolar patients and in animal models. The involvement of serotonin (5-HT) in mood regulation is well established. The levels of 5-HT, the cellular mechanism for its reuptake/degradation and the activity of serotonergic neurons are reported to be dysregulated in mood disorders. Selective Serotonin Reuptake Inhibitors (SSRIs) constitute the most frequently prescribed psycho-active drugs for the treatment of depression and of the depressive phase of bipolar disorder if co-administered with mood stabilizers. Most of the therapeutical effects of SSRIs take place in the hippocampus. Indeed, SSRI-mediated up-regulation of BDNF and TrkB as well as dentate gyrus neurogenesis, both down-regulated in patients and in animal models, are strictly required for antidepressant efficacy, indicating that 5-HT signaling plays a pivotal role in the hippocampal physiology. However, the molecular events underlying 5-HT regulation of hippocampal activity are still obscure. Here, we analyze the impact of brain 5-HT depletion on the genetic signature of the hippocampus by performing Next-Generation RNA sequencing on *Tph2* -/- mice. We found that several transcription/growth factors, immediate-early genes as well as genes involved in synaptic plasticity and transmission are up-regulated in 5-HT depleted mice, suggesting hippocampal hyperactivity. In parallel, *Tph2* -/- mice show reduced anxiety- and depression-like behaviors, escalated aggression and slower habituation in a novel environment, indicating hyperarousal. Conversely, *Tph2* mutants showed an exaggerated susceptibility to chronic mild stress. Biochemical and electrophysiological

analysis performed on *Tph2* -/- mice accounts for their behavior, shedding new lights on the mechanisms by which serotonin governs hippocampal physiology and emotional behavior.

Title: Exposure to homocysteic acid early in postnatal development leads to a mixed depressive/manic behavioral phenotype

Authors: S. SIMKO, J. JOHNSON, G. FLORES, A. KLEPPINGER, C. C. BARNEY, *L. A. CHASE;
Hope Col., Holland, MI

Abstract: Homocysteic acid (HCA), a NMDA receptor agonist, is an endogenous compound formed from the oxidation of homocysteine. Since hyperhomocysteinemia is a risk factor for several neuropsychiatric disorders, including bipolar disorder and major depressive disorder (MDD), we tested the hypothesis that elevated HCA levels in developing rats may induce alterations in NMDA receptor expression and the development of behaviors associated with MDD and/or bipolar disorder. In our first study, postnatal male and female rats were injected daily with either HCA or saline from day P3 to P17. The female, HCA-treated rats displayed increased risk-taking behavior, reduced social behavior, novelty-induced hyper-locomotion, anhedonia, and reduced sensitivity to pain compared to control and male-HCA treated rats, consistent with a depressive state with manic tendencies. As expected, HCA treatment had no effect on motor coordination (Rotarod) or startle behavior (paired-pulse inhibition). In addition to these behavioral changes, an increase in NMDAR2 expression was observed in the cortex and hippocampus of HCA-treated female rats. More recently we extended the injection period from day P3 to P21 and observed that male rats were now more sensitive to HCA treatment. Specifically, both male and female rats exhibited decreased social interaction, increased anhedonia, increased risk-taking behavior, and increased motivational behavior in the Morris Water Maze. HCA-treated rats also gained less weight over the course of the study compared to controls. This may be due to the fact that HCA-treated rats tended to consume less food to be more active, e.g. running more in running wheels. We are currently examining the effect of

extended HCA exposure on NMDAR2 receptor expression in the cortex and hippocampus, however, the behavioral data suggest that early postnatal exposure to HCA may lead to a phenotype that is consistent with bipolar disorder or major depressive disorder. *This research was supported by the Hope College Neuroscience Program, Biology Department and Chemistry Department.*

Title: Long-term and transgenerational depression-like behavior is associated with hippocampal Akt-mTOR signaling deficiency in the offspring of postpartum depression-like mice

Authors: *G. CHEN[1], R. WU[2];
[1]Nanjing Univ. of Chinese Med., Jiangsu, China; [2]Nanjing Univ. of Chinese Med., Nanjing, China

Abstract: Postpartum depression (PPD) increases vulnerability of the offspring to psychiatric disorders such as depression but the underlying mechanisms remain unclear. Akt-mTOR signaling in the hippocampus is implicated in depression on the bsis of emerging evidence, which may play a role in mediating long-term behavioral deficits in the PPD offsrping. By using a prepregnancy stress model of PPD in which female Balb/c mice with experience of chronic prepregnancy stress showed long-lasting postpartum depression-like behavior, we tested depression-like behavior in the PPD offspring (PPD-F1) at juvenile and adulthood. Additionally, PPD-F2 mice generated by cross of the PPD-F1 males with normal females were also investigated for transgenerational neuromolecular and behavioral effects. Hippocampal Akt-mTOR signaling was examined in the F1 and F2 generations of PPD mice, as well as in PPD-F1 mice treated with a single dose of the rapid antidepressant reagent ketamine or the traditional herb medicine Yueju. PPD-F1 mice showed depression-like behavior at juvenile and adulthood, evidenced by reduction in the test of sucrose preference (SPT), longer immobility time in the

forced swim test (FST), and longer latency to feed and less food consumed in the novelty suppressed feeding (NSF) test. PPD-F1 showed Akt-mTOR signaling deficiency in the hippocampus, with the down-regulated expression of p-Akt, p-mTOR and p-p70S6K. A single dose of ketamine or Yueju reversed the behavioral deficits and the impairment in Akt-mTOR signaling in PPD-F1. Furthermore, the PPD-F2 mice remained deficient in the SPT and NSF tests and hippocampal Akt-mTOR signaling, although the performance in FST was normal, indicating a contineous but partially revocered behavioral response. The present study demonstrated the long-term and transgenerational effects of PPD on the depression-like behaviors of offspring, likely via deficient early-life maternal care, and suggested impaired Akt-mTOR signaling may play an important part.

Title: Role of leukocyte derived microRNAs in stress induced inflammation and depression

Authors: ***M. L. PFAU**[1], G. E. HODES[1], V. KANA[1], C. MENARD[1], H. ALEYASIN[1], Y. LAVIN[1], P. OGRODOWSKI[2], A. VENTURA[2], M. MERAD[1], S. RUSSO[1];
[1]Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Mem. Sloan-Kettering Cancer Ctr., New York, NY

Abstract: We have previously identified circulating Interleukin-6 as an important mediator of behavioral response to repeated social defeat stress (RSDS). In the 10-day RSDS paradigm, a C57BL/6 mouse is individually exposed to a larger, novel CD-1 mouse for 10 minutes of physical aggression followed by overnight sensory exposure through a plastic partition. RSDS produces two phenotypes: resilient mice that behave similarly to unstressed controls, and susceptible mice that display a constellation of depression-like symptoms, including social

avoidance and heightened peripheral inflammation. As microRNAs (miRs) are important regulators of immune response, we sought to examine their role in mediating inflammatory and behavioral response to RSDS. We collected mouse blood 48 hours post-RSDS and isolated leukocyte populations via fluorescence-activated cell sorting. We find that, in both susceptible and resilient mice, RSDS produces an increase in circulating neutrophils coupled with a decrease in B cells. T cells and Ly6c^{high} inflammatory monocytes are selectively decreased and increased, respectively, only in susceptible mice. Within Ly6c^{high} monocytes, we profiled miR and target mRNA expression via quantitative real time PCR. Of the miRs in our panel, 8 are significantly regulated by RSDS. miR-25-3p, a member of the miR-106b-25 cluster with known roles in inflammatory signaling and myelopoiesis, is upregulated in inflammatory monocytes of susceptible mice. We identified concurrent downregulation of several miR-25-3p target genes. In order to determine the role of miR-25-3p in behavioral response to RSDS, we generated miR-106b-25 cluster knock out (KO) bone marrow chimeric mice and subjected them to RSDS, finding that KO chimeric mice display enhanced behavioral resilience. Our results suggest a role for miRs as regulators of stress-induced inflammation and depression, and identify miR-25-3p as a novel potential therapeutic target.

Title: Cellular adaptations in the lateral habenula in a model of early-life stress.

Authors: *A. TCHENIO, S. LECCA, M. MAMELI, 75005;
INSERM UMR S 839, Paris, France

Abstract: Stressful experience during the postnatal period, including maternal separation (MS) produces a wide range of modifications within distinct neuronal circuits and trigger depressive-like symptoms. Evidences suggest that dysfunction of monoaminergic systems partly contributes

to these cellular and behavioral adaptations. The lateral habenula (LHb) exerts strong control over monoaminergic systems and its hyperactivity is crucial for depressive symptoms. Whether adaptations within the LHb occur after early life stress remains unknown. Our hypothesis is that MS produces higher neuronal activity within the LHb thereby contributing to the emergence of depressive like symptoms in adulthood. We established a paradigm for MS in mice by separating offsprings from their mother for one week. We then we used whole-cell patch clamp techniques in mouse brain slices. Current-clamp recordings were performed from LHb neurons, and cell excitability was assessed by postsynaptic current injections capable to trigger action potentials. We observed an increase in LHb neurons excitability in slices from MS mice. Within the LHb, $GABA_B$-R-GIRK signaling tightly controls neuronal excitability. We found that, in voltage-clamp mode, pharmacological activation of $GABA_B$-R-GIRK signaling via the $GABA_B$-R agonist Baclofen led to outward currents. Baclofen-evoked currents were smaller in slices from MS than control mice. To conclude, we have shown that MS mice present cellular adaptations within the LHb (hyperexcitability and reduced in $GABA_B$-GIRK signaling) that may represent a mechanism through which early life stress produces a depressive phenotype.

Title: Subanesthetic ketamine and cortical regional functional connectivity in a mouse model of depression resolved with depolarization and glutamatergic sensors.

Authors: *A. MCGIRR[1], J. LEDUE[2], A. W. CHAN[1], Y. XIE[1], T. MURPHY[1];
[1]Psychiatry, [2]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Ketamine is a prototype antidepressant that results in rapid, albeit temporary, clinical improvement in human treatment resistant Major Depressive Disorder (MDD). Using wide-field *in vivo* cortical imaging with fast voltage and glutamate sensors, we characterize cortical regional functional connectivity in the chronic social defeat (CSD) mouse model of depression, as well as the acute and longitudinal effects of subanesthetic ketamine. After CSD, we observe greater inter-regional synchrony in depressed animals than control animals with both depolarization and glutamate sensors. Subanesthetic ketamine has unique effects in depressed animals not observed

in control animals. Acutely, we observed a global and sustained cortical increase in extracellular glutamate, global cortical glutamate transients, and increased midline and association area functional connectivity. Twenty-four hours later, normalization of depressive-like behaviour predicted by acute glutamate transients is accompanied by a reduction in glutamate functional connectivity, before returning to a hyper-connected state after 7 days. We suggest that the mechanism and potential treatment for depressive symptoms is not localized within a single cortical network but expressed widely across cortex. Given network-wide activity changes and response to treatment, there may be new opportunities based on knowledge of large scale circuit interactions and the central role of glutamate.

Title: Sex-dependent effects of forced swim and chronic mild stress on immobility behavior and VTA DA neuron activity: Impact of ketamine

Authors: *M. RINCÓN CORTÉS, A. A. GRACE;
Neurosci. and Physiol., Univ. of Pittsburgh Dept. of Neurosci., Pittsburgh, PA

Abstract: Females are more susceptible than men to stress-related mental illness and twice as likely to be diagnosed with depression. Depression has recently been linked to alterations in dopamine (DA) and is characterized by DA system down-regulation. Stress exposure is tightly linked to the development of depression and alterations within the DA system. However, despite clinical findings indicating increased female susceptibility and preclinical studies establishing a causal link between the DA system and depression, a role for DA in stress-induced depression vulnerability in females has not been examined. To this end, we assessed effects of the forced swim test (FST) and chronic mild stress (CMS) on immobility behavior and ventral tegmental area (VTA) DA neuron activity in rats of both sexes. We also assessed whether ketamine, a novel fast-acting antidepressant known to exert sex-dependent effects, could reverse deficits in

behavior and VTA activity. Male and female rats were exposed to 4-6 weeks of CMS or control housing conditions and tested for immobility behavior in the Forced Swim Test (FST). Extracellular recordings were conducted in the VTA within a week post-FST to determine CMS-induced alterations in VTA DA neuron activity parameters including: number of active DA neurons per track, firing rate and amount of burst firing. Whereas DA neuron activity was comparable in nonexposed males and females, following initial pre-exposure to FST, in the second test exposure females exhibited roughly double the amount of FST immobility duration and approximately 40% lower DA neuron activity compared with similarly treated males. Furthermore, CMS induced greater immobility in the FST and reduced VTA DA neuron activity by approximately 50% and these effects were more pronounced in females. In a separate experiment, ketamine (10mg/kg i.p.) or saline (1mg/kg i.p.) was administered prior to the FST to assess restorative effects on stress-induced alterations in immobility behavior and to assess DA activity. Ketamine reduced immobility duration in stress groups (control females, CMS males, CMS females) and restored post-FST VTA DA activity in control females and CMS rats. These data suggest that increased female susceptibility to depression-like phenotypes (i.e. increased immobility, VTA hypofunction) may be associated with higher sensitivity of the DA system and behavior to stress in females relative to males. Understanding the neural underpinnings of sex differences in stress vulnerability and the antidepressant response will provide insight into the mechanistic bases for sex vulnerability differences and provide insights into optimizing therapeutic approaches.

Title: The dissociative drugs ketamine and DOI attenuate both positive and negative affective biases in rats.

Authors: *S. A. STUART, E. S. J. ROBINSON;
Physiology, Pharmacol. and Neurosci., Univ. of Bristol, Bristol, United Kingdom

Abstract: Ketamine has been shown to have rapid onset antidepressant efficacy in humans, and our previous work in rats using a novel affective bias test (ABT) suggests that this may involve the attenuation of negative affective bias mediated through the medial prefrontal cortex (mPFC). The present study assessed whether a mPFC infusion of ketamine has a similar effect on positive affective bias in the ABT, as well as testing the effects of another dissociative compound, the 5-HT2A agonist, DOI. We also test the mGlu2/3 antagonist, LY-341,495, which we have previously shown attenuates negative affective bias in rats when administered systemically. 16 male Lister hooded rats were implanted with a bilateral mPFC cannula prior to ABT training. The ABT uses a bowl-digging task where rats encounter two independent positive experiences (finding food reward in a specific digging substrate). Treatment or control is administered prior to the experience, and the absolute reward value is kept consistent across all sessions. Affective bias is quantified in a preference test where both rewarded substrates are presented together and the rats' choices recorded over 30 randomly reinforced trials. All animals underwent pairing sessions where they received either corticosterone (10mg/kg, s.c.) vs. vehicle to induce a negative affective bias, or the antidepressant venlafaxine (10mg/kg, i.p.) vs. vehicle to induce a positive bias. A targeted mPFC infusion of either ketamine (1ug/ul), LY-341,495 (3ug/ul), DOI (3ug/ul) or vehicle (0.1M PBS) was then administered 5 min before preference testing using a within-subject counterbalanced design. An infusion of either ketamine or DOI into the mPFC significantly attenuated both corticosterone-induced negative affective bias ($F_{3,42} = 3.37$, $p=0.04$), and venlafaxine-induced positive affective bias ($F_{3,42} = 3.63$, $p=0.03$) compared to vehicle treatment. LY-341,495 had no significant effect on either positive or negative bias. These data suggest that both ketamine and DOI have a non-specific effect on affective biases in that they attenuate both positive and negative bias through disruption of prefrontal function. Since this effect was not observed with the non-dissociative drug LY-341,495, the results may be related to the dissociative nature of the drugs.

Title: Selective deletion of mTOR in DA neurons causes a depressive phenotype that can be rescued by ketamine

Authors: *M. GUO[1], D. ZHAO[1], F. J. SUN[1], M. WANG[1], X. Y. LU[1,2];
[1]Binzhou Med. Univ. Hosp. / IMND, Shandong, China; [2]Dept. of Pharmacol., The Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX

Abstract: The mammalian target of rapamycin (mTOR) is a serine/threonine protein kinase that regulates protein synthesis and synaptic plasticity. mTOR signaling in the forebrain has been previously shown to be involved in the mechanisms underlying the rapid antidepressant actions of ketamine, an *N*-methyl-D-aspartate receptor antagonist. Given the critical role of midbrain dopamine (DA) neurons in mediating depression-related symptoms, this study investigated whether mTOR signaling in these neurons participates in mediating depressive behaviors and whether it is necessary for ketamine's antidepressant-like effects. To delete mTOR specifically in midbrain DA neurons, mice homozygous for a loxP-modified mTOR allele were bred with transgenic mice expressing Cre recombinase driven by the dopamine transporter (DAT) promoter. Mice lacking mTOR in midbrain DA neurons ($mTOR^{flox/flox}$/DAT-Cre) exhibited reduced reward-seeking behavior, increased behavioral despair and enhanced learned helplessness. These behavioral changes were accompanied by reduced DA neuron population activity with normal firing rate and burst firing of DA neurons in the ventral tegmental area (VTA). $mTOR^{flox/flox}$/DAT-Cre mice were highly sensitive to ketamine. The depressive-like behavioral deficit could be rescued by ketamine treatment. These results suggest that mTOR signaling in midbrain DA neurons plays an important role in regulating DA neuron activity and the development of a depressive-like state and that ketamine’s anti-depressive effects are mediated by mechanisms independent of mTOR signaling in DA neurons.

Title: Interactions between Ghrelin and Ketamine in the Forced Swimming Test: Implications for novel antidepressant treatments

Authors: *J. A. LANDRIGAN, S. HAYLEY, A. ABIZAID;
Neurosci., Carleton Univ., Ottawa, ON, Canada

Abstract: The efficacy of ketamine to alleviate depressive symptoms has promoted a wealth of research exploring alternate therapeutic targets for depression. Given the caveats of ketamine treatment taken together with the increasingly greater emphasis on combinatorial therapeutic approaches to depression, we sought to asses whether the hypothalamic “hunger hormone”, ghrelin, would augment the effects of ketamine. Indeed, ghrelin has recently been found to possess antidepressant potential and may be especially effective against the metabolic and feeding deficits observed with depression. Two studies were performed: 1. mice were given an intraperitoneal injection of ghrelin (80μg/kg) or saline, followed by a saline or a low or high dose of ketamine (5 or 10 mg/kg) and 2. mice received 10 mg/kg of ketamine together with saline or the ghrelin receptor antagonist JMV2959 (3 or 6 mg/kg) and Forced Swim Test (FST) performance was assessed. In both studies, ketamine alone reduced FST immobility. Similarly, ghrelin alone reduced swim immobility suggesting an antidepressant-like response. However, ghrelin did not augment the impact of ketamine when co-administered and in fact, it appeared to antagonize its actions at the lower dose. As well, JMV2959 did not significantly influence FST performance. These data confirm the antidepressant-like effects of ketamine and further suggest that ghrelin might have similar properties. Yet, our results caution against combinatorial treatment with these agents, probably owing to unexpected allosteric or other antagonist actions.

Title: Effects of ketamine on psychostimulant withdrawal and stress induced anhedonia in rats.

Authors: *A. DER-AVAKIAN, A. MARKOU;
Psychiatry, Univ. of California San Diego Dept. of Psychiatry, La Jolla, CA

Abstract: Major depressive disorder is a chronic mood disorder that can be triggered by stress and is characterized by loss of pleasure (i.e., anhedonia) and disturbances in the brain's reward circuitries. Symptoms of depression, such as anhedonia, are also present during withdrawal from chronic psychostimulant drug use. Ketamine has been shown to have rapid antidepressant effects in some patients with treatment-resistant depression. However, little is known about whether ketamine would be effective in reversing drug withdrawal- or stress-induced anhedonia. In an initial experiment, using adult, male Wistar rats, the antidepressant efficacy of acute ketamine treatment (10 mg/kg, ip) was first assessed in the forced swim test (FST). Brain reward function was then assessed in separate groups of rats using the intracranial self-stimulation (ICSS) procedure. Bipolar stimulating electrodes were surgically implanted in the posterior lateral hypothalamus and rats were trained on a discrete-trial current-intensity ICSS procedure. Rats were then either exposed to chronic (7 days) nicotine treatment (6.3 mg/kg/day, base, sc), chronic (7 days) amphetamine treatment (10 mg/kg/day, sc), or repeated (21 days) social defeat. During withdrawal from either psychostimulant drug or after termination of social defeat, a single dose of ketamine (10 mg/kg, ip) was administered prior to assessment of brain reward thresholds. Ketamine decreased immobility and increased swimming behavior without affecting climbing behavior in the FST. In the ICSS tests, ketamine reversed acute nicotine withdrawal-induced elevations in reward thresholds, but did not reverse amphetamine withdrawal- or stress-induced reward threshold elevations. The decrease in immobility in the FST in response to ketamine, which is consistent with results from other laboratories, confirms the antidepressant efficacy of ketamine in patients with depression. However, the differences in effectiveness of ketamine as a treatment to reverse psychostimulant- or stress-induced reward threshold elevations suggests that this medication may only be partially effective in treating anhedonia, a core symptom of depression.

Title: Role of the medial prefrontal cortex-dorsal raphe circuit in the antidepressant actions of ketamine

Authors: *A. M. THOMAS, B. HARE, E. S. WOHLEB, R.-J. LIU, G. K. AGHAJANIAN, R. S. DUMAN;
Dept. of Psychiatry, Yale Univ. Sch. of Med., New Haven, CT

Abstract: A single, low dose of ketamine produces an antidepressant effect in human patients within a few hours of administration lasting for up to a week, making it one of the most promising possibilities in the search for antidepressants that are faster-acting and more effective than those currently available, which require up to eight weeks to produce an effect. However, little is known about the neural circuitry by which ketamine exerts its antidepressant effect. It has been shown that ketamine induces glutamate release in the medial prefrontal cortex (mPFC), and that blocking glutamate transmission in the mPFC also blocks its antidepressant effect in the forced swim test (FST) and novelty suppressed feeding test (NSFT). We have recently demonstrated that it is possible to produce a long-lasting antidepressant-like behavioral response in rats (both FST and NSFT) with a single, one-hour, 10-Hz optogenetic stimulation of excitatory neurons in the mPFC, using an rAAV2-CaMKIIα-ChR2(H134R)-EYFP vector. Here, we show that a one-hour stimulation of axon terminals in the dorsal raphe (DR) nuclei, which project from cell bodies in the mPFC that are infected with the same vector, is also sufficient to produce an antidepressant-like effect in the FST 24 hours after stimulation. Ongoing immunohistochemical studies will assess how stimulation of these terminals affects neural activity in the DR and which cells within the DR are targeted by the activation of these axons. Further experiments will include optogenetic stimulation of mPFC-originating axon terminals in the nucleus accumbens (NAc) to determine if antidepressant response in the FST is specific to mPFC-DR terminal stimulation, or if mPFC-NAc terminal stimulation also produces antidepressant response in the FST, as well as other behavioral models. It is an intriguing but unproven possibility that these optogenetically induced antidepressant effects utilize the same neural circuits that ketamine does. To examine this hypothesis, we will infuse 8OH-DPAT, which inhibits the release of serotonin, into the DR to test whether serotonin release is necessary for the antidepressant effect of ketamine.

Title: RAGE null mice show resilience to depressive-like behaviors after chronic unpredictable stress

Authors: *T. C. FRANKLIN, Y. ZHANG, E. S. WOHLEB, R. S. DUMAN;
Yale Univ. Sch. of Med., New Haven, CT

Abstract: Maladaptive alterations that result from severe or chronic stress exposure are associated with increased risk for Major Depressive Disorder (MDD). Chronic stress promotes dysregulation of the innate immune system leading to enhanced inflammatory signaling often associated with depressive symptomology. Growing evidence suggests that innate immune cells such as microglia, promote neuroinflammation in response to stress by releasing danger associated molecular pattern (DAMP) molecules leading to increased inflammatory signaling. One DAMP of interest is the endogenous factor high mobility group box 1 (HMGB1), which promotes inflammatory signaling through its ligation to pattern recognition receptors such as toll-like receptor 4 (TLR4) and the receptor for advanced glycation end products (RAGE). Our preliminary studies show that HMGB1 and RAGE are upregulated in microglia in response to chronic unpredictable stress (CUS). Most importantly, enhanced microglial HMGB1-RAGE expression coincides with the *onset* and *recurrence* of stress-induced depressive-like behaviors. These novel findings suggest that stress-induced depressive like behaviors may be mediated through enhanced microglial HMGB1-RAGE signaling. We therefore hypothesize that RAGE deletion will attenuate depressive-like behaviors following stress due to suppressed HMGB1 signaling. In this presentation, we will present data from ongoing studies that examine the role of RAGE signaling in the development of depressive-like behaviors following chronic stress. Constitutive RAGE knockout (KO) mice will be tested for cognitive, anxiety and depressive-like behaviors at baseline and after CUS exposure using novel object recognition (NOR), open field test (OFT), elevated plus maze (EPM) and sucrose consumption test (SCT). Microglial morphological changes will be assessed immediately following CUS exposure to determine if RAGE deficient mice display reduced microglial reactivity following chronic stress exposure compared to littermate controls. Together, these data will provide novel insights into the role of

RAGE signaling in stress-induced microglial reactivity and the development of depressive-like behaviors. *Supported by NIMH Grants MH045481 and MH093897, and the State of CT.*

Title: Interplay between BDNF and VEGF signaling in the medial prefrontal cortex is required for sustained antidepressant effects of ketamine

Authors: *S. DEYAMA[1], E. BANG[1], T. KATO[1,2], X.-Y. LI[1], R. S. DUMAN[1];
[1]Dept. of Psychiatry, Yale Univ. Sch. of Med., New Haven, CT; [2]Drug Develop. Res. Labs., Sumitomo Dainippon Pharma Co., Ltd., Osaka, Japan

Abstract: Growing evidence demonstrates that growth factors play a significant role in the pathophysiology and treatment of mood disorders. Previous studies have shown that brain derived neurotrophic factor (BDNF) signaling in the medial prefrontal cortex (mPFC) mediates the antidepressant effects of ketamine. Recently, we found that the antidepressant effects of ketamine are blocked by neuronal specific deletion of either vascular endothelial growth factor (VEGF) or its receptor Flk-1. We have also found that intra-mPFC infusion of an anti-VEGF neutralizing antibody (VEGF nAb) completely blocks the antidepressant effects of ketamine. These findings indicate that VEGF, as well as BDNF, signaling in the mPFC plays a crucial role in the antidepressant effects of ketamine. However, it remains unclear whether these growth factors act in series or parallel. Thus, we hypothesize an interplay between BDNF and VEGF signaling in the mPFC that underlies the rapid antidepressant response to ketamine. In support of this hypothesis, we found that BDNF incubation induces VEGF release and vice versa in primary cultures of rat cortical neurons. Next, to determine the role of BDNF and/or VEGF signaling in the mPFC, wildtype mice were infused with either recombinant BDNF or recombinant mouse VEGF into the mPFC, and tested in antidepressant behavioral models, including the forced swim test (FST), female urine sniffing test (FUST) and novelty-suppressed feeding test (NSF). A

single intra-mPFC infusion of either BDNF or VEGF produced sustained antidepressant effects in these tests without affecting ambulation. These antidepressant effects were maintained for at least 5 days after the infusion. These results indicate that increases of either BDNF or VEGF signaling in the mPFC are sufficient to produce sustained antidepressant effects. Preliminary results demonstrate that the antidepressant effects of intra-mPFC BDNF infusion is blocked by co-infusion of VEGF nAb or neuron specific deletion of VEGF (CaMKII-Cre X $VEGF^{flox/flox}$ mice), indicating that BDNF requires VEGF signaling to produce sustained antidepressant effects, although additional studies are needed. We are currently examining whether the antidepressant effects of intra-mPFC VEGF infusion can be blocked by co-infusion of BDNF neutralizing antibody to further test the hypothesis that interplay of BDNF and VEGF signaling in the mPFC mediates the rapid antidepressant effects of ketamine.

Title: Role of mTORC1 and BDNF signaling in the rapid antidepressant actions of GLYX-13

Authors: ***T. KATO**[1,2], S. DEYAMA[1], X.-Y. LI[1], R. DUMAN[1];
[1]Lab. of Mol. Psychiatry, Yale Univ. Sch. of Med., New Haven, CT; [2]Drug Develop. Res. Labs., Sumitomo Dainippon Pharma Co., Ltd., Osaka, Japan

Abstract: GLYX-13 is a NMDA receptor modulator with glycine-site partial agonist properties that is reported to show fast acting and long-lasting antidepressant effects in animals and depressed patients. Importantly, it lacks the psychotomimetic and dissociative side effects of ketamine. Studies were conducted to examine the mechanisms underlying the actions of GLYX-13 to enlighten future development of rapid, efficacious antidepressants with low side effects. We examined the molecular and behavioral actions of GLYX-13, particularly the involvement of the mechanistic target of rapamycin complex 1 (mTORC1) and BDNF signaling pathways. The

results demonstrate that single dose of GLYX-13 (i.v.) activated the mTORC1 pathway in the prefrontal cortex (PFC) and hippocampus 1 hr after injection; this effect lasted at least 24 hr after injection. GLYX-13 also increased postsynaptic protein levels in PFC, including PSD95, GluA1, and synapsin 1. To examine the role of mTORC1 signaling in mPFC in the behavioral actions of GLYX-13, the mTORC1 selective inhibitor rapamycin was microinjected into medial PFC (mPFC) before GLYX-13 injection. GLYX-13 produced a robust antidepressant response in the rat forced swim test (FST), female urine sniffing test (FUST), and novelty suppressed feeding test (NSFT) without effecting locomotor activity; these effects were completely blocked by rapamycin infusion. We also found that GLYX-13 rapidly increased the expression of c-Fos in crude nuclear extracts of PFC, similar to the actions of ketamine, suggesting that both agents cause neuronal activation. Our recent studies demonstrate a role for activity dependent release of BDNF via L-type voltage-dependent calcium channels (VDCC) in the actions of ketamine. To determine if GLYX-13 acts via a similar pathway, we examined the impact of VDCC blocker verapamil (i.p.) and mPFC infusions of an anti-BDNF neutralizing antibody on the behavioral actions of GLYX-13. Verapamil pretreatment or anti-BDNF antibody infusion completely blocked the actions of GLYX-13 in the FST, FUST and NSFT. Taken together, these results indicate that activation of the mTORC1 and BDNF signaling pathways in mPFC are essential for the antidepressant actions of GLYX-13, indicating a mechanism similar to the actions of ketamine. Further studies are being conducted to examine the role of NMDA receptors on glutamate pyramidal neurons vs. tonic firing GABA neurons in the actions of GLYX-13.

Title: Brain-derived neurotrophic factor is necessary for the antidepressant actions of scopolamine

Authors: ***S. GHOSAL**, M. GIRGENTI, B. HARE, X.-Y. LI, R. S. DUMAN;
Yale Univ., New Haven, CT

Abstract: Clinical studies demonstrate that scopolamine, a non-selective muscarinic acetylcholine receptor (mAchR) antagonist, produces rapid therapeutic effects in depressed patients, and preclinical studies reveal that the action of scopolamine is associated with increased glutamate transmission and synaptogenesis in the medial prefrontal cortex (mPFC). To further elucidate the cellular mechanisms underlying the novel rapid-acting antidepressant action of scopolamine, the present study examined the role BDNF release and the activation of L-type voltage-dependent calcium channels (VDCCs) on the behavioral and synaptic actions of scopolamine. The results demonstrate that infusion of a neutralizing BDNF antibody into the mPFC blocks the behavioral effects of scopolamine in the forced swim test (FST) and in the novelty suppressed feeding test (NSFT). Moreover, pretreatment with verapamil, a VDCC antagonist, blocks the behavioral effects of scopolamine in the FST and NSFT. Finally, we show that scopolamine treatment increases mTORC1 signaling within the mPFC and this is dependent on activation of VDCCs. Collectively, these results indicate that the release of BDNF and L-type VDCCs activation is critical for the antidepressant effect of scopolamine. Characterization of the cellular mechanisms for scopolamine will lead to identification of novel targets for safer, rapid-acting antidepressants.

Title: Distinct effects of ketamine and GLYX-13 on attentional performance

Authors: *B. D. HARE, S. M. GROMAN, C. A. GIANESSI, J. R. TAYLOR, R. S. DUMAN; Dept. of Psychiatry, Yale Sch. of Med., New Haven, CT

Abstract: The rapid antidepressant response to ketamine, an open channel NMDA receptor antagonist, in treatment resistant individuals has produced great excitement in the field of depression. The antidepressant response to ketamine is associated with synaptic strengthening that is evident as increased sensitivity to serotonin (5-HT) and hypocretin/orexin in the medial prefrontal cortex (mPFC). Cortical synapses in the mPFC have been implicated in attentional performance. The serial reaction time task (SRTT) requires rodents to attend to multiple

apertures awaiting a visual stimulus and is utilized to assess attentional and executive functions. Manipulation of the stimulus duration, and interval before stimulus presentation in the SRTT can challenge attention or impulsivity respectively. Increased sensitivity to 5-HT after ketamine is mediated by 5-HT2A receptors that are known to impair performance on attention tasks by increasing impulsivity. In contrast, glutamate release stimulated by hypocretin/orexin application to thalamo-cortical synapses in the mPFC enhances attentional performance by reducing incorrect responses at short stimulus durations. It was, therefore, hypothesized that ketamine administration would impact separable behavioral components of the SRTT to produce enhanced attentional performance and increased impulsivity. Consistent with our hypothesis, we demonstrate that ketamine (10mg/kg) enhances attentional performance when stimulus duration is reduced and increases impulsivity when the pre-stimulus interval is lengthened. GLYX-13, a NMDA receptor modulator with glycine site partial agonist properties, produces rapid antidepressant responses but with fewer psychotomimetic side effects than ketamine. We have found that GLYX-13 (3mg/kg) increases synaptic responses in response to hypocretin/orexin but not 5-HT, and produced a similar increase in attentional performance without the negative effect of increased impulsivity that was observed after ketamine administration. These findings demonstrate that distinct aspects of the pharmacological response to ketamine and GLYX-13 can be mapped onto separable SRTT performance profiles. Additionally, the findings suggest that the ketamine/GLYX-13 regulation of the hypocretin/orexin system may play an important role in the beneficial actions of rapid-acting antidepressants.

Title: Dynamic role of prefrontal cortex GABA interneurons in the effects of rapid-acting antidepressants and stress-induced depressive behaviors

Authors: *E. S. WOHLEB, M. J. GIRGENTI, D. M. GERHARD, R. S. DUMAN;
Yale Univ., New Haven, CT

Abstract: Major depressive disorder (MDD) is a recurring psychiatric illness that causes significant health and socioeconomic burden. Recent studies in our lab show that the antidepressant-like behavioral effects of scopolamine are due to increased glutamate release, activation of mTORC1 signaling, and enhanced dendritic spine density on pyramidal neurons in the prefrontal cortex (PFC). Further studies in the lab suggest that acute blockade of M1-type muscarinic acetylcholine receptors (M1-AChR) in the PFC engages specific microcircuitry to initiate activity-dependent molecular cascades and subsequent behavioral effects. Through viral-mediated knockdown of M1-AChR expression in specific neuronal subtypes we show that PFC GABA interneurons are critical mediators of the antidepressant-like effects of scopolamine. Additional studies revealed that M1-AChR expression in somatostatin (SST) interneurons is necessary for the rapid antidepressant-like effects of scopolamine. Together these findings indicate that GABA interneurons act as a "cellular trigger" in the PFC, with acute blockade of M1-AChR leading to disinhibition of pyramidal neurons and resultant glutamate release. To further examine molecular differences in PFC GABA interneurons, transgenic male and female mice with fluorescently-labeled (tdTomato) parvalbumin (PV) or SST interneurons were used for cell sorting and RNA-Seq analyses. These results show varied neurotransmitter and neuropeptide receptor expression between PV and SST interneuron subtypes in the PFC. We also found that exposure to chronic unpredictable stress (CUS, 14 days), which causes depressive-like behaviors, selectively reduces the number of SST-tdTomato interneurons in the PFC of male and female mice. Further molecular studies are being conducted to determine the corresponding changes in the SST interneuron transcriptome following exposure to CUS, as well as after administration of rapid-acting antidepressants. The results show that PFC GABA interneurons have a dynamic role in synaptic plasticity and behavioral regulation: on one hand, acute blockade can initiate rapid antidepressant-like effects, and on the other chronic stress exposure causes GABA interneuron dysfunction that may precipitate maladaptive neuroplasticity of pyramidal neurons underlying depressive-like behavior. *Supported by NIMH Grants MH045481 and MH093897, and the State of Connecticut*.

Title: A role for NR2B-containing NMDA receptors on prefrontal cortex interneurons in the rapid antidepressant effects of ketamine

Authors: *D. M. GERHARD[1], E. S. WOHLEB[2], R. S. DUMAN[2];
[1]Psychology, [2]Mol. Psychiatry, Yale Univ., New Haven, CT

Abstract: Recent studies highlight the rapid antidepressant actions of the NMDA receptor antagonist ketamine. Rodent studies show that ketamine rapidly increases glutamate release, activates mTORC1 signaling and increases translation of synaptic proteins in the medial prefrontal cortex (mPFC) shortly following acute treatment. Furthermore, additional studies show that selective NR2B receptor antagonists produce similar behavioral and molecular signaling effects. However, the initial cellular trigger underlying the actions of ketamine has not been identified. Collectively, these studies suggest that blockade of NR2B-containing NMDARs may be a critical mediator for the rapid antidepressant effects of ketamine. We used CaMKII-, GAD67-, parvalbumin (PV)-, and somatostatin (SST)-Cre mice and viral-NR2B shRNA to produce Cre-dependent knockdown of NR2B receptors in glutamate and GABA neurons, as well as subpopulations of GABA neurons. Mice were then tested in a preswim and open-field test (OFT) to measure baseline effects of cell-specific NR2B knockdown. Viral NR2B shRNA was infused into the mPFC of the cre recombinase lines and after 3 weeks to allow for recovery and viral expression, the mice were tested before and after ketamine administration in the forced swim test (FST) and novelty suppressed feeding test (NSFT). Viral-mediated knockdown of NR2B in the mPFC of GAD67-Cre mice produced a significant antidepressant response in the FST, and occluded the antidepressant effects of ketamine in this model; preliminary studies suggest similar effects in the NSFT. Knockdown of NR2B on pyramidal neurons in CaMKII-Cre mice did not significantly block the antidepressant response to ketamine in the FST or NSFT. Preliminary findings suggest that NR2B on SST-, but not PV-Cre neurons, mediates the actions of ketamine. These findings indicate that the ketamine produces a burst of glutamate in the mPFC via an indirect mechanism: blockade of tonic firing GABA interneurons and disinhibition of glutamate transmission that leads to increased synaptic connectivity and rapid antidepressant behavioral responses. Studies are being conducted to confirm these findings and to extend the results to other behavioral models.

Title: NMDA antagonist ketamine accelerates fear extinction via mTORC1 signaling

Authors: *M. J. GIRGENTI, S. GHOSAL, D. LOPRESTO, J. R. TAYLOR, R. S. DUMAN; Dept. of Psychiatry, Yale Univ. Sch. of Med., New Haven, CT

Abstract: Post-traumatic stress disorder (PTSD) is a chronic and debilitating disorder that may occur after a severe traumatic event. PTSD symptoms, particularly those related to re-experiencing the traumatic event, may fall within the fear-conditioning paradigm of psychobiology. Classical antidepressants, particularly selective serotonin reuptake inhibitors, are reported to reduce PTSD symptoms in humans and fear in rodents when combined with extinction therapy. In the present study we examine the mechanisms underlying the actions of ketamine in a rodent model of fear conditioning, extinction, and relapse. Rats received ketamine (10 mg/kg; i.p.) or saline twenty-four hours after fear conditioning (foot shock paired with an auditory cue) and were then subjected to extinction-training on each of the following two days (exposure to auditory cue without foot shock). Ketamine administration enhanced extinction on the second day of training (i.e., reduced freezing behavior to cue). In animals receiving ketamine and extinction training, there was an increase in levels of cFos in the medial prefrontal cortex (mPFC) but reductions of this activity-dependent immediate early gene in the amygdala after the second day of extinction recall. In addition, ketamine plus extinction training increased mTORC1 signaling in mPFC, a region that is instrumental in the acquisition and retrieval of extinction. Interestingly, pretreatment with the AMPA receptor blocker 2,3-dihydroxy-6-nitro-7sulfamoyl-benzol(f)quinoxaline-2,3-dione (NBQX) 10 minutes before ketamine administration partially blocked the enhancement of extinction 24 hours later. Moreover, infusion of the selective mTORC1 inhibitor rapamycin into the mPFC blocked the enhancing effects of ketamine on extinction. Taken together, our findings support the hypothesis that ketamine produces long-lasting protein synthesis dependent effects on neuronal circuits that enhance the recall of extinction and could represent a novel approach for the treatment of PTSD and other fear disorders.

Title: Role of mitogen-activated protein kinase phosphatase-1 (MKP-1) in rapid antidepressant responses

Authors: J. KAPUSCINSKI, R. DRISCOLL, L. SEMKE, *L.-L. YUAN, V. DURIC;
Dept. of Physiol. and Pharmacol., Des Moines Univ., Des Moines, IA

Abstract: The pathophysiology of major depressive disorder (MDD) is complex, and the exact neural mechanisms involved are yet to be identified. However, our recent studies of postmortem depressed human brains as well as preclinical models of depression suggest that increased expression of mitogen-activated protein kinase (MAPK) phosphatase-1 (MKP-1), a key negative regulator of the MAPK cascade, plays a significant role in depression pathophysiology. Moreover, MKP-1 was shown to be both necessary and sufficient for development of depressive-like behavioral responses in animal models. Though, its potential role in treatment of depression, especially in response to rapid-acting antidepressants, such as ketamine, is yet to be determined. In this study, we investigated activation of MKP-1 and its main MAPK substrates after ketamine treatment in both dose- and time-dependent manner. Biochemical analysis showed that ketamine administration evokes robust increases in MKP-1 activation via phosphorylation at 1, 6, and 24 hours within synaptoneurosomes isolated form the prefrontal cortex (PFC) tissue. These changes in activated protein levels were also accompanied by significant increases in MKP-1 mRNA levels at 1 hour, followed by significant decreases at 24 hours. However, ketamine-induced activation of MKP-1 does not appear to be correlated with, and thus driven by, changes in activation of MAPK signaling. Thus, additional studies are underway to potentially identify the exact substrate targets that are responsible for induction of MKP-1 activation following ketamine treatments. Altogether, our findings in the PFC support the idea that MKP-1 may play an important role in ketamine-mediated rapid antidepressant responses, which could potentially contribute to discovery of novel drug targets.

Title: Role of MKP-1-mediated inhibition of hippocampal JNK in the development of depressive-like behaviors

Authors: *B. J. LAMB, JR, C. LANGRECK, L. SEMKE, E. WAUSON, L. YUAN, D. VANJA;
Des Moines Univ., Des Moines, IA

Abstract: Major depression disorder (MDD) has been linked to changes in function and activity of the hippocampus, one of the limbic regions involved in regulation of emotions and mood. Our previous work demonstrated that mitogen-activated protein kinase phosphatase 1 (MKP-1) plays an important regulatory role in hippocampal pathophysiology of depression. However, the potential role of JNK, its main neuronal substrate, has not been well described in mood disorders. In this study we investigated whether MKP-1-mediated specific inhibition of JNK is sufficient to produce a depressive-like phenotype in a rodent model. We used recombinant adeno-associated virus (rAAV) vector to locally express a mutated MKP-1 (i.e., MKP-1^{ASA}) in the hippocampal subfields of a rat brain. MKP-1^{ASA} is only able to bind and inactivate JNK pathway without interfering with ERK and p38 signaling. The effects of the MKP-1^{ASA} mutant on development of depressive- and anxiety-like behaviors were compared to animals infused with AAVs expressing either GFP (i.e., control) or wild-type MKP-1. Initial behavioral analysis showed that infusion of wild-type MKP-1 virus into unstressed rats produced robust anhedonic responses (e.g., significantly decreased sucrose preference), while infusion of the MKP-1^{ASA} mutant virus resulted in partial behavioral deficits. These preliminary results suggest that MKP-1-mediated inhibition of JNK may contribute to development of depressive-like responses to some extent; however, additional studies are currently underway to further characterize the role of JNK in depression. Together these studies may contribute to a better understanding of the pathophysiological events underlying the development of MDD and to identification of potential therapeutic and diagnostic targets for this disorder. Title: Hippocampal mechanisms linking chronic pain and development of depressive-like behaviors

Authors: M. CARDER, C. LANGRECK, M. LEONG, B. LAMB, L. SEMKE, M. SPOCTER, L.-L. YUAN, *V. DURIC;
Physiol. and Pharmacol., Des Moines Univ., Des Moines, IA

Abstract: Clinical reports indicate that many chronic pain patients also develop symptoms of mood disorders, especially major depressive disorder (MDD); however, the underlying neural mechanisms linking chronic pain conditions and depressive behaviors are still poorly understood. Our previous studies have demonstrated that rodent models of chronic pain mimic some of the stress-like alterations in intracellular signaling and cellular architecture (e.g., decreased MAPK signaling and reduced rate of neurogenesis) within the hippocampus, a limbic brain region involved in regulation of mood. Thus, in this study, we examined the effects of persistent pain on activation of immune-inflammation processes in the hippocampus. Male rats were initially exposed to either injection of complete Freund's adjuvant (CFA; model of chronic inflammatory pain) or spared nerve injury (SNI; model of chronic neuropathic pain). Both pain models produced robust mechanical hypersensitivity throughout the 21 or 42 day period, accompanied by depressive-like phenotype. Biochemical analysis of hippocampal tissue showed that exposure to inflammatory, but not neuropathic, chronic pain induces changes in expression of proteins involved in activation of interlukin-1-beta (IL-1ß)-mediated mechanisms, specifically members of Nod-like receptor (NLR) family of inflammasome multiprotein complex. Chronic inflammatory pain also evoked elevated levels of IBA1 protein within specific subareas of the hippocampus, suggesting potential increases in microglial activation which may, in part, underlie enhanced activation of NLRP3 inflammasome. These results resemble previous findings linking stress-induced IL-1ß up-regulation and suppression of neurogenesis in the adult rat hippocampus and, thus, may present novel factors contributing to the depressive-like behaviors observed in chronic pain models. Furthermore, pain also evoked increased activation of the hippocampal MKP-1 protein, a negative regulator of MAPK signaling that we recently demonstrated to be overactive in depressed hippocampus. Thus, similarities in dysregulation of hippocampal MKP-1 and MAPK signaling in pain and stress may represent an additional neural mechanism that potentially links these two conditions. Together these studies may ultimately contribute towards

the identification of new treatment targets and the development of novel clinical strategies to diminish the mental health consequences of chronic pain.

Title: Ketamine diffusion in brain tissue: implications for *In vitro* studies of drug mechanisms

Authors: *Z. S. GEIGER[1], B. VANVELLER[2], J. S. CHEN[2], A. K. HARRATA[2], L. SEMKE[1], S. SAICHELLAPPA[1], L.-L. YUAN[1];

Abstract: Ketamine has been in use for over 50 years as a general anesthetic, acting primarily through blockade of N-methyl-D-aspartate receptors in the brain. Recent studies have demonstrated that ketamine also acts as a potent and rapid-acting antidepressant when administered at sub-anesthetic doses. However, the precise mechanism behind this effect remains unclear. We examined the diffusion properties of ketamine in brain tissue to determine their effects of *in vitro* studies related to the actions of ketamine. Brain slices from adult mice were exposed to artificial cerebrospinal fluid (aCSF) containing ~17 μM ketamine HCl for varying amounts of time. The amount of ketamine within each slice was then measured by tandem high performance liquid chromatography - mass spectrometry to characterize the diffusion of ketamine into brain tissue over time. We successfully modeled the diffusion of ketamine into brain tissue using a mono-exponential function with time constant τ=7.04 minutes. This curve was then compared to a one-dimensional model of diffusion yielding a diffusion coefficient of approximately 0.12cm2·s-1 for ketamine diffusing into brain tissue. The brain:aCSF partition coefficient for ketamine was determined to be approximately 2.5. Our results suggest that the diffusion properties of ketamine have a significant effect on drug concentrations achieved within brain tissue during *in vitro* experiments. Ketamine is highly soluble in both water and lipid, quickly equilibrating in lipid-rich brain tissue at concentrations up to 2.5 times higher than the

surrounding aCSF. The ketamine concentration in aCSF thus represents an underestimation of the ketamine concentrations actually achieved within brain tissue by nearly 60%. Due to the concentration-dependent nature through which ketamine exerts its differential actions, these diffusion properties should be considered when interpreting or designing *in vitro* studies related to the actions of ketamine, and caution should be exercised when interpreting results derived from previous in vitro studies in which the concentrations of ketamine used greatly exceed those which produce specific effects *in vivo*.

Title: Alpha5 subunit-selective negative allosteric modulators of GABA-A receptors exert a rapid antidepressant action with low potential for addiction

Authors: *S. M. THOMPSON[1], M. NELSON[1], P. ZANOS[1], S. KRIMMEL[1], H. PRIBUT[1], C. KOSTELNIK[2], H. STARNES[2], A. BAILEY[2], T. GOULD[1];
[1]Univ. of Maryland Baltimore, Baltimore, MD; [2]St. Mary's Col. of Maryland, St. Mary's City, MD

Abstract: Depression is one of the leading causes of mortality and morbidity worldwide. Current therapeutic treatments based on monoamine reuptake inhibition are effective in only half of patients and, when effective, require long-term administration. Ketamine has recently gained widespread attention as a novel fast-acting antidepressant and may act by promoting high frequency oscillatory activity, apparent as an increase in EEG power in the gamma frequency band (30-80 Hz) (Zanos et al., Nature, 2016). We have recently shown that a single administration of negative allosteric modulators of GABA-A receptors containing alpha5 subunits, such as MRK-016 or L-655,708, reverses anhedonia in chronically stressed mice and rats (Fischell et al., Neuropsychopharmacology, 2015). Consistent with these findings, we

observed that control male C57BL/6J mice prefer to interact with a swab doused in female urine, compared to male urine, and that this preference is lost in mice subjected to 14 days of multimodal stress. Both MRK-016 (3mg/kg) and ketamine (10mg/kg) restored the preference for female urine 24hrs after injection. EEG recording revealed that MRK-016 induced a selective increase in EEG power in the gamma frequency band beginning within 10min of injection and persisting for ca. 60 min, suggesting that the decrease in depression-like behavior at 24hrs is triggered during a brief induction period. We next asked whether GABA-NAMs elicit signs of abuse and addictive potential. Administration of ketamine induced a conditioned place preference in both mice and rats, whereas MRK-016 and L-655,708 (0.7mg/kg) did not, indicating a lower abuse potential. Negative allosteric modulators of GABA-A receptors containing alpha5 subunits thus represent a novel class of fast acting antidepressant drugs that are potentially less addictive than NMDA receptor blockers. This class of compounds may thus have clinical utility in the treatment of depression.

Title: The role of erk in synaptic plasticity: novel insights from serotonin signaling in the hippocampus

Authors: *A. M. VAN DYKE, A. J. KALLARACKAL, X. CAI, S. M. THOMPSON; Physiol., Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: Plasticity of AMPA receptors (AMPARs) is the fundamental cellular substrate for learning and memory; defects in synaptic plasticity contribute to a multitude of neurological and neuropsychiatric disorders. Our laboratory has shown that serotonin-mediated signaling can potentiate temporoammonic (TA) to CA1 pyramidal cell synapses in the hippocampus via 5-HT_{1B}R activation and that this process is required for the antidepressant actions of selective serotonin reuptake inhibitors in rodent models. Like long-term potentiation (LTP), serotonin-

induced potentiation is mediated by the activation of calmodulin-dependent protein kinase II (CaMKII) and the subsequent phosphorylation of the AMPA receptor subunit GluA1 at serine 831 (S831). As predicted by a shared expression mechanism, electrically evoked LTP and 5-HT_{1B}R-mediated potentiation occlude each other. There is considerable evidence that LTP requires the activation of extracellular signal-regulated kinase (ERK). We hypothesized that 5-HT_{1B}R activation activates ERK, as well as CaMKII, and that the activation of both enzymes is required for the phosphorylation of GluA1 at S831 and potentiation. We tested this hypothesis using pharmacological tools and determined electrophysiological and biochemical endpoints in acute hippocampal brain slices. Using phospho-specific antibodies, we observed an increase in ERK activation in response to the 5-HT_{1B}R selective agonist anpirtoline and after acute elevation of endogenous serotonin with the SSRI fluoxetine. This elevation in activated ERK was concomitant with the activation of CaMKII, the phosphorylation of GluA1 S831, as well as the potentiation of AMPAR-mediated transmission at TA-CA1 synapses. Pharmacological inhibition of ERK prevented both potentiation of TA-CA1 synapses and the phosphorylation of GluA1 S831, but did not prevent the activation of CaMKII. We conclude that ERK activation is required for potentiation of excitatory synapses by both activity- and serotonin-dependent potentiation acting as a permissive gate, allowing activated CaMKII to phosphorylate its GluA1 S831 substrate.

Abstract: Major depressive disorder affects approximately 16 percent of the world population at some point in their lives and is one of the leading causes of death. Despite a number of available monoaminergic-based antidepressants, these drugs require long-term administration to be effective, and many patients never attain sustained remission of their symptoms. Although the non-competitive glutamatergic *N*-methyl-*D*-aspartate receptor (NMDAR) antagonist, (R,S)-ketamine (ketamine) exerts rapid and sustained antidepressant effects, other NMDAR antagonists do not manifest similar actions, suggesting a differential mechanism of action of ketamine. We show that NMDAR inhibition is not responsible for the antidepressant actions of ketamine since (R)-ketamine, which has lower affinity for the NMDAR, exerts superior antidepressant responses compared to (S)-ketamine, and MK-801 (another NMDAR antagonist) does not exert the sustained effects observed following ketamine administration. We also demonstrate that production of the (2S,6S;2R,6R)-hydroxynorketamine metabolite is essential for ketamine's antidepressant effects, and that the (2R,6R)-HNK enantiomer exerts behavioral, electroencephalographic, electrophysiological and cellular antidepressant actions *in vivo*. Importantly these effects are NMDAR inhibition-independent but they involve early and sustained α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor activation. This metabolite did not exert ketamine-associated abuse potential (measured with intravenous self-administration), sensory dissociation (measured with pre-pulse inhibition) or stimulant side effects. Our results indicate a novel mechanism underlying ketamine's unique antidepressant properties, which involves the required activity of a distinct metabolite and which is independent of NMDAR inhibition. These findings have relevance for the development of next generation, rapid-acting antidepressants.

Title: Drebrin in the nucleus accumbent mediates behavioral and structural plasticity following opiate exposure

Authors: *J. A. MARTIN[1], Z.-J. WANG[1], M. S. HUMBY[1], A. CACCAMISE[1], L. E. MUELLER[1], J. N. SIEMIAN[1], C. T. WERNER[1], R. L. NEVE[2], J.-X. LI[1], A. M. GANCARZ[1], D. M. DIETZ[1];
[1]State Univ. of New York At Buffalo, Buffalo, NY; [2]MIT, Cambridge, MA

Abstract: Opiate addiction has become a worldwide epidemic with great societal and financial burdens. Drug addiction, defined as a chronic relapsing disease, is characterized by persistent behavioral and cellular plasticity in several key regions of the mesolimbic dopaminergic system, including the nucleus accumbens (NAc). Opiates, such as morphine and heroin, lead to decreases or pruning of dendritic spines on neurons in the NAc. To date, there is little known about the cellular neurobiology of opiate-induced structural plasticity. Following exposure to morphine or heroin, we found decreased expression of the actin-binding protein drebrin in the NAc, which is likely mediated by an increase of HDAC2 binding on the drebrin promoter. To assess the functional and behavioral roles of drebrin expression following opiate exposure, we overexpressed drebrin in the NAc using viral-mediated gene therapy. Overexpression blunted morphine-induced locomotor sensitization and responses to a morphine challenge compared to controls. Additionally, we assessed the role of drebrin in mediating relapse-like behaviors. Following self-administration of heroin, overexpression of drebrin attenuated drug-primed reinstatement, which was accompanied by a reversal of the heroin-induced structural plasticity. Drebrin overexpression also produced a downward vertical shift in a within-session dose response paradigm, demonstrating that drebrin decreases the reinforcing properties of heroin. Taken together, these data demonstrate an essential role for drebrin in mediating the molecular mechanisms underlying opiate-induced behavioral and structural plasticity.

Title: The role of Cornichon homolog-3 (CNIH3) in opioid-induced plasticity and conditioned behavior

Authors: *H. E. FRYE[1], C. TROUSDALE[1], E. C. NELSON[2], J. DOUGHERTY[3], J. A. MORON[1];
[1]Pain Center, Dept. of Anesthesiol., [2]Dept. of Psychiatry, [3]Dept. of Genet., Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: In 2015 the CDC reported a drastic increase in heroin use in men and women, in nearly all age groups, and across the spectrum of socioeconomic status. The major predictive factor for heroin abuse was addiction to medically prescribed opioid pain medications. In a previous genome-wide association study comparing non-dependent with dependent opioid misusers, the strongest correlation to differences in addiction following opioid misuse were found to be single nucleotide polymorphisms (SNPs) in cornichon family AMPA receptor auxiliary protein 3 (CNIH3) (Nelson *et al*. 2016). Limited information is available on the basic function of CNIH3 in the neurons, but it is suspected to play an important role in AMPA receptor trafficking to the post-synaptic density (PSD). This study investigates the function of CNIH3 in the hippocampus, a key brain region in drug associated memory and learning, and its effect on morphine conditioning in CNIH3 -/-, +/-, and +/+ mice. Western blotting and co-immunoprecipitation will be performed to compare the effect of CNIH3 expression on hippocampal AMPA receptor trafficking between animal genotypes with and without morphine exposure. Field recordings will be used to measure CNIH3-mediated effects on long-term potentiation in mouse hippocampal slices. We will also examine the behavioral effect of CNIH3 genotype on morphine conditioned place preference to investigate its effects in environmental drug association. Finally, a viral construct developed by our lab to overexpress wild-type CNIH3 will be injected into the mouse hippocampus to study its effects on hippocampal plasticity and CPP. This study will use physiological, biochemical, and behavioral assays to investigate the role of CNIH3 in response to opioids.

Title: Kappa opioid system in nucleus accumbens mediates pain-induced decrease in motivated behavior

Authors: *T. MARKOVIC[1], N. MASSALY[2], A. POE[2], R. AL-HASANI[2], D. BHATTI[2], M. BRUCHAS[2], J. MORON[2];
[1]Anesthesiol., Washington Univ. Sch. of Med., Saint Louis, MO; [2]Washington Univ. in St. Louis, Saint Louis, MO

Abstract: Chronic pain affects millions of Americans, representing a big health and economic problem in the United States. In addition to sensory disturbances, patients are commonly present with other side effects including reduced quality of life, dysphoria, anhedonia, and psychiatric disorders such as depression. The mechanism behind the emotional processing of pain is still unknown and understanding it is crucial in developing better therapeutic strategies. Because pain patients commonly experience psychiatric disorders linked with decreased dopamine levels within the mesolimbic reward pathway it is likely that this pathway is impaired in chronic pain as well. Dopamine release in the mesolimbic pathway is controlled by the action of opioid peptides on their receptors. We have recently reported that opioid-evoked dopamine release in nucleus accumbens (NAc) is blunted in the presence of persistent pain. Additionally, previous studies have shown that activation of kappa opioid system causes dysphoric, anhedonic states in humans and aversive behaviors in animals. We hypothesize that the activation of kappa opioid system within mesolimbic pathway in the presence of pain causes dysregulation of dopamine transmission leading to motivational deficits and aversive behaviors. In this work, we utilized optogenetics, PET imaging, behavioral pharmacology, and chemogenetics to determine the mechanism of pain-induced alterations in motivation and opioid intake. Here, we show that blockade of kappa opioid receptor (KOR) using NorBNI (a selective kappa opioid antagonist), reverses motivation for natural reinforces in animals experiencing persistent pain. Furthermore,

chemogenetic inhibition of dynorphin release (an endogenous KOR agonist) in the NAc restores motivation as well. In addition, specific activation of dynorphin-containing neurons in the NAc induces real time place aversion, which is potentiated in the presence of pain, mimicking negative emotional component of the pain. These results indicate that kappa opioid system in the NAc is necessary for expression of the motivational deficits and aversive states induced by pain. Moreover, modulation of kappa opioid system suggests a novel strategy in modulating dopamine transmission and treating negative mood disorders in people suffering from chronic pain.

Title: Heroin, oxycodone and fentanyl induce hyperglycemia in the rat nucleus accumbens

Authors: *E. SOLIS, JR[1], E. A. KIYATKIN[2];
[1]Behavioral Neurosci. Br., NIH/NIDA IRP, Baltimore, MD; [2]Behavioral Neurosci. Br., NIH/NIDA-IRP, Baltimore, MD

Abstract: Opiates have long been used as analgesic agents and they possess high addictive properties. Recently we have reported differential effects of various addictive drugs on extracellular glucose levels in the rat nucleus accumbens (NAc). For example, cocaine elevated glucose levels whereas MDPV, a synthetic cathinone, decreased glucose levels. By using glucose biosensors coupled with fixed-potential amperometry in freely-moving rats, we examined how three opioid drugs—heroin, oxycodone, and fentanyl—affect NAc glucose levels. We observed that each drug dose-dependently increases glucose levels. When administered intravenously (iv) at a typical self-administering dose (100 µg/kg) heroin increased NAc glucose levels 30-40% above baseline for 30-40 min, and the hyperglycemic effect progressively weakened during repeated injections within a session. The hyperglycemic effect of heroin strongly increased with dose increases, up to a two-fold basal glucose level increase at 300 µg/kg. At these high doses, we observed an immediate transient fall in glucose (within 2 min post-injection) associated with a period of behavioral freezing and inhibition of respiration. Iv oxycodone mimicked heroin in its effects on NAc glucose, but the effects were weaker, appearing at 150 µg/kg and progressing

with dose increases. Fentanyl was the most potent drug, inducing a discernable hyperglycemic effect starting at a dose of 1-3 μg/kg and greatly progressing at higher doses. Currently, we are examining the possible role of local vasodilation of cerebral vessels in mediating brain hyperglycemic responses of opiate drugs.

Title: GABRA2 variations affect the disrupted connectivity of impulsivity-control system in heroin abusers

Authors: *Y. SUN[1], R. JIN[2], Y. FAN[3], L. LU[1], J. SHI[1];
[1]Peking Univ., Beijing, China; [2]Brainnetome Center, Inst. of Automation, Chinese Acad. of Sci., Beijing, China; [3]Dept. of Radiology, Sch. of Medicine, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Introduction: Drug addiction is a chronic mental disorder characterized by loss of inhibitory control for compulsive drug seeking. Heroin abuse remains a great challenge in the world with high relapse rate. Impulsivity plays a critical role in the recidivism of drug use. The imbalance of the impulsivity and control systems could trigger off addicts' loss of willpower in resisting drugs. In order to clarify the neural-circuits basis under the impulsive heroin use, we firstly identified the structural connectivity alterations in impulsivity-control network. After found the abnormal connectivities in heroin addicts converged on the attenuated control system and considered the implication of *GABRA2* for against risk of addiction, we assessed the effects of *GABRA2* variations on the impulsivity-control network for further searching the potential predictive markers of impulsive heroin use.
Methods: MRI data were acquired from 78 male heroin addicts and 79 male healthy controls. Their global-cognition, impulsivity and decision-making were measured. The genetic samples were collected from 1035 heroin addicts and 2887 healthy controls. The anatomical connectivity was calculated by probabilistic fiber tracking in FSL, and the edge weights were measured by the mean FA values. Nonparametric permutation testing was implemented 10000 times to group analysis at a threshold of $p<0.0001$. SNPs were genotyped by using the Sequenom Mass Array system.
Results: Heroin addicts had decreased small-world property and increased global efficiency of

the impulsivity-control network. All the abnormal connectivities were significantly decreased in heroin group. The mean connectivity was positively associated with cognition and negatively related to impulsivity. The changes almost converge on the connectivities that liked with bilateral ACC. The rs279858, rs519270, rs693547 and rs279871 in *GABRA2*, which located in a strong linkage-disequilibrium block, were significantly interacted with heroin addiction to affect most of the abnormal connectivities. The rs279871 A allele was significantly increased in heroin group and associated with more serious abnormality of heroin addicts.
Conclusion: The impulsive drug use seems to be more likely due to the attenuated control system rather than the enhanced impulsive system. The risk allele of *GABRA2* variations could increase the susceptibility to heroin addiction and related abnormality of impulsivity-control network. We are now analyzing the methylation level of *GABRA2* promoter for further exploring the interaction effects.

Title: Determination of morphological and molecular adaptations in ventral tegmental area dopamine neurons by chronic morphine.

Authors: *S. E. COOPER[1], M. MAZEI-ROBISON[2];
[1]Neurosci. Grad. Program, [2]Physiol., Michigan State Univ., East Lansing, MI

Abstract: Opiate drugs are the leading treatment for severe or chronic pain in the USA despite their extremely addictive properties. Chronic opiate exposure induces neuroadaptations in the mesocorticolimbic system, particularly in ventral tegmental area (VTA) dopamine (DA) neurons. For example, opiates reduce VTA DA neuron soma size, a change correlated with increased DA activity and decreased drug reward. Prevention of this morphological change is sufficient to rescue the morphine-induced changes, highlighting its functional significance. While VTA DA structural and functional plasticity are central to morphine reward and addiction, the molecular mechanisms driving these neuroadaptations remain elusive due to two main sources of VTA

heterogeneity: multiple cell types and diversity within cell type based on projection target. In order to address these variables, we examined DA neuron-specific gene expression and projection-specific DA morphological response to chronic morphine. We determined gene expression changes specifically in VTA DA neurons using Translating Ribosome Affinity Purification (TRAP). By crossing DA neuron Cre-driver lines, (tyrosine hydroxylase (TH)-Cre or dopamine transporter (DAT)-Cre) with Rosa26 EGFP-L10a mice, we generated THEGFP-L10a and DATEGFP-L10a mice for isolation of mRNA from VTA DA neurons. We found significant enrichment of TH and DAT mRNA and significant depletion of GABAergic markers glutamic acid decarboxylase (GAD) and vesicular GABA transporter (vGAT) in bound fractions compared to input controls. We are now examining morphine-induced changes in the expression of candidate genes in THEGFP-L10a and DATEGFP-L10a mice subcutaneously implanted with either a sham or morphine pellets and future studies will use RNA sequencing for an unbiased assessment of morphine-induced changes in VTA DA neurons. In order to address whether morphine-induced neuroadaptations are limited to specific subsets of VTA DA neurons based on projection target, we are comparing the morphology VTA DA neurons that project to the nucleus accumbens (NAc) versus the prefrontal cortex (PFC). We labeled NAc- and PFC-projecting DA neurons via infusion of retrograde Cre-dependent viral constructs (AAV2/5-DIO-eYFP and AAV5-DIO-mCherry) into TH-Cre and DAT-Cre mice and are now examining VTA DA soma size under basal and chronic morphine conditions. Combined, the goals of these studies are to uncover the molecular mechanisms that underlie opiate-induced neuroadaptations in the VTA in order to identify novel targets for improved therapeutics.

Title: Effects of remifentanil on c-fos expression in the reward circuit of environmentally enriched and isolated rats

Authors: *R. S. HOFFORD, U. Z. HAMID, M. T. BARDO;
Dept. of Psychology, Univ. of Kentucky, Lexington, KY

Abstract: Opioid addiction is a major epidemic around the world, with rates of abuse in the millions. One major risk factor for the development of opioid addiction is early life stress. Preclinical studies often employ the social isolation paradigm to measure the effects of early life adversity on behavior and brain physiology in rodents. Using this paradigm, rodents raised in isolated conditions (IC) are often compared to rodents raised in enriched conditions (EC). When tested for drug self-administration, IC rats self-administer more drugs of abuse than EC rats. Recently, this was demonstrated with the short-acting opioid remifentanil. However, it is currently unknown how these housing conditions affect neurobiology as related to opioid-taking behavior. The immediate early gene *cfos* is often used as a marker of cellular activity in brain. Acute administration of most drugs of abuse increases c-fos expression in the nucleus accumbens and prefrontal cortex, but the magnitude of this expression might differ between IC and EC rats. The current study sought to measure levels of c-fos expression in rats after their first exposure to remifentanil. Rats were raised in either IC (n= 16) or EC (n=14) conditions from PND 21 until the end of the experiment. One week following catheter surgery, each rat was placed in an operant conditioning box where they received 10 i.v. infusions of either saline or 3 ug/kg remifentanil (1 infusion every 90 s). Rats were perfused ninety minutes after the last infusion. Immunohistochemistry was performed on sections containing the nucleus accumbens and prefrontal cortex. This infusion schedule was similar to a self-administration autoshaping session and was chosen to mimic c-fos expression in rats that continued on to the self-administration study. Results indicated that IC rats had more c-fos+ cells in nucleus accumbens and prefrontal cortex, but remifentanil did not increase the number of c-fos+ cells in either group of rats in any of the brain regions examined. Results from this study suggest that housing conditions can alter c-fos expression. However, more work must be conducted to understand the cellular events that may explain why enrichment protects against opioid self-administration.

Title: Comparison of (+) and (-)-naloxone on the acute psychomotor stimulating effects of heroin, 6-acetylmorphine, and morphine in mice

Authors: *J. MORLAND[1], G. S. ERIKSEN[1], J. M. ANDERSEN[1], F. BOIX[1], M. S. S. BERGH[1], V. VINDENES[1], K. C. RICE[2], M. HUESTIS[3];
[1]Norwegian Inst. Publ. Hlth., Oslo, Norway; [2]Section on Drug Design and synthesis, NIDA and NIAAA, Bethesda, MD; [3]Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: After intake heroin is rapidly metabolized to 6-acetylmorphine (6-AM) and further to morphine. Many (most?) of heroin's effects are thought to be mediated by these metabolites which are much more active at opioid receptors (OR) than heroin. Toll-like receptor 4 (TLR4) signaling is implied in opioid reinforcement, reward, and withdrawal. Here, we explored if TLR4 signaling is involved in the acute psychomotor stimulating effects of heroin, 6-AM, and morphine, and further if there are differences between the three opioids regarding TLR4 signaling. To address this, we examined how pretreatment with (+)-naloxone (a TLR4 active, but OR inactive antagonist) affected the acute increase in locomotor activity induced by heroin, 6-AM, or morphine in mice. The effect of (-)-naloxone (a TLR4 and OR active antagonist) pretreatment was also assessed, as well as the pharmacokinetic profiles of (+) and (-)-naloxone in blood and brain. We found that (-)-naloxone reduced the acute opioid induced locomotor activity in a dose dependent manner. By contrast, (+)-naloxone, administered in doses assumed to antagonize TLR4 but not ORs, did not affect the acute locomotor activity induced by heroin, 6-AM, or morphine. Both naloxone isomers exhibited similar concentration versus time profiles in blood and brain, but the brain concentrations of (-)-naloxone reached higher levels than those of (+)-naloxone. However, the discrepancies in their pharmacokinetic properties did not explain the marked difference between the two isomer's ability to affect opioid induced locomotor activity. Our results underpin the importance of OR activation and do not indicate an apparent role of TLR4 signaling in acute opioid induced locomotor stimulation in mice. Furthermore, there were no marked differences between equivalent doses of heroin, 6-AM, and morphine regarding involvement of OR or TLR4 signaling. These findings add novel information for evaluating the role of TLR4 signaling in processes related to mechanisms underlying opioid reinforcement, reward, and addiction.

Title: Brain and body temperature effects of heroin: state dependency and environmental modulation

Authors: *E. A. KIYATKIN, R. A. BOLA;
Behavioral Neurosci Br., NIDA-IRP, NIH, DHHS, Baltimore, MD

Abstract: Here we examined how intravenous heroin at a typical self-administering dose (0.1 mg/kg) affects brain temperature homeostasis in freely moving rats under conditions that mimic human drug use. When administered under standard laboratory conditions (quiet rest at 22°C ambient temperature), heroin induced moderate increases in brain temperature (1.0-1.5°C). Through simultaneous temperature recordings in the temporal muscle and skin, we demonstrate that this effect results from a joint contribution of two basic physiological mechanisms: moderate intra-brain heat production due to metabolic brain activation, and the inhibition of heat loss due to strong and prolonged skin vasoconstriction. The hyperthermic effects of heroin remained relatively stable during repeated injections, but they show relatively weak but significant within-session habituation. Heroin-induced brain temperature increases were significantly potentiated when the drug was administered under conditions of behavioral activation (social interaction) and in a moderately warm environment (29°C). By calculating the "net" effects of the drug in these two conditions, we show that this state- and environment-dependent potentiation results from the summation of thermogenic and vasoconstrictive effects of heroin with similar effects induced by either social interaction or a warm environment. When the dose of heroin was increased to two and four times the typical self-administering range (0.2 and 0.4 mg/kg, respectively), brain temperature showed a biphasic down-up fluctuation (hypothermia followed by hyperthermia). This initial hypothermia was dose-dependent and associated with a transient inhibition of metabolic neural activity coupled with skin vasodilation—inhibitory effects typically induced by general anesthetics. This rapid inhibition of brain activity induced by large-dose heroin injections appears to be related to serious, even fatal, health complications typical to heroin overdose in humans. Supported by the NIDA-IRP.

Title: Intermittent versus sustained morphine treatment regimens on molecular and behavioral markers of withdrawal

Authors: *K. LEE[1], S. BRIDGES[1], C. CAHILL[2], C. EVANS[1], A. TAYLOR[1];
[1]UCLA, Los Angeles, CA; [2]UC Irvine, Irvine, CA

Abstract: Opioid dependence has been linked to profound changes in brain circuitry that lead to a negative hedonic state. We have previously shown that chronic, intermittent morphine treatment leads to significant microglial activation in reward and affective pathways, and blocking microglial activation restores reward behavior in opioid dependent animals. We hypothesized that the repeated withdrawal associated with the intermittent morphine treatment exacerbates neuroinflammation and negative affective states associated with dependence. In order to test this hypothesis, male C57Bl/6 mice were treated with either subcutaneous morphine pellet (25mg) or intermittent morphine injection (10-40mg/kg, i.p.) for four days. A tail flick assay confirmed that morphine injection and pellet develop equivalent tolerance to morphine, suggesting each paradigm administers comparable amounts of drug. Twelve hours after the last intermittent morphine injection, molecular and behavioral assays of neuroinflammation and dependence were assessed and compared between groups. Microglia activation was measured by immunostaining IBA1 in the ventral tegmental area (VTA). Reward behavior was assessed in a balanced two-chamber conditioned place preference (CPP) apparatus, using cocaine (10mg/kg) as the reward stimulus. We have previously shown that intermittent morphine injection impairs cocaine preference using this paradigm. Here, we demonstrate that intermittent morphine injection, but not morphine pellet, significantly increases microglial cell body size in the VTA and impairs cocaine place preference. This suggests cellular and behavioral adaptations in reward circuitry following chronic morphine exposure is due, at least in part, to the repeated periods of withdrawal, rather than direct effects of the drug itself.

Title: Sex differences in spontaneous somatic morphine withdrawal and associated CREB activation in the tail of the ventral tegmental area

Authors: S. A. MORRIS BOBZEAN, M. M. WHITE, *L. I. PERROTTI;
Psychology, UT Arlington, Arlington, TX

Abstract: Opiate withdrawal syndrome is a feature common to chronic opiate use that often serves as a powerful motivator of continued drug use. GABA-ergic neurons in the tail of the ventral tegmental area (tVTA) are implicated in mediating responses to opiates, including withdrawal. The tVTA regulates the effects of opiates on VTA dopamine neurons and a number of earlier studies have shown that changes in levels of CREB within the VTA affect drug-motivated behaviors. To date, the mechanisms underlying morphine withdrawal have been studied almost exclusively in men and male animals. As a result, there is a considerable gap in our current understanding of the mechanisms underlying sex differences in opiate withdrawal behaviors and the specific effects of opioid withdrawal on CREB activity in the VTA. The purpose of the present study was to use a preclinical model of morphine dependence to investigate the influence of sex on the expression and duration of spontaneous somatic morphine withdrawal syndrome; and to characterize the relationship between spontaneous somatic withdrawal symptoms and expression of pCREB in GABAergic cells of the tVTA. Intact adult, male and female Long Evans rats were made morphine-dependent using 10 days of twice-daily s.c. injections of escalating doses of morphine (2.5-40mg/kg). All animals then underwent 72 hours of spontaneous withdrawal and somatic symptoms were assessed every 12 hours over the withdrawal period and all animals were sacrificed via
exsanguination after the last behavioral observation (72 hours). Both male and female morphine-dependent rats developed somatic symptoms of withdrawal, however, males expressed more severe symptoms earlier in withdrawal (in the first 36 hours) compared to females. While, females demonstrated lower overall symptom severity, these symptoms persisted for a longer period of time; as a result, withdrawal symptoms in females were more severe than males' at the 72-hour time point. CREB activation in tVTA GABA-ergic cells was significantly higher in morphine-withdrawn females compared to controls 72 hours after the end of treatment. These results demonstrate sex differences in the timing of the expression of somatic withdrawal. Moreover, our data suggest sex differences in the timing of withdrawal-induced activation of tVTA CREB. Current experiments are underway to assess the level of pCREB expression in

tVTA GABA-ergic neurons at earlier time-points of the spontaneous morphine withdrawal paradigm.

Title: The influence of social housing conditions on morphine-induced gene expression.

Authors: *M. BATES, M. A. EMERY, P. J. WELLMAN, S. EITAN;
Texas A&M Univ., College Station, TX

Abstract: Drug abuse is strongly influenced by socio-environmental factors. Our previous studies demonstrated that social housing conditions alter the propensity to acquire morphine reward and dependence in adolescent mice. Morphine-treated animals that are housed only with other morphine-treated animals (referred to as 'morphine only' animals) acquire morphine CPP significantly faster than morphine-treated animals that are housed with drug-naïve mice (referred to as 'morphine cage-mates'). Similarly, morphine only animals extinguished their morphine place preference at a significantly and markedly slower rate than the morphine cage-mates. This indicates a stronger and more robust acquisition of morphine CPP in animals housed with only other morphine-treated animals than in animals housed with drug-naïve animals. Lastly, morphine only animals display distinctly greater morphine withdrawal symptoms than morphine cage-mates. These results demonstrate that exposure to drug-naïve animals has a protective effect on development of opioid dependence, as well as the acquisition and maintenance of opioid reward. This further supports the notion that social conditions alter the propensity for developing opioid addiction.
Despite the preponderance of behavioral evidence, little is known about the potential mechanisms for the differential effects of social housing. In the current study, we examined the role of social environment on modulation of striatal gene expression. Specifically, adolescent mice housed in the various social housing conditions were injected with saline or morphine (20 mg/kg) for 14 days. Twenty four hours after the final injection, striatal tissue was dissected. Following this, RNA was extracted and high throughput next generation sequencing was used to

examine the mouse genome. Subsequently, we used RT-PCR to confirm the results for selected candidate genes.
Interestingly, we found that multiple genes were differentially altered in morphine-treated animals housed in different social housing conditions. In morphine only animals, 248 genes were up-regulated, and 252 genes were down-regulated. Conversely, in morphine-cage mates, only 73 genes were up-regulated, while 46 genes were down-regulated. Only 61 genes were similarly altered between the two groups. Our findings suggest that social environment may influence alterations on the genetic level and provide further evidence for a role of social environment in morphine reward and dependence.

Title: Mu opioid receptor ligand bias on GPCR signaling pathways

Authors: *X. ZHANG[1], S. HUTCHINS[2], R. GILMORE[2], E. VALLENDER[2];
[1]Program in Neurosci., [2]Dept. of Psychiatry and Human Behavior, Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: Opioids are commonly used as analgesics, but they are highly addictive. Mu opioid receptors, a subgroup of G-protein coupled receptors (GPCRs), bind natural peptides, including beta-endorphin, as well as opiate drugs, including morphine and fentanyl, with high affinity. Ligand binding to GPCRs triggers downstream signaling pathways. Recent work now shows that these pathways can be differentially activated by diverse ligands, a phenomena still under study that is termed ligand-biased signaling. The investigation of ligand-biased signaling in mu opioid receptors may contribute findings that can improve analgesic efficacy and decrease side effects, importantly including a reduced abuse liability. The main goal of this study is to delineate the effects of mu opioid agonists across secondary signaling pathways. We have stably transfected the human mu receptor into a Chinese hamster ovary (CHO) cell line. We then tested downstream signaling using GPCR 10 pathway Reporter Arrays (QIAGEN), divided into four groups: CHO-saline, CHO-ligand, CHO:OPRM1-saline and CHO:OPRM1-ligand. In these arrays, a firefly luciferase reporter, downstream from a transcriptional response element for each

pathway-of-interest, was introduced into the cell line, along with a Renilla luciferase gene, which acts as a transfection/transduction control. Ligand concentrations ranging from 0.1umol to 100umol of DAMGO, beta-endorphin, morphine and fentanyl were tested in the arrays. Firefly and Renilla intensity was measured, and the ratio used to compare differences among groups. Complete dose response curves are generated to compare EC50 and bias across signaling pathways. The data collected from the study may contribute to the genetic aspect of treating opioid addiction.

Abstract: Phasic dopamine release is an important contributor to the striatal control over a variety of behavioral functions as well as psychiatric disorders such as addiction. Recently, it has been shown that μ-opioid receptors (MORs) in the nucleus accumbens core (NAC) mediate reward-dependent motivated behavior in rats. However, it is unknown whether MORs contribute to motivation via dopamine-dependent mechanisms. It is well known that dopamine release in the striatum is primarily self-regulated via D2 autoreceptors and partially controlled by cholinergic interneurons. We hypothesized that local MORs also regulate phasic dopamine release in the NAC of rats. To test this we locally applied μ-opioid receptor antagonist while measuring phasic dopamine release in the NAC of rats with fast-scan cyclic voltammetry (FSCV).
Male adult Long-Evans rats were anesthetized with urethane for the entire recording. Phasic

dopamine release was induced by electrical stimulation of the ventral tegmental area and measured in the core with FSCV. The selective MOR antagonist CTAP (2, 4, and 8 μg) or saline was infused to the area of dopamine measurement via an infusion cannula approximately ~150 μm from the voltammetric sensor. The dopamine transporter blocker, nomifensine, was infused in a separate group of rats as a positive control for the infusion.
The higher doses of CTAP, 4 and 8 μg, robustly decreased evoked dopamine release to undetectable levels immediately after infusion into the NAC. While dopamine release did not recover within 60 min after 8 μg CTAP infusion (n=4), dopamine release recovered to 75% of pre-infusion amounts within 25 min after 4 μg (n=1). The low dose of CTAP, 2 μg, had no reliable effect on the dopamine release (n=3). While saline (n=5) had no effect on electrically evoked dopamine release, nomifensine (n=4) robustly increased the evoked signal immediately after the infusion by 300%, as expected. In vitro measurements verified that CTAP did not alter the sensitivity of the carbon-fiber sensor.
While this study is ongoing, the experiments revealed that local antagonism of the MOR blocks VTA-evoked phasic dopamine release. While future studies must determine the mechanism, two possibilities involve GABAergic and cholinergic interneurons which both regulate dopamine release within the NAC.

Title: Further characterization of the discriminative stimulus effects of naltrexone in rats with limited access to sucrose

Authors: *J. L. HERRMANN[1], K. F. JAMES[1], D. M. PAUKNER[1], S. M. MOE[1], E. M. DE ROACH[1], M. A. MAREK[1], L. R. ALTENDORF[1], A. S. LEVINE[2], D. C. JEWETT[1]; [1]Psychology, Univ. of Wisconsin - Eau Claire, Eau Claire, WI; [2]Univ. of Minnesota, Minneapolis, MN

Abstract: The excessive sugar intake that results from daily, limited access to sugar in rats has been reported to increase dopamine and endorphin function in the brain. Naltrexone (NTX), an opioid antagonist, is not discriminable at typical doses in standard operant paradigms in opioid-naïve subjects. We attempted to establish naltrexone as a discriminative stimulus in rats given 12-hour access to 25% or 32% sucrose solutions, 0.1% saccharin solutions, or water. After establishing the sucrose or saccharin baseline, rats were given daily injections of either saline or NTX (3.2 mg/kg, 15 min PT) one hour after access to the solution began. After the training session rats were returned to their home cages for the remainder of the 12-hour access period, followed by a 12-hour water access period. During the training session, correct lever presses (left following NTX, right following saline) were reinforced with a food pellet. Training continued until subjects exhibited 80% or more condition-appropriate responses for eight out of 10 consecutive sessions. NTX was established as a discriminative stimulus in 16 of 17 subjects with 12-hour access to sucrose in a mean of 72 sessions (Md = 63, range 27-135). No significant difference in rate of acquisition or initial NTX dose effect functions were noted between sucrose concentrations. Acute water substitution did not alter the discriminative stimulus effects, suggesting that sucrose consumption produced a long-term change in endorphin function. Chronic (2 week) water substitution eliminated the discriminative stimulus effects of NTX. Rats with constant water or limited saccharin access were unable to discriminate NTX. We wondered if rats with chronic, limited access to sucrose could discriminate between a smaller dose of NTX and saline. Rats with access to 10%, 25% or 32% sucrose solutions were injected with 0.1 mg/kg NTX or saline. Seven of twenty-one subjects acquired the discrimination in a mean of 57 sessions (Md = 55, range = 41-71). At least one subject from each of the sucrose concentration groups acquired the discrimination, with no difference in rate of acquisition. After 81 sessions, discrimination training was suspended for the 14 rats that did not acquire the discrimination of 0.1 mg/kg NTX. The NTX discrimination acquisition data and water substitution results suggest that chronic sucrose consumption results in a long-term but not permanent change in endogenous endorphin function that enables NTX to serve as a discriminative stimulus in rats. NTX's ability to serve as a discriminative stimulus depends upon NTX dose and solution type; sucrose concentration (10%-32%) had no effect on NTX function.

Title: The effect of coerulear orexin and dynorphin receptor antagonism on morphine withdrawal induced conditioned place aversion

Authors: *A. MOHAMMADKHANI[1], H. AZIZI[2], S. SEMNANIAN[2];
[1]Inst. For Res. In Fundamental Sci. (IPM), Tehran, Iran, Islamic Republic of; [2]Physiol., Tarbiat Modares Univ., Tehran, Iran, Islamic Republic of

Abstract: Locus coeruleus (LC), a pontine brainstem structure has been shown to be importantly involved in opiate dependency. LC neurons are innervated by dense hypothalamic fibers which contain two neuropeptides, Orexin and Dynorphin, coexpressed in the same synaptic vesicles. LC neurons express both kappa-opioid (KORs) and orexin type 1 receptors (OX1Rs). The functional interaction between these two neuropeptides during addictive behaviors, including morphine place aversion, has not been well studied. Here, we examined the role of LC KORs and OX1Rs blockade, separately and together to investigate naloxone-induced conditioned place aversion (CPA) of morphine-dependent rats. In this study we used CPA in male Wistar rats, made them morphine dependent by subcutaneous injection of morphine sulfate (10 mg/kg) at an interval of 12 h for 9 days. On the conditioning days, naloxone (1 mg/kg, i.p.) was injected 2 h after morphine administration. Intra-LC injection of NorBNI (KORs antagonist) and SB334867 (OX1R antagonist) prior to each conditioning session was used to assess the effect of blockade of these receptors. We found that disruption of orexin function in the LC reduced the expression of morphine CPA. Also our results showed that blockade of KORs, 24 h before conditioning session, reduced morphine CPA, while concomitant antagonism of OX1Rs and KORs abolishes this behavioral effect. These results reveal an interaction between dynorphin and orexin in the LC during conditioned place aversion. Blocking the dynorphin and orexin system within the LC separately reduces the negative emotional state of withdrawal which would be expected to reduce the probability of relapse. Identifying the mechanisms underlying the loss of the CPA effect in the presence of concomitant use of dynorphin and orexin receptor antagonists, needs further evaluations.

Title: Tegmental circuits controlling morphine locomotion: feedback between rostromedial tegmental GABA and dorsal tegmental cholinergic neurons.

Authors: *D. I. WASSERMAN[1], J. M. J. TAN[2], J. KIM[2], J. S. YEOMANS[2];
[1]Psychology, Univ. of Guelph, Guelph, ON, Canada; [2]Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: Opioids induce rewarding and locomotor effects largely by inhibiting rostromedial tegmental (RMTg) GABA neurons expressing μ-opioid receptors. In turn, these GABA neurons inhibit ventral tegmental area (VTA) dopamine (DA) neurons as well as laterodorsal and pedunculopontine tegmental (LDT and PPT) cholinergic and glutamatergic neurons. These LDT and PPT neurons then directly excite DA neurons via M5 muscarinic receptors (with faster excitatory effects via glutamate and nicotinic receptors). Inhibition of RMTg GABA neurons with M4D DREADDs in GAD2::Cre mice increased morphine locomotion, while excitation of these RMTg GABA neurons with M3D DREADDs decreased morphine locomotion (Wasserman et al., 2016). Many of these LDT and PPT cholinergic neurons projecting to VTA also send collateral projections to RMTg. On RMTg GABA neurons expressing μ-opioid receptors, 84% were found to also express the inhibitory M4 receptor, while 22% were found to express excitatory M3 receptors. Further, LDT and PPT GABAergic neurons were found to project only to RMTg but not to VTA. We propose that dorsal tegmental cholinergic neurons further facilitate effects of morphine on locomotion, by increasing inhibitory opioid actions on RMTg neurons. This results in a reciprocal feedback loop in which disinhibition of PPT and LDT ACh neurons not only increases DA output via excitatory M5 receptors, but strengthens the inhibitory effects of opiates on RMTg via inhibitory M4 receptors. This cholinergic feedback loop to RMTg may account for DA-dependent and DA-independent effects of opioids, and the critical importance of RMTg, PPT, and LDT neurons in opioid reward.

Title: HSV-mediated transfer of MnSOD into the PAG attenuates morphine physical withdrawal response in rats.

Authors: T. IIDA[1], S. LIU[1], H. YI[1], Q. LIU[1], *D. IKEGAMI[1], W. F. GOINS[2], J. C. GLORIOSO[2], D. A. LUBARSKY[1], S. HAO[1];

Abstract: Opioid drugs are potent analgesic agents but the use of these drugs is complicated by the development of tolerance and physical dependence, which substantially limit the long-term use of these drugs. The mechanisms underlying these phenomena are poorly understood. Studies have implicated the midbrain periaqueductal gray (PAG) in the pathogenesis of morphine withdrawal. ROS is involved in the morphine withdrawal response. Manganese superoxide dismutase (MnSOD) may reduce mitochondrial ROS product. Replication-defective herpes simplex virus (HSV) vectors-mediated expression of MnSOD prevented radiation enteritis which is related to ROS. Here we report that chronic morphine withdrawal-induced upregulation of mitochondrial superoxide in the ventrolateral PAG (vlPAG), and lowered the MnSOD activity. Microinjection of mitochondrial targeted superoxide scavenger Mito-Tempol reduced morphine withdrawal response. MnSOD mitochondrial superoxide mainly I was expressed in the neurons of the PAG in the morphine withdrawal. HSV-based vector expressing MnSOD microinjected into the PAG induced over-expression of MnSOD and reduced the naloxone-precipitated withdrawal response, and suppressed MitoSox (a mitochondrial superoxide indicator) profile cells. These results support the concept that mitochondrial superoxide expressed in neurons in the PAG may play an important role in the pathogenesis of morphine withdrawal response, providing a novel approach to treating morphine dependence. Title: Probabilistic reversal learning in rodents: Technical issues and open-source software and hardware

Authors: M. J. PRESTON[1], T. K. SWANSON[1], L. M. AMARANTE[1], B. B. AVERBECK[2], *M. LAUBACH[1];

Abstract: A major goal of rodent research is to map findings in behavioral studies onto the existing literature from humans and primates. Probabilistic reversal learning tasks have been used to study the flexible control of action selection and learning. To date, only a few papers have reported successful training of probabilistic reversal learning in rodents. We implemented positional and visually guided reversal tasks using behavioral procedures from these published studies, and discovered several limitations in how rats learned the tasks. For example, without immediate feedback at the time of action selection about the success or failure on a given trial, rats will adopt undesired spatial strategies such as traveling in circular patterns and visiting the set of response ports until the currently baited port is discovered. As a result, actual random responding can appear as low-success probabilistic choice, thereby raising serious concerns about several published probabilistic learning studies. Video assessment and initial training under deterministic conditions are therefore crucial to ensure that rats adopt optimal behavioral strategies. Once this is done, they can be trained to overall success rates >75% within 13±3 sessions at probabilities of 90/10 and 80/20, and rates >70% at 70/30. We forced the probabilities to switch every 30 trials, to allow a better fit for our algorithms (e.g. Costa et al., 2015). Previously published studies used a criterion of 8 consecutive correct trials to switch (Bari et al. 2010; Dalton et al. 2014). A theoretical analysis suggests that rats must exhibit at least 6 switches per 200 trials and exhibit runs with >13 consecutive correct choices with an average success rate of 75% to perform the task better than expected by chance. Rats trained with the procedures described here outperformed this expectation. Here, we will offer suggestions for improving research designs involving probabilistic reversal learning and share code for the freely available

Python language for evaluating random responding and quantifying results using reinforcement learning algorithms. We will further present (and share online) designs for 3D-printed response and reward ports and 8x8 LED matrices controlled by Arduino microcontroller boards. The 8x8 LED matrices allow for presenting dynamic visual stimuli in a low-cost design that should enable many new experiments on decision making and executive control in rodents.

Title: Predictive neural activity of others' behavior in the macaque medial frontal cortex

Authors: *R. CIRILLO, R. FALCONE, A. GENOVESIO;
la Sapienza Univ. of Rome, Roma, Italy

Abstract: Monitoring others' behavior to predict their future behavior is a fundamental skill in primate social life. We explored the role of medial frontal cortex (MFC) in representing the prediction of other agents' behavior while two male rhesus monkeys performed a spatial non-match-to-goal task in a human-monkey (H-M) paradigm. In each trial, 2 spatial identical targets appeared at two of 4 spatial locations of a touchscreen. The monkey or the human, in turn, was required to choose the target at the location that did not match the previously chosen one. Each agent had to monitor the other's action for selecting the correct target in the subsequent trial after discarding the previous chosen target. We recorded 273 neurons and analyzed the spatial modulation in the delay period, before any action was required. We found 68 (25%) only Monkey agent cells, 59 (22%) only Human cells, and 29 (11%) Both agents' cells. We found that the Human and Both cells could represent a prediction of other's action. These neurons, in fact, encoded the spatial target before the human agent was acting. Moreover, 12/29 (41%) of Both cells showed different spatial preferences in human and monkeys trials, indicating an independent coding of the two agents behaviors and not just or only a simulative mechanism. These neurons were broadly distributed among three MFC regions, including the Supplementary motor area (SMA), Pre-supplementary motor area (pre-SMA) and Area 9. These results suggest that MFC activity underlies the ability to operate self and other's distinctions that can lead to an independent prediction of what others will do. Our findings indicate that the MFC supports

social interactions at the service of the ability to predict other's intentions on which relays successful social life.

Title: Representation of movement by thalamic and prefrontal cortical neurons in rats during DNMTP

Authors: E. K. BRASLEY, R. L. A. MILLER, C. J. THERIAULT, M. J. FRANCOEUR, H. D. ROBERTSON, H. J. GUSTIN, J. C. MCKEE, A. G. DRAKE, B. M. GIBSON, *R. G. MAIR; Psychology, Univ. of New Hampshire, Durham, NH

Abstract: Higher-order thalamic nuclei, like the mediodorsal (MD) and rostral intralaminar (IL) nuclei, receive driver inputs from layer V cortical neurons that are hypothesized to represent information about motor commands (Sherman, Curr Opin Neurobio 2007, 17:417-22). Medial prefrontal cortex (mPFC) sends driver (layer V) and modulatory (layer VI) projections to MD, from which it receives its main driver thalamocortical input (Xiao, et al., Neurosci 2009, 161:1067-81). Single cell recordings from mPFC and MD have revealed distinct response types reflecting information necessary for successful task performance in rats running a delayed non-match to position (DNMTP) task. Movement responses are defined by PETH activity beyond the 99% confidence interval either leading into all lever presses (movement 1) or only when moving to reinforced levers (movement 2). Neurons active during movement responses were the most prevalent cell type in both mPFC (28%) and thalamus (MD= 70%, IL= 41%). Place map analyses confirm this pattern of activity showing that movement 1 cells fire along all 4 possible paths of travel where as movement 2 cells are restricted to only 2 paths of travel directed toward reinforcement locations. Event-specific place maps indicate that movement 2 cells conjunctively encode spatial location and direction toward the correct choice. Thus movement 2 responses seem to serve a decisional function, driving movement toward sample or choice levers, whereas movement 1 codes behavioral sequences more broadly. Individual neurons represent a small fraction of the movement patterns needed to accomplish the task, while population-level coding represents a more complete picture. To examine the influence of decision making rats were trained to perform a serial lever press (SLP) task that eliminates the choice while preserving the sequence of overt actions in DNTMP. Eliminating the choice in this manner substantially

reduces the number of movement responses seen in mPFC (by 90%). Thus, movement related activity seems critical for decision making. The greater number of movement responses in MD is consistent with the hypothesis that corticothalamic projections represent information about impending actions. The finding that thalamic and prefrontal cortical neurons encode specific information about movements seems inconsistent with a simple role in movement-related arousal.

Title: Rat prefrontal cortical neurons reflect manipulations of stimulus properties signaling reinforcement

Authors: *M. J. FRANCOEUR, E. BRASLEY, A. C. AASEN, C. L. HOLLER, A. L. MARINO, B. C. DOWNEY, B. M. GIBSON, R. G. MAIR;
Psychology, Univ. of New Hampshire, Durham, NH

Abstract: Medial prefrontal cortex (mPFC) integrates information about stimuli, actions, and reinforcement to guide decision making. Our previous single cell recordings from rat mPFC revealed neurons that fired in anticipation of reinforcement, during reinforcement delivery, and when expected reinforcement failed to materialize following errors during a delayed non-match to position (DNMTP) task. DNMTP requires rats to form expectations and predictions about which of two levers will be reinforced based on the preceding sample trial. Here we simplified cognitive demands by training rats to perform a serial lever press (SLP) task that eliminated the choice between two response alternatives while maintaining the overt action sequence of DNMTP. Previously, reinforcement consisted strictly of two 0.1 s pulses of water, signaled by a panel light that was illuminated during the reinforcement event. We manipulated stimulus properties of reinforcement events during SLP to discover how information about reinforcement is represented in mPFC. First, we compared light and water (always associated with the sound of the solenoid valve) to water and no light, light and no water, and no light and no water. To investigate Pavlovian coding we then compared light preceding water delivery to unsignaled water delivery and varied the amount of water delivered (0, 1, or 4 pulses) to examine coding of

reinforcement magnitude. We found a surprising variety of reinforcement-related responses revealed by these manipulations. Some cells responded primarily to the light, others to water delivery, and some to the contingency of light and water. Place field analyses provided evidence of multi-dimensional coding of information about reinforcement and the spatial text of reinforcement. Our results show that mPFC provides detailed encoding of stimulus events associated with reinforcement, including anticipatory responses that predict likely action outcomes.

Title: Single trial beta and gamma burst dynamics during cognitive control.

Authors: *C. R. WILSON[1,2], E. PROCYK[1,2];
[1]INSERM U1208, Stem Cell & Brain Res. Inst., Bron Cedex, France; [2]Univ. Lyon, Univ., Lyon 1, France

Abstract: Beta and gamma oscillations are proposed to have pivotal and differing roles in coordinating cognitive control in frontal cortex. For example, we have shown that prefrontal beta power is increased at the initiation of trials which require higher levels of control, whilst gamma power has been posited as an index of the encoding and recall of information in executive tasks. Importantly, when studied at the level of the single site and single trial, oscillatory power at both frequencies occurs in circumscribed bursts, rather than in the temporally elongated bands often

represented in trial averaged figures. Here we show that analysis of the properties of these individual bursts is critical to revealing the role of oscillatory phenomena within frontal cortex. Two monkeys learned the Problem Solving Task, a test of cognitive control in which they repeatedly moved between exploration and exploitation periods, using feedback to search for, find, and repeat rewarded responses. The monkeys were chronically implanted with at least 22 electrodes resting on the dura mater to provide electroencephalographic (ECoG) recordings of both prefrontal and sensorimotor cortex. We recorded multiple days of task performance with concurrent ECoG recordings from each monkey.
We used complex Morlet wavelet convolution to perform time-frequency analysis on the data trial by trial. We then extracted significant bursts of oscillatory power for each trial, a burst being an epoch where the power significantly surpassed the mean for that trial at that frequency, and did so for at least three cycles at that frequency. We then studied the effect of the cognitive control task on the length, frequency, timing, and power of the bursts at different epochs of the task. This approach permitted precise analysis of the roles of and relationship between bursts at beta and gamma frequencies.
We confirm that frontal oscillations are discrete burst phenomena, and that long duration bands of oscillatory power are mostly an effect of cross trial averaging. The power of bursts at beta frequencies reflects cognitive control for that trial, similarly to trial-by-trial mean beta power. But separate cognitive information is encoded in beta burst frequency and timing, so burst analysis is essential to a precise understanding of the true role of oscillatory phenomena. Finally, we demonstrate a contrast between the encoding properties of beta and gamma bursts. We consider the timing and phase relationships between beta and gamma bursts, both within and between recording sites.

Pharmacol., Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL; [5]Univ. de Buenos Aires, Capital Federal, Argentina

Abstract: It has been proposed that neural populations in the prefrontal cortex (PFC) maintain stimuli information by means of recurrence-driven sustained activity, achieving stimulus selectivity and distractor rejection through an interplay with the ventral tegmental area (VTA). However, the precise computation by which such functional interaction occurs remains elusive. To understand how VTA modulates information coding in the PFC, we made simultaneous single unit recordings in the PFC and the VTA of rats performing a GO/NOGO task. Mutual information between stimuli and neural activity in the PFC increases as soon as stimuli are presented, being higher when pairs of neurons are considered. Moreover, we found a VTA-dependent enhancement of information coding in the PFC, which is mainly governed by the activity of dopamine neurons. Together, these results indicate that the PFC-VTA interaction enables mechanisms by which information is encoded in the noisy activity of the population.

Title: C-FOS expression in the mPFC associated with reproductive state and maternal nest building behavior in female rabbits (Oryctolagus Cuniculus)

Authors: *H. CANO[1,2], K. HOFFMAN[1];
[1]CIRA, [2]Doctorado en Ciencias Biologicas, CTBC, Univ. Autonoma De Tlaxcala - CINVESTAV, Tlaxcala, Mexico

Abstract: Nest building behavior in the female rabbit can be considered a model for studying a natural goal-oriented behavior. In laboratory conditions, 3 days before parturition (gestation: 31

days), the rabbit collects straw and carries it into her nest box, where she constructs a maternal nest. This “straw carrying” behavior has 4 components: a) collecting straw with the mouth, b) entering the nest box, c) scratching the nest box floor and depositing the straw, d) exiting the nest box. These elements are a behavioral sequence that is persistently repeated 30 to 40 times in order to complete the nest. After completing the nest, the female does not re-initiate nest building behavior, even if the finished nest is removed from the nest box. Thus, the motivation to collect and carry straw is “quenched” by the process of completing the nest, making this model a useful one for defining brain mechanisms that are involved in the initiation and termination of a natural, motivated behavior. In the present study, we examined the number of c-FOS immunoreactive cells in the anterior cingulate, infralimbic, and prelimbic cortices of: (1) 28-day pregnant female rabbits that were given straw at the start of the observation period (t=0 min) and had displayed straw carrying behavior; (2) 28-day pregnant rabbits that were not given straw; (3) estrous females that given straw at t=0 min; (4) estrous females that were not given straw. All groups comprised 8 multiparous females and all females were housed in maternal cages that contained a nest box. Females given straw were allowed to interact with it until t=30 min. All females were sacrificed and processed for brain c-FOS immunoreactivity at t=60 min. We found that pregnant rabbits showed lower latencies to interact with the straw than the estrous females, and that pregnant rabbits invariably displayed straw carrying, while estrous females had little interaction with the straw, other than nibbling or eating it. Pregnant rabbits that were not given straw displayed behavior indicating a state of higher arousal, compared to estrous females that were not given straw. These observations were associated with differences in c-Fos IR labeling in the mPFC: pregnant females that carried straw had the highest c-FOS labeling density compared to the other treatment groups. We conclude that increased arousal and intense motivation of pregnant females to collect and carry straw is associated with increased c-FOS labeling in the anterior cingulate cortex, and to a lesser extent in the prelimbic and infralimbic cortices. c-FOS expression in the mPFC might reflect increased neuronal activity associated with motivational drive to initiate this goal oriented maternal behavior.

Title: Primate frontal eye field and multi-factorial decision making during perceptual judgment

Authors: *H. SEO, D. LEE;
Neurosci., Yale Univ. Sch. of Med., New Haven, CT

Abstract: Perceptual decision making in a two-alternative forced choice task is often modeled as a process of accumulating noisy and momentary sensory evidence over time towards a decision boundary. However, real-life perceptual decisions must incorporate not only sensory evidence, but multiple types of non-sensory information, such as expected payoffs and time constraint in order to achieve the optimal outcomes. Nevertheless, little is known about how the brain combines multiple sources of information during perceptual decision making. To address this question, we recorded single-neuron activity in the primate frontal eye field (FEF) while rhesus monkeys were performing a color-discrimination task, where payoffs for correct choice and temporal predictability of discriminative stimulus were systematically manipulated. At each trial, green and blue disks were first presented as saccade targets, on the left and right side of the central fixation target. Magnitude of reward available from each target in the correct trials was indicated with thin or thick square around the targets. Next, a square consisting of green and blue pixels that were dynamically rearranged at the rate of 20 Hz was presented. This stimulus was temporally divided into non-informative and discriminative stimulus. The non-informative stimulus consisted of green and blue pixels in equal numbers and lasted for 0, 0.4, or 0.8 s. This was followed by the discriminative stimulus in which the ratio between the numbers of blue and green pixels varied randomly across different trials. Animals were allowed to shift its gaze towards one of the targets any time after the onset of the discriminative stimulus, but rewarded only when they chose the target with the same color as the majority of the pixels. We found that animals tended to choose the high-reward target more frequently, in particular when the color of the discriminative stimulus was ambiguous and when the temporal uncertainty of the discriminative was low. This reward-related behavioral bias was reflected in the FEF activity. Namely, FEF activity increased when the large-reward target was in their receptive field and as the temporal uncertainty of the discriminative stimulus was reduced. FEF activity also increased with the strength of accumulated sensory evidence. These results suggest that the decision variables encoded in the FEF adaptively combine temporal and motivational factors as well as sensory signals.

Title: Galanin improves the performance of rats during the auditory discrimination tasks

Authors: ***L. DANYI**[1], Z. ZHANG[1,2], X. CHEN[1], J. HE[1];
[1]Dept. of Biomed. Sciences, City Univ., Hong Kong, Hong Kong; [2]Lab. of Applied Neuroscience, Dept. of Rehabil. Sciences, The Hong Kong Polytechnic University,, Hong Kong, Hong Kong

Abstract: In another study, we have found that the neurons in the auditory cortex of anesthetized rat increased their responses to the auditory stimulus each time after direct local infusion of galanin. In the present study we investigated whether galanin application can amplify the neuronal signals in the auditory cortex produced by electrical stimulation in the cortex. We adopted a behavioral apparatus having three holes. The rat approached the center hole before approaching the leftmost and the right most holes after a cue was delivered. The rat with bilateral implantations of electrode arrays in both hemispheres of the auditory cortex was trained to approach the left or right hole of a behavioral apparatus to retrieve a reward depending on whether the right or left auditory cortex was electrically stimulated. A drug infusion cannula was implanted in each hemisphere of the auditory cortex. After training, the rat was able to perform the task with the correct rate of 100%. We will then adjust the current of electrical stimulus to adjust performance to a correct rate of about 70% and examine whether infusion of galanin into one hemisphere would increase the correct rate of reward retrieval in the opposite hole. At a different session at which we set the baseline performance at 80% correct rate, infusion of galanin antagonist (M40) worsened the performance in the correct rate. Moreover, Artificial Cerebral Spinal Fluid (ACSF) was used as the vehicle control to make sure the increase or the decrease of the correct rate is correlated to galanin or M40. Our results of the present study would provide strong evidence that galanin is an attention related chemical from behavioral experiment. Keyword: ATTENTION, Galanin, AUDITORY CORTEX. Title: Prospective memory-like behavior predicts impulsivity in wistar and sprague dawley rats but not alcohol preferring 'p' rats: exploring the role of the prefrontal cortex in prospection during delay discounting

Authors: *D. N. LINSENBARDT, M. S. SMOKER, S. S. JANETSIAN, D. STEMPKY, C. C. LAPISH;
Addiction Neurosci. - Psychology, Indiana Univ. - Purdue Univ. Indianapolis, Indianapolis, IN

Abstract: Individuals that are family history positive for an alcohol use disorder (AUD) as well as rodent models with analogous familial background - those selectively bred for excessive drinking - tend to exhibit an impulsive behavioral phenotype. Memory deficits have also been reported in these populations. However, measures routinely used to assess impulsivity typically do not simultaneously assess the involvement of memory-related processes, and vice versa. Furthermore, the extent to which similar brain mechanisms mediate these cognitive processes is unknown. The primary goal of this work was to determine the involvement of prospective memory in impulsive behavior. Alcohol-preferring (P) rats and heterogeneous Wistar and Sprague Dawley rats were used in a delay discounting task to assess differences in the tendency to favor small immediate rewards at the expense of larger delayed rewards. A separate group of Wistar rats were then implanted with electrodes within the PFC to determine how neural activity

in this region was altered prior to and during delayed vs. immediate decisions. Wistar and Sprague Dawley rats were less impulsive than P rats and more likely to make a reward choice on the same lever used to initiate a trial (i.e. 'consistent' choices), suggesting that choice behavior was planned prior to the start of each trial in these two heterogeneous rat populations. Furthermore, choice trial consistency was significantly negatively correlated with delay discounting in Wistar and Sprague Dawley rats but not in P rats, providing additional evidence that prospective memory-like processes may be directly involved in delayed decision-making. Different patterns of neural activity were observed in response to trial initiations, trial choices, and reward delivery for consistent/inconsistent as well as delay vs immediate choices. These data provide additional support that a family history of excessive alcohol consumption may regulate impulsivity and vulnerability to alcohol intake, and suggest that this effect may be mediated in part by heritable differences in ability and/or use of prospective memory. These results also provide support for the PFCs involvement in integrating prospective information to guide reward-based behavioral decisions.

Title: Diverse inhibitory synaptic properties in primate anterior cingulate versus lateral prefrontal cortices

Authors: *M. MEDALLA, J. P. GILMAN, J. WANG, J. I. LUEBKE;
Anat. & Neurobio., Boston Univ. Sch. of Med., Boston, MA

Abstract: The organization of inhibitory circuits within functionally distinct prefrontal areas in primates is not well understood. Using electrophysiological and multi-scale anatomical

techniques in rhesus monkeys, we compared the functional and structural properties of inhibitory synapses in lateral prefrontal (LPFC) versus anterior cingulate (ACC) cortices- two prefrontal areas with distinct roles in executive function. The frequency of spontaneous inhibitory postsynaptic currents (sIPSC) was ~ 3.6x higher in ACC than in LFPC ($p < 0.01$) layer 3 (L3) pyramidal neurons. Consistent with this finding, the density of vesicular GABA transporter (VGAT+)-immunoreactive appositions onto somata (app/μm^2 surface area) and dendritic shafts of apical dendrites (app/µm length, $p < 0.05$) was greater in ACC than LPFC. Dendritic VGAT+ app/µm peaked at 50 µm proximal to the soma in both areas, but was greater in ACC than in LPFC neurons ($p < 0.05$). We next used triple immunofluorescence staining to study co-localization of perisomatic VGAT+ appositions with parvalbumin (PV+) or cholesystokinin (CCK+), which label two distinct populations of perisomatic inhibitory axon terminals. The density of VGAT+ app/μm^2 on somata of L3 pyramidal neurons was ~ 1.5x greater in ACC than LPFC. Moreover, the density and proportion of VGAT+ perisomatic appositions double-labeled with PV+ versus CCK+ differed between the two areas. The density of VGAT+PV+ app/μm^2 was similar, but the density of VGAT+CCK+ app/μm^2 was higher in ACC than LPFC ($p < 0.05$). Of the total perisomatic VGAT+ appositions on L3 neurons in ACC, ~ 48% were co-localized with PV+, ~ 35% with CCK+, and ~ 17% co-localized with neither marker. In LPFC, ~ 73% of VGAT+ perisomatic appositions co-localized with PV+, and the rest (~ 28%) were CCK+. Finally, serial electron microscopy and 3D stereology revealed that the density of inhibitory "symmetric" synapses/μm^3 volume of L3 neuropil was ~3.3x higher in ACC than LPFC ($p < 0.05$). Moreover, the densities of symmetric synapses/μm^2 surface area on somata and proximal apical dendrites were both greater in ACC than in LPFC ($p < 0.05$), consistent with the confocal data. In summary, our findings reveal that inhibition is functionally and structurally more robust and diverse in ACC than LPFC. Perisomatic inhibition in ACC is mediated by at least three neurochemically-distinct populations of inhibitory interneurons, while in LPFC it is largely provided by PV+ inhibitory neurons. Differential engagement of the diverse proximal inhibitory circuits of the two prefrontal areas suggests a mechanism for flexible control during the constantly changing processing demands of behavior.

Title: Heterogeneity of frontal and visual cortical areas in mice and monkeys.

Authors: *J. I. LUEBKE, J. GILMAN, A. HSU, M. MEDALLA;
Anat. & Neurobio., Boston Univ. Sch. of Med., Boston, MA

Abstract: A principal challenge of systems neuroscience is to understand the unique characteristics of cortical neurons and circuits that enable area- and species-specific sensory encoding, motor function, cognition, decision-making and behavior. To address this issue we compared properties of layer 3 pyramidal neurons and the neuropil in two cortical areas that span a broad range of cortical function -primary sensory (V1), to cognitive (frontal, FC)- in the mouse and the rhesus monkey. Hierarchical clustering and discriminant analyses of 15 physiological and 25 morphological variables revealed two fundamental principles. First, V1 and frontal neurons are remarkably similar with regard to nearly every property in the mouse, while the opposite is true in the monkey, with V1 and frontal neurons exhibiting significant differences in nearly every property assessed. Second, neurons within visual and frontal areas differ significantly between the mouse and the monkey. Neurons in mouse and monkey V1 are the same size, but differ in nearly every other way; mouse frontal cortical neurons are smaller than those in the monkey and also differ substantially with regard to most other properties. Ultrastructural analyses of L2-3 neuropil of FC and V1 in mouse revealed three fundamental principles. First, in contrast to the diverse synapses in monkey LPFC and V1, asymmetric axospinous synapses in L2-3 neuropil of mouse FC and V1 are remarkably homogenous with regard to presynaptic and postsynaptic entities. Second, asymmetric axospinous synapses in L2-3 neuropil of mouse V1 resemble that of monkey V1 in postsynaptic entities, but differ in presynaptic entity. Third, asymmetric axospinous synapses in L2-3 neuropil of mouse FC and monkey LPFC differ substantially in both presynaptic and postsynaptic entities. These findings have broad implications for understanding the differential contributions of heterogeneous neuronal types and excitatory synapses in construction of cortical microcircuitry in diverse brain areas and species.

Title: Modulation of value information coded in the lateral prefrontal cortex by the decoded neurofeedback with the electrocorticographic (ECoG) signals

Authors: *S. TANAKA[1], K. KAWASAKI[2], I. HASEGAWA[2], T. SUZUKI[3], M. SAKAGAMI[1]; [1]Tamagawa Univ. Brain Sci. Inst., Machida, Tokyo, Japan; [2]Dept. of Physiol., Niigata Univ. Sch. of Med., Niigata, Japan; [3]Ctr. for Information and Neural Networks, Natl. Inst. of Information and Communications Technol., Suita, Osaka, Japan

Abstract: Decision making is one of the important mental processes. For making a decision between multiple options, sometimes the values of the options are used. Many studies show that areas in the prefrontal cortex (PFC) play important roles in economic decision-making and representing value information. However, few studies have directly examined the causal role of these areas in economic decision making. Here, we tried to reveal the role of the lateral prefrontal cortex (LPFC) in economic decision making.

Two monkeys were trained to perform a free-choice task. In this task, two reward cues, which indicated the types of juices, were presented sequentially with a short blank interval. Then, the two cues were presented simultaneously and the monkeys chose one of them to obtain the juice reward. From the choice behavior between the two alternatives, the values of the rewards were estimated.

While a monkey performed this task, the electrocorticographic (ECoG) signals were recorded from ECoG electrodes implanted on the left LPFC.

We first constructed a decoder to decode the values of the juices from the ECoG signals during the first reward cue presentation. We used the wavelet power and phase in six frequency domains (δ, θ, α, β, *low-*γ, *high-*γ) as features and decoded the values of the rewards with Sparse Linear Regression (SLiR) algorithm. The decoded values were significantly highly correlated with the behaviorally estimated values.

Next, we applied the decoded neurofeedback (DecNef) technique on a monkey to modulate the values of the rewards. In the feedback experiment, a positive feedback was applied to one reward cue (Rcue-P) and a negative feedback was applied to the other cue (Rcue-N). The monkeys preferred a juice associated with Rcue-N to a juice associated with Rcue-P. In each feedback trial, one of the two Rcues was presented and the value was decoded from the ECoG signal during the cue presentation. In case of Rcue-P, a juice associated with the cue was delivered after

cue presentation when the decoded value was higher than the threshold but no reward was delivered when the decoded value was lower than the threshold. In case of Rcue-N, a juice associated with the cue was delivered when the decoded value was lower than the threshold. The decoded value for Rcue-P was raised and the decoded value for Rcue-N was decreased by the neurofeedback. Furthermore, the difference between the values of the two juices was reduced after the neurofeedback. However, if we stopped the feedback experiment, the reduced difference was rapidly restored. From these results, we suggest that the LPFC codes the value information related to the choice behavior but is not involved in the value calculation process.

Title: Reward-based training of recurrent neural networks for diverse cognitive and value-based tasks

Authors: *F. SONG, X.-J. WANG;
New York Univ., New York, NY

Abstract: A major challenge in uncovering neural mechanisms underlying complex animal behavior is our incomplete access to relevant circuits in the brain. Recently, the activity of model neural networks optimized to perform the same tasks as behaving animals have been shown to exhibit many features observed in populations of recorded neurons. The analysis of such models, for which we have full knowledge of the system, is therefore a promising tool for understanding biological circuits. However, network training in previous studies have focused on supervised learning on a graded “choice” signal, whereas animals learn by maximizing reward feedback on definite actions, thereby limiting the range of tasks that can be investigated in this approach. Supervised learning is particularly unnatural for value-based decision-making tasks for which there is no “correct” answer (since values are subjectively assigned to choice options), as well as tasks where the optimal behavior is determined not only by the experimentalist but also by the

animal's own actions or internal state of mind during the course of a trial. In this work, we propose a general framework for reward-based training of recurrent neural networks (RNNs) using policy gradient reinforcement learning. The networks consist of two interacting modules: the policy module receives task-relevant inputs and outputs the actions of the network, while the value module uses the activity of the policy network and the chosen action to predict the expected reward at each point in time. Networks can be trained to perform tasks that are as faithful as desired to the temporal structure of the behavior they model, so that diverse experimental paradigms can be straightforwardly translated for network training. We demonstrate the wide applicability of this framework on several value-based decision-making tasks as well as on a postdecision wager task. This work greatly expands the usefulness of trained RNNs as a tool for simultaneously capturing both the behavioral and neural aspects of cognitive and value-based studies in systems neuroscience.

Autónoma de México, México, Mexico; [4]Univ. of Oregon, Eugene, OR; [5]Inst. de Neurobiologie de la Méditerranée, Marseille, France

Abstract: Prior experiences shape the way we perceive the world by creating expectations, a reference frame for generating future decisions and judgements. Little is known however about how the brain builds expectations from experience and how expectations influence our perception and behavior.
We aim to understand how neural circuits integrate the recent history of stimuli and rewards to generate priors and how priors are combined with sensory information across the processing hierarchy to bias decisions. In order to achieve our goal we trained rats in a reaction-time two-alternative forced-choice (2AFC) task with stimuli consisting in a superposition of low and high frequency amplitude-modulated tones (6.5kHz and 31kHz). The relative weight of each tone was parameterized by the coherence c. Rats had to discriminate the dominant tone and seek reward in the associated port. We presented partially predictable stimulus sequences that, once learned, could be used to generate adaptive priors that maximize the performance. These sequences were created using a two-state Markov chain whose stimulus transition probability was fixed in each 200 trials lasting block: In Repeating blocks the probability to repeat the previous stimulus category was 0.7 and in Alternating blocks the probability was 0.2.
To disclose the neural circuits involved in these computations, we simultaneously conducted neural population recordings in the dorso medial striatum (DMS) and we have started to characterize how striatal circuits encode and combine priors with stimulus information to bias perceptual choices.
We found that this design leveraged on the natural tendency of these animals to exhibit history dependent biases, they learned to recognize the changes in the sequence statistics of each block and adapted their behavior to them by developing a repeating choice bias after several correct repetitions and a weaker but reliable alternating bias after correct alternations. The magnitude of the bias built up after each correct response and it seemed to saturate after four consecutive correct responses, but reset to zero after error trials. In the transitions between the Repeating and Alternating blocks, rats took around five trials to modify their belief in the sequence rule. Moreover, animals reaction time was longer for unexpected compared to expected stimuli, but comparable to trials without a define expectation. Finally stimulus impact on choice was smaller when the choice matched the expectation, than when it went against it. Our findings show that priors show build-up-and-reset dynamics across trials allowing animals to capitalize on the predictability of the stimulus sequence.

Title: Role of mouse premotor cortex in action generalization and goal-directed behavior

Authors: *D. C. SCHREINER, C. M. GREMEL;
Psychology, Univ. of California San Diego, La Jolla, CA

Abstract: When encountering a novel situation we must decide whether or not to generalize previously learned rules. Generalizing can be beneficial as it does not require novel learning and thus allows enhanced exploitation; however, if the novel situation is not sufficiently similar, persisting in using an old rule can be problematic. In contrast an exploratory strategy is more flexible, but requires novel learning.
The circuits mediating generalization include the dorsal striatum, with the dorsolateral striatum (DLS) being necessary for action generalization, while the dorsal medial striatum (DMS) was necessary for exploitation. Interestingly these results directly map onto dorsal striatal circuits mediating goal-directed (DMS) and habitual (DLS) action strategies, suggesting that similar neural circuits may control both action generalization and habits.
To test this hypothesis, we chemogenetically attenuated the activity of the premotor cortex (M2) in mice, a cortical region necessary for goal-directed behavior, and predicted that this would reduce goal-directed behavior and increase action generalization.
Mice were given bilateral injections at M2 with a virus expressing cre recombinase (cre) under the CamKIIα promoter (AAV5/CamKIIα-GFP-Cre) and either a virus expressing cre-inducible mCherry (AAV5/hSvn-DIO-mCherry) (controls) or a virus expressing a cre-inducible inhibitory DREADD (AAV5/hSvn-DIO-hm4D-mCherry). Upon recovery mice were trained to press a lever for a pellet reward on a continuous ratio schedule. Mice were then placed on a random interval (RI) schedule that has been shown to bias habitual behavior and action generalization and underwent subsequent testing. Each day prior to schedule training and testing sessions, mice were pretreated with the hM4D-selective agonist Clozapine-N-Oxide.
Although a RI schedule biases habits, we tested for goal-directed control over behavior via an early devaluation test using sensory-specific satiety. Control mice were still goal-directed, while M2 attenuation biased use of habitual action strategies. We next assessed action generalization by presenting a novel lever in addition to the trained lever in the operant chamber. Surprisingly, while control mice pressed the trained and novel levers at a similar rate, mice with attenuation of M2 activity selectively exploited the trained lever.

Thus, M2 attenuation decreased both goal-directed actions and action generalization, revealing a dissociation in neural circuits mediating these behaviors. Further work aims to differentiate the differing cortical and striatal circuits mediating action strategy and action generalization.

Title: Dissociation of deterministic and stochastic components in the timing of voluntary actions in rodent frontal cortex

Authors: *M. MURAKAMI[1], H. SHTEINGART[2], Y. LOEWENSTEIN[2], Z. F. MAINEN[1]; [1]Champalimaud Neurosci. Programme, Champalimaud Ctr. for the Unkown, Lisbon, Portugal; [2]Dept. of Neurobio., The Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: Decisions on selection and timing of actions are subject to deterministic influences, such as sensory inputs and past reward experiences, which contribute to decision bias. In addition, they are influenced by effectively stochastic factors. Although stochastic choice mechanisms can be an important component of exploration and competition, their origin and mechanisms remain poorly understood. Here we used a combination of behavior, pharmacology and electrophysiology to study how neural circuits in the frontal cortex collaborate to determine action timing in rats performing a waiting task. In the waiting task, rats continuously chose whether to wait for a randomly-delayed tone to obtain a large reward or to give up and obtain a smaller reward. We found that the timing of waiting abort varied substantially across trials and well-approximated by a two-stage stochastic model: (1) individual action timings are drawn

stochastically from a distribution and (2) the mean of the distribution, or decision bias, fluctuates over a longer timescale depending on the history of rewards. Inactivation of either medial prefrontal cortex (mPFC) or secondary motor cortex (M2) strongly affected action timing and electrophysiological single-unit recordings revealed a functional dissociation. Both mPFC and M2 neurons reflected experience-dependent deterministic biases in action timing, but only M2 neurons reflected stochastic trial-to-trial fluctuations. This differential coding was mirrored in the relative timescales of intrinsic neural dynamics and timescales of waiting time correlation both within and across trials. The results support a two-stage model in which, together with other areas, mPFC maintains experience-dependent deterministic choice bias signals while M2 contributes to stochastic components of choice.

Title: Adolescent cannabinoid exposure impairs risky decision-making and alters mPFC firing patterns in adult rats.

Authors: *E. JACOBS-BRICHFORD[1], L. R. HORN-AMODEO[2], M. S. MCMURRAY[3], J. D. ROITMAN[1];

Abstract: Adolescence is characterized by increases in risk-taking across a range of behaviors, including experimentation with alcohol and illicit drugs. Cannabis is the most widely used illicit drug among adolescents, and increased use coincides with a period of marked brain development, particularly in the prefrontal cortex (PFC). PFC is important for decision-making processes, and exposure to cannabis during PFC development may lead to impairments in these processes, resulting in increased impulsivity and excessive risk-taking. The medial portion of prefrontal cortex (mPFC) continues to develop throughout adolescence and is thought to be crucial in shifting behavior as rewards become uncertain or less valuable. In this study, we investigated the long-term effects of chronic adolescent cannabinoid exposure on decisions

between certain and uncertain reward, in which reward magnitude, probability and expected value were parametrically varied. Thirty-two male and female Long Evans rats received i.p. injections of WIN 55, 212-2, a CB1 receptor agonist, from postnatal day 30-60. Once animals reached adulthood, their reward preferences were measured using a gambling task. Rats chose between two levers, one of which paid a small-certain reward, and the other paid a large-risky reward. The probability of receiving the large reward varied randomly on each session, ranging from 16.7% to 66.7%. As rats performed this task, we used *in vivo* electrophysiology to record mPFC activity. We hypothesized that chronic treatment with WIN would result in mPFC disinhibition in adulthood. Consistent with this, we found that WIN-treated rats had elevated preference for the risky choice option, and elevated responses to task events. This suggests that adolescent cannabis use may alter the normal development of inhibitory signaling in the PFC, altering decision-making processes.

Title: Single-unit and population activity in rat medial prefrontal cortex during headfixed decision making

Authors: *R. DE HAAN, S. A. VAN DER BURG, A. W. PIENEMAN, V. NIGADE, H. D. MANSVELDER, C. P. J. DE KOCK;
Integrative Neurophysiol., VU Univ., Amsterdam, Netherlands

Abstract: Attention, working memory and executive functions are strongly associated with neuronal activity in rat medial prefrontal cortex (mPFC). Similar to other cortical areas, the mPFC has a laminar architecture containing morphologically and functionally different cell types and layers. However, the contribution of individual layers and cell-types in mPFC to cognitive behavior is only beginning to be understood. To reveal which neurons of the mPFC circuitry orchestrate the diverse repertoire of prefrontal functions, we recorded single-units and population activity at specific cortical depths across layers of the rat mPFC during a whisker-based Go/No-Go task.

Head-fixed rats were trained to determine the location of a pole on the radius of the whisker, where the proximal location should be reported by licking to receive a water reward. When the pole was positioned in the distal location, the rat should not lick to avoid a 5 second time-out. We used 64-channel silicon probe recordings to record from populations of mPFC neurons, from which single units were isolated. We find changes in activity for individual units that correlate to behavioral phases distributed throughout the cognitive task. The strongest neurophysiological correlate involved reward consumption after the rat made a correct decision. Further, we find strong sub-threshold activity in the local field potential when the rat is cued with a sound for trial start, but not for trial end. This difference in physiological response to the same sound could reflect gating of only relevant stimuli into the mPFC and might in this case correspond to a 'reset' of the working memory to prepare for upcoming task execution.

Title: Prelimbic/Infralimbic contribution to contextual memory recall during varying frequency of retrieval demand

Authors: *P. MARTIN;
Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Context roots overlapping memories within a framework and allows for behavioral flexibility during similar situations. The prelimbic cortex in the rodent is thought to be implicated in the contextual memory process. However, how this brain region supports the retrieval of contextual memory is poorly understood. To address this question, we created a task where the rate at which a contextual memory needed to be retrieved was varied. In this task, contexts consisted of temporally continuous, non-spatial, visual and auditory compound cues that signaled a spatial reward location in a modified automated + maze. The demand on the retrieval process was tested by presenting them in alternating blocks of 20 trials, 5 trials, or pseudorandomly, with no more than 3 of the same context presented in a row. Rats learned to discriminate between the contexts, and recall the relevant spatial rule. They were then implanted

with bilateral cannulae targeting the prelimbic/infralimbic region. This region was then temporarily inactivated via a GABAA agonist, muscimol, during the three task conditions. Our results show a strong dependence on the PL/IL during random presentations, but only if it was the first time that they had solved the task without it. During the longer block conditions, the context was retrieved appropriately. These data show that the rate at which retrieving a contextual memory necessitates the PL/IL at different degrees, as well as showing the ability to circumvent this circuit thru learning.

Title: Dysfunctional Learning: A comparison of activity in the motor cortex and dentate nucleus reflecting correct and incorrect motor responses to an acoustic discriminative stimulus (DS).

Authors: *C. D. WOODY;
Ronald Reagan UCLA Med. Ctr., Los Angeles, CA

Abstract: Recordings of single unit activity were obtained from 74 cells of the pericruciate cortex and 203 cells of the dentate nucleus of awake cats that had been trained to perform blink CRs to a 70 dB click CS and not to a 70 dB hiss DS. Concurrent bipolar recordings of EMG activity from the orbicularis oculi muscles during each trial of DS presentation allowed objective assessment of suppressed motor performance while remaining blind to the associated spike activity. The trials were separated into those with correctly suppressed EMG responses to the DS (failed to exceed prestimulus maximum or reach 2Z above baseline activity), inconclusively suppressed (exceeded 2 but did not reach 3Z above baseline), and incorrect ($\geq$3Z above baseline activity) responses. Averages were then made of the PSTHs of spike activity associated with each classification and of the concurrent EMG activity. (Responses to the CS were examined earlier: Woody, C. D., Abstr. Soc. Neurosci. 35, 2009; 558.24, 2014. Those responses were correct if $\geq$ 3Z of baseline and inconclusive or incorrect if not.)
Comparison of the overall averages of EMG activity showed a suppression of response (< 2Z

above baseline) to DS in the 'correct' group from each region, a mean peak response 2.3/8.8 (concurrent with dentate/motorctx spike recordings) Z above baseline in the "inconclusive" group, and in the "incorrect" group a mean peak response 34/24 Z above baseline. The averaged PSTHs of corresponding DS-evoked spike activity showed no significant differences in baseline activity in neurons of any group from either region, and a significant increase ($\geq$3Z) in mean peak response to DS in the "incorrect" group from dentate. There was also a substantial increase in S:N of mean peak dentate spike response to DS (16Z above baseline) in the "incorrect" group. In motor cortex the magnitude of change in spike activity in response to DS was less well correlated with EMG performance errors than that to the CS in earlier studies. In dentate changes in S:N were the major correlate of spike response with performance error. In dentate S:N appears to be the principle means available for error-control in response to either CS or DS. In motor cortex several means, including baseline activity and mean peak response as well as S:N, were available for correcting CS-elicited errors, but none were found for correcting DS-elicited errors. Data from: Woody, C.D. Summary of recordings of spike trains: a database of recordings of spike activity from about 5000 neurons. http:// repositories.cdlib.org/mrrc/1 2005.

Title: The effects of estrogenic components of licorice root on cognition

Authors: *P. KUNDU[1], D. L. KOROL[3], S. BANDARA[4], S. MONAIKUL[2], W. G. HELFERICH[2], S. L. SCHANTZ[2];
[1]Univ. of Illinois at Urbana-Champaign, Urbana, IL; [2]Univ. of Illinois at Urbana-Champaign, Champaign, IL; [3]Biol., Syracuse Univ., Syracuse, NY; [4]Univ. of California, Davis, Davis, CA

Abstract: It is well established that estrogens modulate cognition in a task-dependent manner. Many dietary supplements contain estrogenic compounds, the efficacy and safety of which are poorly understood. This study investigated the efficacy of components of licorice root to alter

performance on a hippocampus-sensitive metric change in object location (MCOL) task. We investigated isoliquiritigenin (ISL), *Glycyrrhiza glabra* root power (LRP), and an ethanol extract of *Glycyrrhiza glabra* root (LRE). LRP is licorice root powder and ISL is a pure compound with estrogenic activity that is found in licorice root. We also explored whether a high fat diet (HFD) would impair performance on this task and whether the botanicals could mitigate any negative effects. Young adult (3-month old) Long-Evans female rats were ovariectomized (OVX) and exposed to either a HFD (44.8% kcal from fat) or a LFD (17.2% kcal from fat) for five weeks prior to testing. A subset of rats on each diet were exposed to ISL, LRP or LRE at a concentration of 0.075%, 5% or .5% respectively of the diet for three weeks prior to testing. Estradiol improves performance on the MCOL task and thus was included as a positive control. Rats in the estradiol group were injected subcutaneously 48 and 24 hours prior to testing with 45 µg/kg of estradiol. In the MCOL task, rats were allowed to explore two objects in a black Plexiglas® chamber while object exploration time was recorded for three 5-min trials with a 3-min inter-trial interval in the rat's home cage. For the fourth 5-min trial, the objects were moved closer together and exploration time was again recorded. An increase in object exploration time in the final trial suggests that the rat detected the change in object locations. As expected, estradiol increased object exploration time on the final trial. ISL and LRE exposure also led to a significant increase in exploration time in the final trial relative to the third trial, indicating better performance on the task. Diet had no effect on its own and did not interact with botanical exposure. In this study we found that both ISL and LRE significantly improved performance on the hippocampus-dependent MCOL task in OVX rats. These compounds could be potentially useful therapeutics to ameliorate some aspects of cognitive decline post-menopause.

Title: Elevated prenatal testosterone may selectively impair female mice in object recognition memory

Authors: *C. S. WASSON[1], C. HOWES[1], A. TIESSEN[2], E. MARTIN[1], A. J. GIUGA[1], H. KATZMAN[1], N. J. MACLUSKY[2], E. CHOLERIS[1];

Abstract: Sexual differentiation is facilitated by gonadal sex hormones such as testosterone (T) and estradiol (E2). These sex hormones act during development to organize morphology and give rise to sex-specific behaviours. Developmental T and E2 have been implicated in learning and memory by facilitating spatial memory-related synaptic plasticity and spinogenesis. While most studies have focused on spatial memory, less research has evaluated declarative/recognition memory, which is less hippocampus dependent. In this study we sought to elucidate how exposure to heightened levels of prenatal T in-utero can affect object recognition memory. We treated pregnant mice with 10µg of testosterone propionate or sesame oil control on embryonic days 12, 14 and 16, which is the critical period for sexual differentiation. Prior to the onset of puberty, mice performed the object recognition (OR) paradigm. Subjects were exposed to two objects in their home cage for 3 four-minute habituation sessions followed by a 4-minute test session, where a novel and previously encountered object were introduced. A preference ratio for the novel object was calculated for the test and the averaged habituation sessions. After prepuberty testing, the mice were gonadectomised (or sham control) and received hormone replacement (12.5µg E2 or crystalline T). Ten-days post hormone replacement the mice were re-tested in the OR at 9-weeks of age. This was done to assess the effect of puberty on object recognition behaviour. Prior to puberty, females who were experimentally exposed to T in-utero showed impairment in object recognition. Further, we found no significant difference between groups in total investigation of the objects, which indicates that our findings are not secondary to effects on investigatory behaviour per se. Thus, prenatal exposure to T seems to impair object recognition selectively in female mice. We are currently in the process of evaluating the activational effects of puberty on object recognition. Title: Circulating progesterone contributes to state-dependent contextual fear in cycling female rats

Authors: *G. M. ACCA[1], B. TSAO[2], A. S. MATHEW[2], A. PHAN[2], S. MAREN[1,2], N. NAGAYA[1,2];
[1]Inst. for Neurosci., [2]Psychology, Texas A&M Univ., College Station, TX

Abstract: Sex differences in susceptibility to stress-related and trauma-related disorders suggest that ovarian steroid hormones may play an important modulatory role in fear and anxiety. We have recently shown that allopregnanolone (ALLO), a progesterone (PROG) metabolite and $GABA_A$ receptor potentiator, within the bed nucleus of the stria terminalis (BNST) can modulate conditioned contextual fear in female and male rats. In addition, we have found (in male rats) evidence that the regulation of contextual fear by intra-BNST ALLO is state-dependent. Given that ALLO levels mirror fluctuations in PROG levels across the estrous cycle, we sought to determine whether hormonal state would modulate conditioned fear in a state-dependent manner in females. To this end, we used the naturalistic model of gonadally intact, cycling female rats in high (late proestrus, HI) or low (late diestrus, LO) PROG states. Animals were conditioned with 5 tone (2 kHz, 10 s, 80 dB) - footshock (2 s, 1 mA) pairings and tested 3 to 6 days later for contextual fear in the conditioning chamber (10 min). Conditioning and testing were timed such that rats were in one of four combinations of estrous cycle stages: HI-HI, HI-LO, LO-LO, and LO-HI. Following testing, plasma was collected and assayed for PROG. Results suggest that natural fluctuations in ALLO levels (as inferred from estrous cycle stage and terminal PROG levels) may confer state-dependence such that rats conditioned and tested in the same hormonal state have elevated levels of contextual fear compared to those trained and tested in different states. These findings suggest that, in females, hormonal state may act as an interoceptive contextual cue to modulate conditioned fear via state-dependent mechanisms.

Title: Contrasting effects of individual versus combined estrogen and progestogen regimens on cognitive function: one plus one does not equal two

Authors: *A. V. PRAKAPENKA[1,4,5], A. M. QUIHUIS[2,4], R. HIROI[2,4], C. G. CARSON[2,4], S. PATEL[2,4], C. CROFT[2,4], C. BERNS-LEONE[2,4], C. FOX[2,4], R. W. SIRIANNI[3,5], H. A. BIMONTE-NELSON[2,4];

Abstract: There are various hormone therapy (HT) options available for women to diminish undesired physiological symptoms associated with menopause (e.g. hot flashes, vaginal atrophy). A commonly used estrogen in HT is 17β-estradiol (E2), the most potent and naturally circulating estrogen in mammals. Studies show that E2 can benefit cognition, and that activation of extracellular signal-regulated kinase 2 (Erk2) is required for E2 to produce this effect. Estrogen-based HT for women with an intact uterus must also include a progestogen component to oppose the associated increase in risk for uterine cancer. Studies evaluating E2 plus natural progesterone treatment in ovariectomized (Ovx) rodents suggest that the addition of progesterone attenuates the beneficial cognitive effects of E2 and the increase in E2-induced Erk2 activation. Levonorgestrel (Levo) is a synthetic progestogen used in HT and contraceptives. We have previously shown that Levo treatment in middle-aged, Ovx rats enhanced cognitive performance. However, the effect of an E2 plus Levo hormone combination treatment on cognitive function has not yet been reported. This is translationally important given that E2 and Levo are administered in combination clinically, such as with the transdermal patch for HT (ClimaraPro). Thus, the aim of our study was to examine the effect of an E2 plus Levo treatment on cognitive function. Middle-aged, Ovx rats were administered vehicle, E2 only, Levo only, or E2 plus Levo hormone treatment. Rats were then tested on a behavioral battery to assess spatial working and reference memory (water radial arm maze) and spatial reference memory (Morris water maze). Following behavior, brain regions involved in learning and memory were processed for western blot analysis of activated Erk2 expression. Results showed that both individual hormone treatments, E2 only and Levo only, enhanced learning on a working memory measure relative to vehicle control. Additionally, contrasting effects of hormone treatment were seen as the working memory demand increased, whereby at the moderate memory load, all hormone treatments enhanced performance, but at the highest working memory load, E2 plus Levo hormone combination treatment impaired performance relative to E2 only and Levo only. Preliminary analyses of activated Erk expression suggest that Erk2 activation in the frontal cortex is correlated with working memory performance, and that this relationship is impacted by whether E2 is given alone or in combination with Levo. Taken together, results from this study suggest that E2 and Levo are acting through different mechanisms, resulting in contrasting effects on cognitive performance.

Title: Menopause and the aging brain: Relationships among ovarian hormone levels, memory, and choline acetyltransferase-containing neurons in the basal forebrain

Authors: *S. V. KOEBELE[1,2], S. E. MENNENGA[1,2], S. PATEL[1,2], R. HIROI[1,2], L. T. HEWITT[1,2], A. M. QUIHUIS[1,2], L. P. MAYER[3], C. A. DYER[3], L. M. DEMERS[4], H. A. BIMONTE-NELSON[1,2];

Abstract: Memory changes during the menopause transition can negatively impact quality of life in women. These alterations in memory function may be related to the characteristic erratic fluctuations followed by the decline in ovarian hormone levels, including estrogens, observed during the perimenopausal period (Sherwin, 2012). Using the 4-vinylcyclohexene diepoxide (VCD) rat transitional menopause model, we investigated menopause- and age- related changes in choline acetyltransferase (ChAT) in the basal forebrain (BF), a primary synthesis site for acetylcholine. The BF is important for cognitive function, as these cholinergic neurons send long-range projections to the hippocampus, a key structure in spatial cognition. It is well established that 17β-estradiol (E2) treatment increases BF ChAT levels (Luine, 1985; Gibbs, 1997, 2000) and BF lesions impair spatial memory and prevent E2-induced memory enhancements (Hagan et al., 1988; Gibbs, 1998, 2002). Thus, fluctuating ovarian hormone levels during the transition to menopause may impact acetylcholine synthesis and the BF-hippocampal cholinergic pathway. Young (6 mo) and Middle-Aged (12 mo) Fischer-344 rats were trained on a

water radial-arm maze (WRAM). Following training, rats were administered Vehicle or VCD treatment, which accelerates depletion of ovarian follicle reserve. Rats were then repeatedly tested on the WRAM for four months, across the menopausal transition to a follicle-deplete state. A subset of rats was sacrificed early in the menopausal transition to evaluate physiological changes that occur early in perimenopause. The remaining rats were sacrificed after six months, when VCD-treated rats were post-follicular depletion. The BF was stained for ChAT-immunoreactive (IR) cells, and unbiased stereology was used to estimate ChAT-IR populations in the medial septum and vertical/diagonal bands. Preliminary results suggest that the ovarian hormone fluctuations associated with follicle depletion are related to ChAT-IR BF estimates, particularly during the early menopause transition time point. Further, the relationship between ovarian hormones and ChAT-IR BF estimates changes with both aging and follicular depletion. Dynamic relationships between hormone levels and ChAT-IR estimates with memory performance will be discussed. Understanding the neurobiological changes that occur early in the menopause transition period may help elucidate a critical window for hormone intervention in at-risk women so they can maintain a high quality of life, and the possibility to postpone or prevent the development of cognitive impairment or dementia later in life.

Title: Long-term tonic estradiol improves, and cyclic estradiol impairs, spatial working memory in ovariectomized middle-aged female rats

Authors: *K. NISHIMURA[1], S. V. KOEBELE[1,2], S. KEMMOU[1], J. B. ORTIZ[1], J. M. JUDD[1], H. BIMONTE-NELSON[1,2], C. D. CONRAD[1];
[1]Psychology, Arizona State Univ., Tempe, AZ; [2]Arizona Alzheimer's Consortium, Phoenix, AZ

Abstract: There has been much research investigating the influence of estrogens on cognition in female rats. Reports demonstrate that many factors can impact outcomes, including, but not limited to, age of the subject, estrogen duration, mode of estrogen administration, estrogen type, stress history, and presence of progestins. Age of the subject is particularly important translationally given that women are living longer with nearly a third of their life in a post-menopausal state. Consequently, understanding the factors by which estrogens could contribute to healthy cognitive aging is of great importance. Previous research from our lab has demonstrated that three months of estrogen treatment via tonic pellet implant or cyclic injections can enhance learning and memory in 12-15 month old female rats (Bimonte-Nelson et al., 2006). It is unknown whether a longer-term, further extended exposure to estrogens would benefit cognitive abilities and whether the mode of estrogen administration would influence these outcomes. Here, we examined the effects of seven months of 17β-estradiol (E2) exposure using a regimen of tonic exposure (silastic capsules), cyclic exposure (bimonthly s.c. injection of 10 µg E2), or tonic + cyclic exposure (silastic capsules + bimonthly s.c. injection of 10 µg E2) on a battery of learning and memory tasks in middle-aged, Ovx female Fischer-344-CDF rats. The treatment regimen continued for the duration of the seven-month study. At the end of month six when rats were 14-15 months old, all groups were tested on a battery of cognitive tests that included the water radial-arm maze (WRAM), Morris Water Maze (MWM), visible platform, open field, object placement, and object recognition. WRAM was used to assess spatial working and reference memory and is considered to be a taxing memory task requiring greater cognitive flexibility as trials increase. Working memory errors decreased with tonic E2 treatment, and were increased by cyclic E2 treatment. For the open field, tonic E2 increased time spent in the center arena, whereas for object exploration, cyclic E2 enhanced overall object investigation. While further data analyses are underway, results thus far point to differences in cognitive outcomes depending upon whether E2 administration was tonic or cyclic over the seven month exposure. Pinpointing the parameters of estrogen administration that optimally enhance cognition, especially regarding long-term treatment, will provide a critical step toward understanding necessary requirements for optimizing cognitive and brain health in women across the lifespan.

Title: 17β-estradiol versus conjugated equine estrogens: Differential interaction of androstenedione with two commonly used hormone therapy estrogens for spatial memory in mice

Authors: *R. HIROI[1,2], S. GRANGER[1,2], M. POISSON[1,2], C. BERNS-LEONE[1,2], D. KIRBY[1,2], S. PATEL[1,2], B. HADDER[1,2], V. CIARAMITARO[1,2], H. A. BIMONTE-NELSON[1,2]; [1]Psychology, Arizona State Univ., Tempe, AZ; [2]Arizona Alzheimer's Consortium, Phoenix, AZ

Abstract: Menopause results in ovarian follicular depletion and consequently, a dramatic reduction of circulating ovarian hormones, including 17β-estradiol (E2). The loss of E2 and other ovarian hormones leads to a shift in hormone milieu with androstenedione (Andro) becoming the primary circulating hormone. Evidence suggests that this change in hormone milieu during the menopause transition is associated with cognitive impairment. In attempt to restore hormone balance, estrogen containing hormone therapies (HT) such as E2 and Conjugated Equine Estrogens (CEE), are prescribed to perimenopausal and menopausal women. Our laboratory has previously shown a negative impact of CEE on cognitive function in a rodent model of menopause with chemically-induced ovarian follicular depletion with ovaries retained, and negative cognitive performance correlated with high endogenous serum Andro levels. In a subsequent study, we found that exogenous Andro treatment in ovariectomized (Ovx) animals was detrimental to cognition. In order to methodically test whether Andro impacts the effects of HT estrogens, the current study was performed. We utilized Ovx C57BL/6J mice to evaluate the effects of these individual and combination hormone regimens on a cognitive maze battery. The most striking findings were that while the combination of CEE and Andro impaired performance on multiple measures, the combination of E2 and Andro did not; in some cases, this E2 plus Andro hormone regimen was the only one to enhance cognition. These results suggest that Andro interacts with E2 in a manner distinct from CEE to regulate cognition. There could be significant clinical implications if these findings translate to women, as the results from this

study indicate that E2-containing HT may pose an advantage over CEE-containing HT for improving cognition in ovary-intact menopausal women with moderate levels of circulating Andro.

Title: The interaction of dietary isoflavones and estradiol replacement on depressive-like behaviors, brain-derived neurotrophic factor and cytokine response in the ovariectomized rat

Authors: *A. L. RUSSELL[1], J. MORAN GRIMES[1], D. O. LARCO[1], D. F. CRUTHIRDS[1], J. WESTERFIELD[1], L. WOOTEN[1], M. KEIL[1], M. J. WEISER[2], M. R. LANDAUER[3], R. J. HANDA[2], T. J. WU[1];
[1]Ob/Gyn, Uniformed Services Univ., Bethesda, MD; [2]Biomed. Sci., Colorado State Univ., Fort Collins, CO; [3]Armed Forces Radiobiology Reserach Inst., Bethesda, MD

Abstract: Removal of endogenous estrogens via ovariectomy (OVX) in the rat alters metabolic regulation, and increases anxiety- and depressive-like behaviors. Readministration of estradiol (E2) reverses this phenotype. Naturally occurring non-steroidal isoflavones, which are present in standard rodent chows, can interact with estrogen receptors and can have both estrogenic and anti-estrogenic effects. These dietary isoflavones can exert sex-dependent effects on anxiety, memory, learning and depression. However, the interaction of dietary isoflavones and endogenous steroids, such as E2, is unknown. The goal of this study was to examine this interaction on depressive-like behaviors using the forced swim test (FST). OVX female rats fed an isoflavone rich diet and treated with E2 had an increased struggle time (decreased depressive-like behaviors) compared to animals given VEH ($P < 0.05$). There was no effect of E2 administration in the isoflavone-free chow animals. To potentially explain these behavioral effects, we measured serum and white adipose tissue cytokines levels in addition to brain-derived

neurotrophic factor (BDNF) from limbic brain regions in response to diet and E2 replacement. The presence of isoflavones in diet decreased serum levels of macrophage colony stimulating factor (M-CSF) but increased serum levels of chemokine (C-X-C motif) ligand 1 (GRO/KC) ($P < 0.05$). White adipose tissue levels of M-CSF and GRO/KC, in addition to erythropoietin were decreased in rats fed an isoflavone-rich diet ($P < 0.05$). E2 treatment decreased WAT GRO/KC, serum monocyte chemoattractant protein 1 and increased vascular endothelial growth factor. Other measured cytokines (19 analytes, including interleukins) revealed no significant difference. Using an ELISA to measure BDNF levels, E2 replacement in rats fed an isoflavone-rich diet increased total BDNF in the amygdala and the hippocampus ($P < 0.05$). E2 treatment decreased BDNF expression in animals on the isoflavone-free diet ($P < 0.05$). Overall, we demonstrate that dietary isoflavones can interact with E2 treatment to alter affective processing and depression-relevant mechanisms. We propose that when examining the effects of E2 replacement dietary content should be carefully considered.

Title: Human chorionic gonadotropin increases ERK phosphorylation, neurite outgrowth and rescues ovariectomy associated deficits in spatial memory

Authors: *J. A. BLAIR[1], H. MCGEE[2], S. BHATTA[1], G. CASADESUS[1,2];
[1]Sch. of Biomed. Sci., [2]Dept. of Biol., Kent State Univ., Kent, OH

Abstract: Ovariectomy and concurrent loss of estrogens impair spatial memory and synaptic plasticity in vivo. However, ovariectomy is also followed by a stark increase in peripheral levels of luteinizing hormone (LH), an aspect that is associated with a marked decrease of brain LH levels. Since we recently discovered a correlation between brain LH levels and spatial memory, we hypothesized that restoring LH signaling in the CNS with an analogue, human chorionic gonadotropin (hCG), would ameliorate spatial memory deficits due to ovariectomy. We ovariectomized C57Bl/6J mice at 3 months of age, infused artificial CSF or hCG (3 or

30mIU/day) to the lateral ventricle at 6 months of age and trained mice to perform the Morris water maze task. Our data show that hCG treatment increases ERK phosphorylation and rescues ovariectomy associated deficits in spatial memory on the probe trial of the Morris water maze task. Additionally, we treated primary neuronal cultures with 300mIU hCG, which increased the number of secondary neurites and branch points, an aspect that may be linked to the ability of hCG to increase ERK phosphorylation in vivo. Together, our data suggest that LH signaling is able to restore spatial memory deficits and increase the complexity of the dendritic arbor.

Title: The brain-derived neurotrophic factor Val66Met variant modulates the effects of estradiol add-back

Authors: *G. H. PETTY, J. MARROCCO, K. H. HAJDAROVIC, E. M. WATERS, B. S. MCEWEN;
The Rockefeller Univ., New York, NY

Abstract: The brain derived neurotrophic factor (BDNF) Val66Met is a common single nucleotide polymorphism in humans, with approximately 30% of the Caucasians being heterozygous for the $BDNF_{Met}$ allele ($BDNF^{+/Met}$). Clinical and animal studies have shown that $BDNF_{Met}$ carriers exhibit an increased risk for affective disorders and metabolic dysfunction. Interestingly, a few findings have highlighted the importance of the estrus cycle to unmask behavioral impairment in the $BDNF_{Met}$ knock-in mouse ($BDNF^{Met/Met}$), an animal model that recapitulates the main hallmarks of humans carrying the $BDNF_{Met}$ allele. The interplay between BDNF and sex hormones is consistent with evidence showing that replacement or endogenous surge of estradiol increases BDNF expression in the brain, notably in hippocampus. Here, we aimed at the determining whether the Val66Met status can alter the effects of 17-β estradiol (E) replacement. To this purpose, we ovariectomized (OVX) $BDNF^{+/Met}$ mice and their matched wild type $BDNF^{+/+}$. After a 7 day-recovery period, cage water bottles were refilled with water

containing either 200 nM E/0.1% ethanol or vehicle (0.1% ethanol). This treatment was provided *ad libitum* for 6 weeks, during which mice underwent a battery of behavioral tests, including light-dark test, splash test, and object placement. Body weight was recorded once per week. Following the behavioral tests, mice were killed and hippocampi, prefrontal cortex, hypothalamus, and uteri were dissected. Blood was collected and peripheral blood mononuclear cells were isolated. E treatment prevented body weight increase in OVX mice of both genotypes. Uteri weights and optical analysis further validated the success of surgery and E treatment. In the light-dark test, E add-back had a more prominent anxiolytic effect in $BDNF^{+/Met}$ when compared to $BDNF^{+/+}$. Curiously, we found that E treatment induced depressive-like behavior in OVX $BDNF^{+/Met}$, which displayed a reduced number of grooming sessions compared to vehicle treated OVX $BDNF^{+/Met}$. Also, we observed that ovariectomy affected cognitive performance in $BDNF^{+/+}$ but not in $BDNF^{+/Met}$. Indeed, only vehicle treated OVX $BDNF^{+/+}$ showed no discrimination of the misplaced object. Thus, there appears to be a procognitive effect of E only in $BDNF^{+/+}$. This suggests that the Met allele might confer cognitive protection during estradiol fluctuation. We are currently examining the gene expression profile in the different tissues collected. These findings lay the groundwork for novel investigations aimed at determining how the interplay between sex hormones and the $BDNF_{Met}$ allele increases the risk for affective disorders at discrete time points in a woman's life.

Title: Sexual dimorphism in dominance hierarchy and learning in the zebrafish, Danio rerio

Authors: *J. M. SUNDVIK, H. PUTTONEN, P. PANULA;
Dept. of Anatomy, Biomedicum Helsinki, University of Helsinki, Finland

Abstract: Social hierarchy exists within the majority of different animal populations including humans. This hierarchy affects both reproductive fitness and individual health. Neuronal mechanisms underlying social hierarchy can be studied by comparing the central nervous system of dominant and subordinate animals; a quite unexplored research area. We set out to study the effect of dominance on exploratory behavior and long and short-term memory in the P generation of both male and female zebrafish, and to establish if this is a trait that is inherited

and if the changes in the aminergic systems will be carried over to the next F1 generation. There were no gender differences in basic locomotion and exploratory behavior. In the hierarchy establishment test the male fish showed a clear spatial hierarchy with the dominant individual patrolling the top compartment of the tank and the subordinate male spend most of the time freezing at the bottom of the tank. In females the hierarchy was also established but not spatially as clearly as in the males. The dominant female was generally chasing the subordinate female. Also, the subordinate female did not spend time freezing in the bottom part of the tank, rather the subordinate female was avoiding all contact with the dominant female. Shor- and long-term memory was reassessed in the dominant and subordinate animals to test if the established hierarchy affected the performance in the T maze. We found that the dominant females performed faster compared with subordinate females. However, there was no difference in their short- or long-term memory formation assessed by T maze. The dominant and subordinate males did not differ in time spent to find the deep (or preferred) compartment in the T maze. Here we found that males were much faster in reaching the deep compartment of the T maze compared with females. To assess the role of dopaminergic and histaminergic signaling in the dominant and subordinate zebrafish, we studied geneexpression in the F1 generation of animals (offspring of wt, dominant or subordinate) by quantitative PCR. The only transcript changed in both dominant and subordinate zebrafish was *hdc* as its mRNA expression was significantly reduced in both dominant and subordinate larvae when compared with wild-type controls. We have shown that both male and female zebrafish form social hierarchies and that the status of the female animals affected their performance in the T maze. The offspring from the dominant and subordinate animals did not differ in regard of the dopaminergic signaling whereas the histaminergic system was significantly reduced in both dominant and subordinate larvae when compared with wild-type controls.

Title: Nootropic potential of cholinesterase inhibitor donepezil is ovarian hormone dependent in female Wistar rats

Authors: R. V. GRANDHI, R. MEDAPATI, J. TADIPARTHY, N. GANUGA, R. ABRAHAM, *P. JAYARAJAN, R. NIROGI;
Suven Life Sci. Ltd, Hyderabad, India

Abstract: Ovarian hormones, especially estrogen has an immense physiological role in cognitive processing through enhancement of synaptic plasticity, hippocampal neurogenesis, neurite outgrowth and long-term potentiation which are essential for episodic memory formation. In postmenopausal women (either natural or by oophorectomy), cognitive function is declined due to insufficient hormones in circulating blood. Women are more susceptible to dementia, particularly Alzheimer's disease (AD), than men. Moreover, hormonal therapy alone does not seem to improve the cognitive function. Studies exploring nootropic potential of cholinesterase inhibitor, donepezil in ovary intact (OVI) and ovariectomised (OVX) female rats are scarce. Hence, we explored, whether donepezil activity was mediated through ovarian hormones in a simple episodic form of memory, essential to perform activities of daily living (ADL). Object recognition task (ORT) was used to assess episodic memory in OVI and OVX female Wistar rats. Object exploration time and discriminative index were calculated and compared among the groups. Rats were subjected to testing after an inter trial interval (ITI) of 3 and 24 h. At an ITI of 3 h, OVI animals remembered the familiar object *(*p<0.05)* and showed discrimination between novel and familiar objects, where as OVX animals did not discriminate novel object. We also found that, donepezil prevented 24 h ITI induced natural deficits of object recognition memory in OVI animals. Significant *(*p<0.05* and***p<0.01)* improvement in discriminative index was noted for OVI animals treated with donepezil (0.3 and 1 mg/kg, *i.p.*) as compared to vehicle. However, donepezil did not alleviate object memory deficits in OVX animals which may be attributed to hormonal insufficiency. In addition, we observed significant gain *(**p<0.01)* in body weight for OVX groups as compared to OVI animals. Furthermore, locomotion was found to be unaffected by ovariectomy. Current study demonstrated that, anti-dementic activity of donepezil is ovarian hormone dependent in female rats. Nootropic potential of donepezil requires presence of ovarian hormones for object recognition and thereby episodic memory processing in female Wistar rats. Earlier clinical report found lack of efficacy of donepezil in postmenopausal women for symptomatic treatment of AD type dementia which is in line with the current preclinical finding. As hormonal therapy alone was found to worsen cognitive function further in post menopausal women, combined donepezil and estrogen therapy would be a promising therapeutic intervention to manage dementia in this population.

Title: Aromatase inhibition impairs cognition and thermoregulation in male and female gonadectomized middle-aged marmosets

Authors: N. J. GERVAIS[1], K. P. WORKMAN[1], M. LACLAIR[2], J. A. MONG[3], L. REMAGE-HEALEY[1], *A. LACREUSE[1];
[1]Psychological and Brain Sci., [2]Neurosci. and Behavior Program, Univ. of Massachusetts Amherst, Amherst, MA; [3]Pharmacol., Univ. of Maryland Sch. Med., Baltimore, MD

Abstract: Estrogen replacement therapy in menopausal women enhances hippocampus (HPC)-dependent cognition, and alleviates hot flashes. While estrogens are synthesized in the ovaries through the conversion of testosterone to 17β-estradiol (E2) by the enzyme aromatase, other tissues, including the brain, produce estrogens. Recent studies in rodents and birds suggest that brain-derived estrogens play an important role in modulating cognition, but studies in primates have been limited. The purpose of the present study was to examine the effects of aromatase inhibition on cognition, behavior, and thermoregulation in gonadectomized middle-aged (6-10 years old) marmosets (*Callithrix jacchus*). Following a baseline period, half the marmosets were given Letrozole (20 µg, p.o; females: $n = 3$, males: $n = 5$) daily for four weeks, while the remaining (females: $n = 3$; males: $n = 5$) received vehicle. HPC-dependent cognition was assessed daily using the delayed matching-to-position (DMP) task. Observations of spontaneous daytime behaviors (duration and frequency) in addition to nighttime activity, was assessed weekly. To determine the effect of Letrozole on thermoregulation, facial temperature in response to a 20-min thermal challenge was recorded once during the final week of drug treatment via thermal imaging. While Letrozole reduced urinary E2 levels in both sexes, it increased E2 levels in the HPC of females, but not males. Letrozole reduced DMP task performance in both sexes and increased facial temperature in response to the thermal challenge. Decrements in DMP task performance were associated with increased E2 levels in the HPC. Letrozole also influenced both daytime and nighttime behaviors. These results indicate that aromatase inhibition modulates HPC-dependent cognition, thermoregulation and behavior in gonadectomized primates. Further studies are needed to elucidate the mechanisms underlying these effects.

Title: Interactive effect of menstrual cycle and dopamine baseline levels on cognitive performance in tasks requiring executive control.

Authors: *E. HIDALGO-LOPEZ[1], B. PLETZER[1,2];
[1]Dept. of Psychology, Univ. of Salzburg, Salzburg, Austria; [2]Ctr. for Cognitive Neuroscience, Univ. of Salzburg, Salzburg, Austria

Abstract: Estradiol affects the synthesis, release and turnover of dopamine (DA), which relates to executive functions in an 'inverted U-shaped' manner with different DA optima for different functions. Accordingly, it has been demonstrated that inhibitory functions of working memory are enhanced or impaired during the high estradiol phase of the menstrual cycle depending on DA baseline levels (Jacobs & D'Esposito, 2011). A similar relationship for other executive functions has yet to be established. The eye-blink rate (EBR) has been suggested as a non-invasive indicator of striatal DA levels. However, the usefulness of this indicator has not been established in menstrual cycle research.
In order to study the interactive effect of estradiol and DA on performance, women with a natural menstrual cycle were tested in three different cycle phases (menses - low progesterone and estradiol; pre-ovulatory - high estradiol; mid-luteal - high progesterone and estradiol). During each session, women performed a verbal n-back task, as measure of working memory, a Stop Signal Task (SST) as measure of inhibitory control, a Stroop task as a measure of cognitive flexibility, and the Balloon-Analogue Risk Task (BART), as measure of impulsive risk taking. Hormone levels were assessed from saliva samples and the spontaneous EBR was recorded as an indicator of striatal DA levels.
Interactive effects between cycle phase and EBR were confirmed. Specifically, in the n-back and Stroop tasks, women with low EBR showed an increased performance during their pre-ovulatory phase, as opposed to a decreased performance in women with high EBR. Conversely, in the SST, women with low EBR were less efficient in inhibitory control during their pre-ovulatory phase, while inhibitory control did not change across the menstrual cycle in women with high EBR. Impulsive risk taking in the BART was increased during the pre-ovulatory phase for all participants, but more strongly for women with low EBR. During the luteal phase performance in

all task reached intermediate levels.
With the present study we demonstrate the usefulness of the EBR as DA indicator in menstrual cycle research and extend the previous findings of DA dependent changes in performance across the menstrual cycle to the luteal cycle phase on the one hand and to a variety of cognitive functions on the other hand. The patterns of interaction between menstrual cycle phase and DA baseline levels in the different tasks also confirm that different levels of DA are optimal for different executive functions. Therefore, we emphasize the importance of taking into account both cycle phase and DA baseline levels when studying these cognitive control functions in women.

Title: Sex differences and menstrual cycle dependent changes in cognitive strategies during spatial navigation and verbal fluency

Authors: *A. SCHEURINGER, B. A. PLETZER;
Dept. of Psychology, Univ. of Salzburg, Salzburg, Austria

Abstract: Sex differences in cognitive performance have been related to sex-specific cognitive strategies on the one hand and influences of sex hormones on the other hand. Specifically, holistic strategies (an orientation in terms of Euclidian distances and the use of an allocentric perspective) and testosterone levels have been related to improved performance of men during spatial tasks, while switching between categories and estradiol as well as progesterone levels, have been related to improved performance of women in verbal fluency tasks. However, a link between sex hormone fluctuations such as during the menstrual cycle and cognitive strategies has not been previously established.
We therefore assessed cognitive strategy use during a 2D-matrix spatial navigation task and a verbal fluency task in 51 men and 49 women. In order to relate cognitive strategies to menstrual cycle changes, men and women were tested twice, with test-sessions in women being scheduled during the early follicular (low estradiol and progesterone) and mid-luteal cycle phase (high estradiol and progesterone). Performance differences between sexes were confirmed in both

tasks and the superior performance of women during verbal fluency was explained by them switching more often between categories. Furthermore, we here demonstrate for the first time a menstrual cycle modulation of strategy use during navigation, with a preference for more holistic strategies in the follicular compared to the luteal cycle phase. No menstrual cycle effects were however observed on switching or clustering during verbal fluency. This suggests a modulation of cognitive strategy use during spatial navigation, but not during verbal fluency, by relative hormone increases during the luteal phase of the menstrual cycle.

Title: Effects of ethinyl estradiol and levonorgestrel on responses to novel objects in adolescence rats

Authors: I. A. PASTOR, C. M. LEW, Z. T. GOODMAN, *D. M. CYRENNE;
California State University, Sacramento, Sacramento, CA

Abstract: While sex differences have been narrowing in risk-taking behavior, researchers have reported stable sex differences over time in Disinhibition on Zuckerman's Sensation Seeking. Since our previous findings in humans showed comparable levels of Disinhibition in females who used hormonal birth control to males, and both groups were higher than naturally cycling females, we designed the present study to examine the influence of oral contraceptive use and its influence on novelty-seeking behavior in rats during adolescence. In human beings, novelty-seeking behavior is high during adolescence, particularly in males, and has been associated with both disinhibition and impulsivity, all of which have associations with the dopaminergic neurotransmitter system. While rodent studies have shown that the dopamine system changes across adolescence and differs in function between males and females, and that gonadal hormone production increases during adolescence in both humans and rodents, few studies have investigated the influence of synthetic hormones on changes in novelty-seeking behavior in adolescence in male and female rodents. In our study, intact female Long-Evans rats were injected with a combination of subcutaneous ethinyl estradiol and levonorgestrel (10/20 μg/rat/day) or vehicle, and intact males received only vehicle, for five days prior to testing on the novel object recognition task at postnatal day 40 (mid-adolescence). The test consisted of a 10-minute familiarization trial, in which the animal was placed in a novel box, followed by i) a 5-

minute trial with 2 novel objects and ii) a 5-minute trial prior to which one of the objects had been replaced with a different novel object. Side preferences in each trial were calculated and adjusted to reflect Novelty Preference Change between the 2 trials, with movement more towards the novel object indicating novelty preference. The results showed that males displayed a higher novelty-preference than hormonally-treated females, while the hormonally-treated females exhibited similar levels of novelty-preference to control females. These results are consistent with prior findings where adolescent males were higher in novelty-preference than females, with no difference in females treated with Antide, a GNRH antagonist, and control females, and Antide treated males lower in novelty-preference than control males. These findings suggest that novelty-seeking behavior may be driven by the influence of testicular hormones rather than estrogens during adolescence, or that synthetic hormones may have lower impact on behavior beyond the critical pre-pubertal period of development.

Title: The influence of parity on hormone replacement efficacy in a rat model of menopause

Authors: M. MEY[1], *A. STAVNEZER[2], R. BRANDON[1], M. PAVESKOVIC[1];
[1]Neurosci., [2]Col. of Wooster, Wooster, OH

Abstract: There are clear physiological changes following pregnancy to the reproductive system, but also to the hormone-sensitive regions of the brain. The vast majority of rodent studies on aging and hormone replacement take place with virgin females. However, this situation ignores the impact of earlier pregnancy on the efficacy of hormone replacement therapy in adulthood and the fact that 75% of all American women give birth at some point in their life. We allowed half of the female rats to give birth to and wean three litters (multiparous), while the other half remained unmated (nulliparous). At 10 months of age all females were ovariectomized and then half of each group received conjugated equine estrogen (Premarin) for two months. These aged multip and nullip female rats, males and young females completed a behavioral testing battery including open field, elevated plus maze, Morris water maze, and water radial arm maze. In addition, regions of the basal forebrain, hippocampus and enthorhinal cortex will be assessed for ACh activity. Preliminary data analysis does not indicate an influence

of parity on hormone replacement efficacy on behavioral tests. Histological results will also be presented.

Title: Women with premenstrual dysphoric disorder (PMDD) differ in baseline and steroid hormone response expression profiles of the ESC/E(Z) pathway compared with asymptomatic controls

Authors: *J. F. HOFFMAN[1,3], N. DUBEY[2], K. SCHUEBEL[3], C. MARIETTA[3], Q. YUAN[3], P. MARTINEZ[2], L. NIEMAN[4], D. RUBINOW[5], P. SCHMIDT[2], D. GOLDMAN[3];
[1]Behavioral Endocrinol. Br., Natl. Inst. of Mental Hlth., Rockville, MD; [2]Behavioral Endocrinol. Br., Natl. Inst. of Mental Hlth., Bethesda, MD; [3]Lab. of Neurogenetics, Natl. Inst. on Alcohol Abuse and Alcoholism, Rockville, MD; [4]Intramural Res. Program on Reproductive and Adult Endocrinol., The Eunice Kennedy Shriver NICHD, Bethesda, MD; [5]Psychiatry, Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Premenstrual dysphoric disorder (PMDD) is characterized by cyclic affective and behavioral symptoms confined to the luteal phase of the normal menstrual cycle. No diagnosis-related differences in reproductive hormone levels distinguish PMDD; however, in PMDD (but not asymptomatic controls) PMDD symptoms recur after re-exposure to physiologic levels of ovarian steroids during GnRH-agonist-induced ovarian suppression. To identify a cellular basis for the differential behavioral sensitivity to ovarian steroids in PMDD, we created lymphoblastoid cell cultures (LCLs) and induced pluripotent stem cells (iPSCs) from blood samples of women with and without PMDD. LCLs (n = 10 PMDD, 9 controls) were exposed 24 hours to vehicle or ovarian steroids (estradiol, E2 or progesterone, P4) and examined for differences in gene expression via whole transcriptome RNA analysis (RNA-seq), followed by pathway analysis (DAVID and GSEA). Among several significantly altered pathways, the ESC/E(Z) complex pathway was chosen for further study because of its role in gene regulation,

modulation of/by steroid signaling, and small number of genes in the pathway. There was increased baseline (diagnosis) mRNA expression in PMDD cell lines over controls, with significant effects in MTF2, PHF19, and SIRT1 ($p<0.05$), (confirmed with qRT-PCR). Further, we found a diagnosis x P4 interaction effect in RNA expression (EED, EZH2, MTF2, $p<0.05$) where expression increased after P4 treatment in control but not PMDD LCLs, and a diagnosis x E2 interaction in RNA expression (JARID2, $p<0.05$) where expression decreased after E2 treatment in PMDD but not control LCLs. Interestingly, protein analysis of baseline ESC/E(Z) complex genes revealed a decreased expression in PMDD LCLs over controls, with MTF2, PHF19, and SIRT1 reaching significance ($p<0.05$). Whole exome sequencing was then performed on DNA extractions from blood of women with and without PMDD (n=52, n=27, respectively) and compared against allele frequencies in Exome Aggregation Consortium to look for potential sequence variants correlated with PMDD. Further, we attempted to differentiate iPSCs into serotonergic neurons to examine a cellular model of PMDD with more direct functional relevance. These data identify a potential cellular basis for the difference in affective/behavioral response to hormones observed in PMDD mediated by a dysregulated ESC/E(Z) complex in the absence of and in response to ovarian steroid hormones.

Title: The influence of biological sex and early-life stress on the long non-coding RNA, Gomafu, within the developing neonatal and juvenile brain

Authors: *A. CUARENTA[1], S. L. KIGAR[2], N. S. ZAHIR[1], L. CHANG[2], V. P. BAKSHI[3], A. P. AUGER[2];

Abstract: While serious mental health disorders affect 4% of the adult U.S. population (NIMH, 2012), both the etiology of many disorders and why some populations are disproportionally affected remain unknown. Intriguingly, there are sex differences in the rates, age of onset, and

progression of a variety of these disorders. Understanding the role biological sex plays in the development of risk or resilience in mental health is therefore critically important to further our understanding of these disorders. Many psychiatric conditions, including schizophrenia, exhibit a high level of alternative splicing of RNA,. While the molecular mechanisms regulating alternative splicing are complex and largely unknown at present, long non-coding RNAs (lncRNA) appear to play an important role in the process. Mutations and dysregulation of lncRNAs have recently been linked to a vast array of human diseases (Wapinkski, O. & Chang, H.Y. 2011). Specifically, Gomafu—a long non-coding RNA—was downregulated in postmortem tissue samples of individuals with schizophrenia (Barry et. al., 2014)..
As there are links between Gomafu expression, anxiety and schizophrenia it is important to understand whether early life stress effects are seen in a biological sex specific pattern. Our laboratory recently looked at the effects of early life stress (ELS) on Gomafu expression by using a novel, neonatal predator odor exposure paradigm. Using RT-qPCR, we examined the interaction of ELS and biological sex during the neonatal and juvenile time periods. Preliminary data has shown sex differences in Gomafu expression levels within the developing amygdala, but no effects of stress. We also demonstrate a stress effect in the neonatal prefrontal cortex, whereas there is no sex difference in this region. Currently very little is known about how Gomafu is transcriptionally or epigenetically regulated, though this will be an important future avenue for study. Key words: early life stress, non-coding RNA, sexual differentiation

Title: Sex dependent programming of dopamine receptor expression within the developing brain by early life stress

Authors: *L. CHANG[1], S. L. KIGAR[2], A. CUARENTA[1], J. H. HO[3], V. P. BAKSHI[4], A. P. AUGER[1];

Abstract: The modification of typical brain development by early life stress (ELS) has the potential to increase risk for developmental neuropsychiatric disorders such as depression and anxiety. Importantly, sex differences are often observed in the prevalence, age of onset, and manifestation of some of these conditions. This suggests that variations in the underlying circuitry between males and females may differentially alter mental health risk or resilience in response to early life perturbations. The dopamine system is often dysregulated in neuropsychiatric disorders, suggesting that disruption of this system may be critical in the etiology of these disorders. For this reason, our goal was to investigate whether ELS alters typical development of the dopamine system within the nucleus accumbens (NAc) and amygdala, two major sites of dopaminergic activity.
We used a variable predator odor exposure paradigm to induce ELS in male and female Sprague-Dawley pups on postnatal days 1 through 3 (P1-P3) for 5 minutes each day. We examined two developmental time points: a neonatal time point 30 minutes after the last predator odor exposure on P3, and a juvenile time point at P33 before the onset of puberty. At P3, ELS decreased the dopamine D_2 receptor (DRD2) expression selectively within the NAc of female rats compared to controls; males showed no significant differences. In contrast, males were affected during the juvenile period, with DRD2 expression in the NAc decreasing in response to ELS, whereas females no longer showed any significant differences. This finding replicates previous studies using maternal deprivation as a stressor, looking solely at adult male rats (Zhang et al., 2013); our study provides new information about an earlier developmental time point and demonstrates sex-specific regulation of DRD2 by ELS within the NAc. In the neonatal P3 amygdala, we did not observe any significant differences. However, at P33, there appears to be a sex-difference in DRD2 expression within controls, with higher levels in females than males. Furthermore, ELS decreased expression in females to a male-typical level without altering male levels. This indicates that ELS regulation of DRD2 expression within the amygdala also depends on the developmental time point as well as biological sex. As ELS alters juvenile DRD2 expression within the female amygdala and the male nucleus accumbens, these data suggest that ELS may induce different behavioral phenotypes in response to the same stressor. Future studies will be done to determine the impact of ELS on other molecules involved in dopamine signaling, and whether alterations in gene expression are being regulated by epigenetic mechanisms.

Title: Post-menopause animal model presents distinct features of anxiety

Authors: *L. C. CASTRO, A. PEREIRA-CAIXETA, L. O. GUARNIERI, C. P. BASTOS, 30310200, G. S. PEREIRA;
Biophysics and Physiol., Federal Univ. of Minas Gerais, Belo Horizonte, Brazil

Abstract: The appearance of mood disorders, such as depression and anxiety, is very common during the menopause. However, there are still very few studies investigating the neural basis of anxiety caused by ovarian hormone deprivation, limiting the development of specific treatments to menopausal women. Our laboratory has shown that female mice submitted to ovaries removal (OVX) present depressive-like behaviors after 12 weeks. Here, we investigated if this animal model of post-menopause also present anxiety-like behaviors. For that purpose, females C57BL/6 mice were divided in 2 groups: SHAM-operated and OVX. Twelve weeks after the surgery both groups were subjected to five behavioral tests to evaluate distinct features of anxiety, named: Elevated Plus Maze (EPM); Light-dark box (LDB); Marble Burying Test (MBT), Novelty-suppressed feeding (NSF) and Open Field (OF). Our results showed that post-menopause female mice present features of anxiety measured in the EPM and LDB, but not in the other tasks. Neural circuits that mediate the different aspects of anxiety are not the same. Additionally, most of studies evaluating the neural circuits of anxiety do not use animals under chronic conditions. Therefore, our next step is to further investigate the neural circuits involved in the anxiety-like behaviors observed in the 12 weeks OVX female mice. Financial Support: CNPq, FAPEMIG and CAPES.

Title: Sex differences in neuronal activity and expression of small conductance calcium-activated potassium channels in the rat basolateral amygdala

Authors: *J. E. VANTREASE[1], S. R. BLUME[3], J. H. URBAN[2], J. A. ROSENKRANZ[1]; [1]Cell. and Mol. Pharmacol., [2]Physiol. & Biophysics, The Chicago Med. School/RFUMS, North Chicago, IL; [3]Anesthesia Res. Div., Children's Hosp. of Philadelphia Res. Inst., Philadelphia, PA

Abstract: Anxiety disorders are the most prevalent form of mental illness in the US and women are twice as likely as men to develop anxiety disorders; yet studies that examine sex differences in the neurobiology related to these disorders are limited. The basolateral amygdala (BLA) is a critical component of the neurocircuits involved in anxiety and fear responses. Furthermore, the amygdala is hyperactive in patients with anxiety disorders and is more active in females during specific affective tasks. This suggests that BLA activity may contribute to the sex differences in the pathophysiology of anxiety. The purpose of this study was to determine if BLA neurons in female rats are more excitable than males. Single-unit extracellular electrophysiological recordings *in vivo* were used to record spontaneous BLA neuronal activity in naïve male and intact cycling naïve female rats. It was determined that, independent of estrous cycle stage, females had a significantly higher basal firing frequency in the BLA compared to males. The activity of these neurons is regulated, in part, by after-hyperpolarization potentials (AHP) that limit neuronal firing frequency. Measurement of membrane excitability *in vitro* found that cycling females also had smaller medium AHP (mAHP) and slow AHP (sAHP) amplitudes compared to males. Since small conductance calcium-activated potassium (SK) channels contribute to the mAHP and sAHP, the relative expression of SK channel mRNA and protein levels in the BLA of naïve male and female rats was measured. Using quantitative real time PCR (qPCR), the relative mRNA levels of all SK channel isoforms (SK1-4) were found to be comparable between sexes. However, Western blot analysis revealed that SK2 channel protein expression was significantly reduced in intact female rats, irrespective of estrous cycle stage, compared to males. Together this suggests that sex differences in SK2 protein expression are not likely due to differences at the level of transcription, rather SK2 protein levels may be altered in females through differential post-translational modifications or recycling of the channel, and that this is not dependent on estrous cycle stage. These results implicate a role for SK2 channels in the sexually divergent BLA neuron activity and AHP amplitudes in naïve rats. Moreover these studies identify a potential therapeutic target for the treatment of anxiety related disorders, and enhance our understanding of sex differences in anxiety.

Title: A unique subdivision of serotonergic neurons in the dorsal raphe nucleus projects to the basolateral amygdala complex to enhance fear-conditioned behaviors

Authors: *C. S. BERNABE[1,2], I. F. CALIMAN[5,2], A. R. R. ABREU[6], A. SHEKHAR[3,1,4], P. L. JOHNSON[2,1];

Abstract: The basolateral and lateral amygdala nuclei complex (BLC) is implicated in a number of emotional responses including fear and anxiety. Previous studies have shown that increased serotonin release in the BLC enhances fear conditioned behaviors, and we recently demonstrated that pharmacologically depleting serotonin in the BLC using 5,7-dihydroxytryptamine (5,7,DHT) injections disrupted fear conditioned behaviors. In 2005 Abrams and colleagues determined that there were robust BLC projections that originate from the midline dorsal (DRD) and ventral (DRV) subdivisions of the dorsal raphe nucleus (DRN), but it was not determined that they were serotonergic. Here we injected a saporin (SAP) toxin coupled to a serotonin transporter (SERT) into the BLC to selectively lesion local serotonergic fibers which replicated disrupted fear conditioning behaviors that was observed in the BLC 5,7DHT study. Since the SERT-SAP can retrogradely lesion the associated cell bodies (Shen et al., 2007) via fast retrograde microtubule associated transport, we also injected the retrograde tracer cholera toxin B (CtB) into the BLC via same the cannula that SERT-SAP was injected. This was done to not only verify loss of serotonergic neurons in DRN subdivisions, but also to specifically verify BLC projecting serotonergic neurons. We later used immunohistochemistry (IHC) to detect SERT in the BLC and observed a 90% decrease in local SERT-immunoreactive fibers. We also verified that almost all CtB-immunoreactive BLC projecting neurons in DRN were also positive for tryptophan

hydroxylase (TPH: a serotonergic specific enzyme). We further determined that BLC projecting neurons immunoreactive for both CtB and TPH were primarily located within the midline DRD and DRV divisions of the DRN, and not in the lateral wing (DRVL) divisions of DRN. Regardless of location, the SERT-SAP group had 72% to 74% less CtB/TPH-double immunoreactive neurons than control-SAP group. These data elucidate the roles of serotonergic networks in the pathophysiology of fear, and especially focus on the origins of these pathways as a way to identify potential novel therapeutic targets.

Title: Estrogen replacement during pre-exposure enables latent inhibition of fear conditioning in the rat

Authors: *M. E. LONG[1], W. P. JORDAN[2];
[1]Psychology, St. Mary's Col. of Maryland, Mechanicsville, MD; [2]Psychology, St. Mary's Col. of Maryland, St Mary's City, MD

Abstract: Latent inhibition (LI) and prepulse inhibition (PPI) are disrupted in schizophrenia patients and used to model schizophrenia in animals. The estrogen hypothesis of schizophrenia suggests that schizophrenia symptoms are more severe when estrogen levels are low during the menstrual cycle or after menopause, predicting that both LI and PPI may be restored with estrogen administration. Current literature is conflicting about the relationship between estrogen levels and LI and does not provide a clear explanation for how estrogen produces these effects (Arad & Weiner, 2009; Nofrey, Ben-Shahar, & Brake, 2008).
Manipulations of serotonin (5-HT), but not dopamine (DA), alter LI during the pre-exposure (PE) stage, while the opposite has been found with drug treatments during conditioning (Weiner, 2003). Atypical anti-psychotic drugs (APDs) disrupt LI by acting on 5-HT during PE, an effect not seen for typical APDs (Shadach, Gaisler, & Schiller, 2000). If the estrogen hypothesis is true, it is not clear whether estrogen is acting more like an atypical or typical APD to restore LI. The present experiment tested the effects of estrogen replacement during PE in an LI design.
14 of 28 ovariectomized female Sprague-Dawley rats received subcutaneous injections of 17β-estradiol (150 μg/kg BW) for three days prior to PE. Control animals received vehicle injections

of corn oil. Half of each group received 20 white noise stimuli (88dB, 20s) on each of two PE days in a standard operant chamber. Non-preexposed (NPE) rats received a single stimulus presentation to reduce unconditional responding to the to-be-CS. A three day break before conditioning without replacement therapy was followed by six daily presentations of a single noise CS paired with a foot shock US (0.5mA, 0.5s). Freezing to the CS was scored from video recordings of each session. Following LI testing, estradiol was administered again for three days prior to the PPI test consisting of startle stimuli (110dB, 50ms) alone mixed with startle stimuli preceded by either a 72dB or 78dB prepulse (20ms, 100ms inter-pulse interval).
NPE ovariectomized rats conditioned normally; however, the PE group failed to show LI. LI was present in estrogen-treated rats. PPI also was present following estrogen replacement, but was diminished in ovariectomized animals. The failure of ovariectomized rats to show LI under conditions where estrogen replacement during PE is sufficient for LI suggests that estrogen may be required for normal LI. Estrogen confined to the 5-HT-dependent PE stage altered LI, suggesting that estrogen may be affecting 5-HT, similar to an atypical APD.

Title: Effects of female gonadal hormones on fear associated learning using the SPS rat model of PTSD

Authors: *C. V. CHEN, I. LIBERZON;
Univ. of Michigan, Ann Arbor, MI

Abstract: Post-traumatic stress disorder (PTSD) is a deleterious mental health condition with a lifetime prevalence of 6-9% in the US, affecting twice as many women as men. Since gonadal hormones play a crucial role in many sex differences, they may contribute to sex differences in the etiology and prevalence of PTSD. Using a PTSD rodent model, Single Prolonged Stress (SPS), our lab has shown that male rats exposed to SPS develop a deficit in retention of fear extinction, a postulated key deficit in PTSD. Here, we sought to determine how hormones controlling the estrous cycle in female rats affect various aspects of fear associated learning like fear conditioning (FC), fear extinction (FE), and SPS-induced extinction recall (ER) deficits.

Adult female rats were first ovariectomized and later treated with a single s.c. injection of estrogen (E), progesterone (P), both (EP) or vehicle (sesame oil) on the day of SPS, FC or FE. Findings indicate that activational effects of P enhanced fear acquisition on the day of FC, and E or P exerted activational anxiolytic effects on the day of FE. In addition, while P had the capacity to increase memory consolidation of both fear and safety information, E only enhanced consolidation of safety memory. Interestingly, when animals had been exposed to SPS trauma, these hormonal effects on behavior were altered. Finally, when EP was given on the day of SPS, rats showed decreased fear trace on the day of FE. Together, these data indicate that female gonadal hormones modulate fear associated learning behaviors and that the experience of trauma alters these hormonal effects.

Title: The effects of sex and gonadal hormones on anxiety behaviour in mice

Authors: *C. HOWES[1], C. WASSON[1], E. MARTIN[1], A. GIUGA[1], H. KATZMAN[1], A. TIESSEN[1], E. CHOLERIS[2], N. MACLUSKY[3];
[2]Psychology - Neurosci. and Applied Cognitive Sci., [3]Biomed. Sci., [1]Univ. of Guelph, Guelph, ON, Canada

Abstract: Women exhibit a much greater prevalence of anxiety disorders than men. Animal models have examined the potential role for gonadal hormones as an underlying mechanism driving sex differences in anxiety behaviour. In female rodents, estrogen receptor alpha has been shown elevate anxiety behaviour, while estrogen receptor beta activation appears have an anxiolytic effect. In male mice, testosterone rapidly reduces anxiety behaviour, pointing at an activational role for gonadal hormones in mediating anxiety. However, little is known about how gonadal hormones may impact anxiety behaviour developmentally. Given the importance of testosterone for the masculinization of the male fetus, we hypothesize that sex differences in anxiety behaviour may be driven in part by the developmental action of testosterone. Thus, we administered either 10µg testosterone propionate or sesame oil control to pregnant CD1 mice 12, 14, and 16 days following conception. This dosage is at the low end of a range of doses which

have been shown to produce behavioural effects, and administration was timed to coincide with prenatal sexual differentiation of the male fetus. Animals underwent a series of behavioural tests prior to the onset of puberty, including a dark-light test for anxiety-like behaviour. Following the prepuberty set of behavioural tests mice underwent one of three surgical interventions sham surgery, gonadectomy, or gonadectomy with hormone replacement via implantation of a capsule containing either crystalline testosterone (males) or 17-beta-estradiol dissolved in sesame oil (females). 10 days following hormone replacement, mice underwent the behavioural test battery again in adulthood, at 9 weeks of age. Prior to puberty, we found that mice treated with testosterone prenatally exhibited greater anxiety-like behaviour than control animals. This effect was observed only in male mice on some of the behaviours we measured, suggesting that males may be more vulnerable to the effects of elevated testosterone during development. We are in the process of examining the effects of our prenatal treatment and surgical interventions on anxiety-like behaviour in adulthood.

Title: Long-term administration of nandrolone decanoate induces hyperarousal and anxiety-like behavior in adult male rats

Authors: *I. F. CALIMAN[1,2], A. R. R. DE ABREU[7,2], C. S. BERNABE[3,4,5], A. DIETRICH[4], W. A. TRUITT[4,3], P. L. JOHNSON[4,3], A. SHEKHAR[2,3,6], A. I. MOLOSH[2,3];
[1]Federal Univ. of Espirito Santo, Vila Velha, Brazil; [2]Dept. of Psychiatry, [3]Stark Neurosciences Res. Inst., [4]Dept. of Anat. and Cell Biol., [5]Program in Med. Neurosciences, [6]Indiana Clin. and Translational Sci. Inst., Indiana Univ. Sch. of Med., Indianapolis, IN; [7]Dept. of Biol. Sci., Federal Univ. of Ouro Preto, Ouro Preto, Brazil

Abstract: Nandrolone Decanoate (ND) is an Anabolic Androgenic Steroid (AAS) that is often chronically abused for physical enhancement and results in multiple adverse side effects, such as anxiety, aggression, and impulsivity as well as disruption of physiological functions. Although the negative impacts of AAS misuse are well recognized, the exact mechanisms of AAS mediated adverse effects are still poorly understood. To better understand long-term behavioral and neurobiological consequences of AAS abuse, we carried out a comprehensive battery of assessments in order to investigate the consequences of long-term ND administration (20mg/Kg/week for 13 weeks total) in adult gonadally intact male rats. After 4 weeks of ND treatment, we observed a reduction in weight gain, lower food intake and alterations in body composition (less total body fat and higher body lean mass) in ND-treated male rats, confirming the anabolic effects of this AAS. We also detected an anxiety-like behavior in ND-treated animals in several behavioral tests, including open field (decreased total time in center zone, increased freezing), social interaction (reduction in interaction and proximity with the partner), elevated T-maze (increased latencies for inhibitory avoidance and escape behavior), acoustic startle reflex (increased in acoustic startle response), pre-pulse inhibition (reduced PPI) and light-enhanced startle (enhanced startle during light onset). Moreover, in the defensive burying test, ND-treated rats displayed passive coping (increased immobility/freezing), indicating a different behavioral expression of anxiety (a passive form of shock-prod avoidance behavior). We did not observe alterations in memory and learning components assessed by the novel object recognition test. We hypothesize that the anxiety-like behaviors induced by ND in treated males are likely due to alterations in key structures regulating metabolism and anxiety such as the ventromedial and perifornical hypothalamus, the bed nucleus of the stria terminalis (BNST), and the medial amygdala. Further research is needed to elucidate the cellular and molecular mechanisms of AAS long-term effects in these brain regions.

Abstract: The serotonin system is implicated in the etiologies and treatment of mood and anxiety disorders, which are characterized differently in men and women and are more commonly diagnosed in women. Sex-associated differences in anxiety- and depression-like behaviors have been reported in animal models, including mice with constitutive loss of the serotonin transporter (SERT). We have observed differences in basal and stimulated extracellular serotonin between male and female mice in the context of female estrous phases.[1] Here, we report the interacting effects of sex and *Sert* genotype in anxiety- and depression-like behaviors in mice. In the novelty-suppressed feeding test we report significantly decreased latencies to feed in female mice, compared to male mice, independent of *Sert* genotype. Genotype-associated differences in emotion-like behavior are sex-dependent in the forced swim test, where immobility times were significantly different in SERT wildtype *vs.* SERT-deficient male mice, but not female mice. Interactions between sex and genotype in widely used tests for anxiety- and depression-like behavior in mice and their relevance to human affective and anxiety disorders will be presented.

Title: Serotonin stimulation modulates waiting through direct effects and associative learning

Authors: *M. S. FONSECA, M. MURAKAMI, E. LOTTEM, Z. F. MAINEN;
Champalimaud Neurosci. Programme, Champalimaud Ctr. for the Unknown, Lisbon, Portugal

Abstract: Neuromodulators can affect behavior by directly modulating neural circuits and by indirectly shaping them through learning. This is exemplified by the dual roles played by dopamine (DA): directly energizing behavior and indirectly reinforcing appetitive actions. The case for other neuromodulators is less clear. Photostimulation of dorsal raphe nucleus (DRN) 5-HT neurons enhances patient waiting, biasing the competition between competing patient and impulsive actions. These effects are rapid and transient and have been interpreted as complementing DA's direct function. 5-HT is also known to modulate cortical plasticity and to contribute to reversal learning tasks, but 5-HT stimulation does not appear to drive appetitive or aversive learning. Hence the involvement of 5-HT in associative learning processes remains unclear. Here, we sought to test whether 5-HT stimulation effects include an associative component. We reasoned that if 5-HT acted solely through an immediate and direct effect, then its effects should be independent of context and stimulation history. To test this, we modified the previously studied waiting paradigm by training mice to wait for randomly delayed tones at two spatially distinct ports. In one port, waiting was paired with optogenetic activation of DRN 5-HT neurons in 80% of trials and in the other only 20% of trials. Surprisingly, preliminary results show that waiting developed to be longer in the high probability port and that this difference reversed upon reversal of stimulation probabilities (n=6 mice). Control experiments showed that the effects were not accounted for by change in success, and thus reward, rate. These results suggest that 5-HT modulation of waiting may not be fully explained by immediate and direct effects on action circuits and that, like DA, 5-HT may also contribute to directly or indirectly driving contingency-sensitive associative learning processes.

Title: Posterior piriform cortex in an odor-guided spatial navigation task

Authors: *C. POO, N. BONACCHI, A. CRUZ, Z. F. MAINEN;
Champalimaud Neurosci. Programme, Champalimaud Ctr. for the Unknown, Lisboa, Portugal

Abstract: Olfaction is one of the most dominant senses across many organisms, including rodents. The context in which odors are experienced is a critical component for decoding the behavioral significance of the odors. In addition, these associations powerfully influence the perceptual qualities of odors. The posterior piriform cortex (pPC) receives olfactory information from the olfactory bulb, anterior piriform cortex, as well as top-down inputs from higher-order brain regions such as hippocampus and entorhinal cortex. However, relatively little is known about the role of pPC in olfaction. Here, we explore the encoding of odor associations using extracellular tetrode recordings of pPC and hippocampal area CA1 neurons in freely behaving rats. We develop a novel 4 alternative-forced choice odor-guided spatial navigational task, where odor stimuli are mapped to reward locations following an allocentric rule. Rats were trained on an elevated plus maze with a port at the end of each arm. For a given trial, rats received 1 (out of 4) odor at a give port and then were required to navigate a specific port for water reward. Solving this task requires a cognitive map of space along with representation of odors and with their associated spatial outcome locations. Our preliminary results show that neurons in pPC are active conjunctively to odor identity and the spatial location in which odors were sampled. In particular, we find that pPC neurons selectively fire to odors when odors are sampled at the predicted reward outcome location. Our data suggests that pPC neurons not only encode odor identity, but also the spatial context in which odors are experienced.

Title: Orbitofrontal cortex and the representation of outcome locations

Authors: *N. BONACCHI, C. POO, A. CRUZ, Z. F. MAINEN;
Champalimuad Neurosci. Programme, Champalimaud Ctr. for the Unknown, Lisboa, Portugal

Abstract: The orbitofrontal cortex (OFC) is thought to be involved in the representation of anticipated behavioral outcomes that drive goal-directed behavior. Among the properties of goals or outcomes that may be represented in the OFC is their spatial location, a fundamental feature of goals for animals that rely heavily on locomotion for foraging. Previous studies have described neural correlates of choice and goal location in rats performing spatial two-alternative choice tasks. However, relatively little is known about the spatial properties of these OFC neural representations. In previous tasks, the constrained spatial extent of the behavioral arena did not allow characterization of the detailed spatial properties of representations. Furthermore, because the location of the reward and the choice side were always correlated, the data could not disambiguate between representations of the nature of the action and the spatial location of the goal. Here we show that the OFC is necessary to maintain performance in a spatially extended 2 alternative free choice task only if the subject is required to initiate a trial by visiting the opposite side of the box but not in a simple spatial reversal task. The introduction of this spatial/navigational component seems to be the key variable responsible for our results. In order to better investigate these spatial properties we developed a 4 alternative forced choice odor guided spatial navigation task where odor stimuli are mapped to outcome locations using an allocentric rule. Solving such task requires a cognitive map of space and a representation of the cued outcome spatial location. Indeed we find that previously rewarded locations, more so than actions, bias the behavior of the animal suggesting that outcome location value is being used as a relevant decision variable. We performed extracellular tetrode recordings in the rat's OFC to reveal their role in coding for outcome locations and spatial navigation.

Title: A computational account of foraging in probabilistic environments and its modulation by dorsal raphe serotonergic neurons

Authors: *P. VERTECHI, E. LOTTEM, M. OUDE LOHUIS, D. BANERJEE, D. SARRA, Z. F. MAINEN;
Champalimaud Neurosci. Programme, Champalimaud Ctr. for the Unknown, Lisbon, Portugal

Abstract: Deciding when to abandon a given resource to explore elsewhere (the "explore/exploit dilemma") is a key component of foraging behavior and has been studied extensively in the field of behavioral ecology. However, how different neural systems impact this process is not well understood. On-going experiments in our laboratory have implicated the central neuromodulator serotonin (5-HT) in foraging behavior. We study a foraging task in which mice obtain water rewards by nose poking at two resource sites. Reward size is constant but reward probability decreases over time. Optogenetic activation of 5-HT neurons in the dorsal raphe nucleus (DRN) promotes exploitation: when stimulated during a site visit, mice make more nose pokes before abandoning the site. Within the framework of optimal foraging theory, several explanations could account for prolongation of exploitation by 5-HT, including increased estimation of the travel cost, increased uncertainty about the inferred probability of site depletion, or decreased opportunity cost of time. To better understand the role of these factors, we used a modified task in which reward probability is initially constant but with a low probability switches to a depleted state in which rewards are no longer available. We then manipulated orthogonally reward size, travel time and reliability of reward delivery. We found that the main factor shaping the animals' behavior was the statistical uncertainty of reward delivery: when reward was delivered in smaller but more reliable amounts the mice required fewer failed reward attempts to be confident that the site had been depleted. To analyse this aspect of the behavior quantitatively, we derived the strategy that maximizes reward over time in the general framework of partially observable Markov decision processes. The optimal agent estimates the probability that the foraging site is no longer rewarding and leaves when this probability exceeds a given threshold. We show that this process can be modeled by an accumulate-to-threshold or drift diffusion process in which a particle representing the inferred probability of site depletion is driven by unrewarded pokes until reaching a fixed bound that signals the decision to leave. We found that this model can provide a parsimonious description of mice's foraging behavior. Interestingly, we found that within this framework the effect of DRN 5-HT activation is captured by a single parameter: 5-HT reduces the drift rate, thereby increasing the time taken to reach the threshold. We suggest that this model-driven approach represents a promising avenue to elucidate neuromodulatory function at an algorithmic level.

Title: Serotonergic modulation of decision making in a foraging task

Authors: *D. SARRA, E. LOTTEM, P. VERTECHI, D. BANERJEE, M. OUDE LOHUIS, Z. F. MAINEN;
Champalimaud Neurosci. Programme, Champalimaud Ctr. for the Unknown, Lisbon, Portugal

Abstract: The central neuromodulator serotonin (5-HT) has been implicated in impulse control. Activation of dorsal raphe nucleus (DRN) serotonin neurons has been shown to promote patience in mice trained to wait for randomly delayed rewards, and inhibition of these neurons in a similar task results in premature leaving. These effects may be the result of a direct reduction in movement vigor or “behavioral inhibition”. Alternatively, 5-HT might modulate decision-making to favor actions associated with waiting. In particular, waiting for delayed rewards could be considered a type of exploitative foraging behavior under conditions of uncertainty. Mice continue to wait in hopes of garnering randomly delayed reward rather than giving up and exploring elsewhere. To distinguish between these alternatives we developed a probabilistic foraging task in which mice obtained rewards by performing nose pokes at two sites. In each site visit reward size was constant but reward probability decreased exponentially with the number of pokes made. Similar to waiting tasks, mice were faced with the challenge of tolerating delayed rewards and deciding when to give up. But whereas waiting tasks required only passive waiting, in the foraging task mice were required to actively nose poke in order to exploit a given site. We reasoned that if 5-HT acts by behavioral inhibition, then activating 5-HT neurons ought to decrease the rate or number of pokes per visit. If, instead, 5-HT enhances exploitation behavior it ought to increase poking. Consistent with the latter alternative, we found that optogenetic activation of DRN 5-HT neurons significantly increased the average number of nose pokes mice

made before leaving (n = 10 SERT-Cre mice infected with AAV2/9-Dio-ChR2-EYFP virus). Wild type control animals (n = 6, infected and stimulated similarly to SERT-Cre mice) showed no effects. Furthermore, optogenetic activation of DRN 5-HT neurons during switching, while animals moved from one site to the other, had no effect on movement speed. While our results are consistent with earlier accounts linking 5-HT to inhibition of impulsive responding, they challenge a simple notion of "behavioral inhibition" in which 5-HT activation reduces activity or movement vigor. Instead, they suggest that DRN 5-HT activation biases action selection processes away from certain classes of behaviors and towards others. Some classes of behaviors, such as those involved in resource exploitation, are actually enhanced rather than inhibited by 5-HT.

Title: Differential regulation of reward-seeking under conflict by distinct nucleus accumbens subregions

Authors: *P. T. PIANTADOSI, D. C. M. YEATES, M. WILKINS, S. B. FLORESCO; Psychology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Adaptive expression of motivated behavior requires mechanisms to both promote and inhibit output depending on changes in motivational state. Although the cortico-limbic-striatal circuitry contributing to the promotion of appetitive behavior are fairly well described, less is known about how such circuitry may inhibit reward-seeking that may be punished. Recent reports suggest that the medial prefrontal cortex and basolateral amygdala (BLA) act to suppress reward-seeking during punishment, as inactivation of either structure disinhibits punished reward-seeking. Notably, both structures can modulate goal-directed behavior (in part) via largely segregated projections to the two major subregions of the nucleus accumbens (NAc). It is currently unknown whether these two subregions, the core (NAcC) and shell (NAcS), differentially modulate punished reward-seeking. Here we examined the effects of reversible inactivations of the BLA, NAcS, and NAcC on a "Conflict" task where rats had access to a lever

that delivered sucrose reinforcement during three distinct 5 min phases. During the first and last phases of a session, rats lever-pressed for sucrose delivered on a VI-15/FR5 schedule. In between these phases, a cue-light signaled a "Conflict" period, whereby each lever-press was reinforced on a FR1 schedule with sucrose, but was simultaneously punished on 50% of presses with a foot-shock (0.3-0.8 mA). Individual foot-shock intensities were titrated over training until rats received less than 20 foot-shocks during the "Conflict" period. Under control conditions, well-trained rats pressed freely during the two VI-15/FR5 periods, but reduced responding during the punished "Conflict" period. Inactivation of either the BLA or the NAcS via infusions of baclofen/muscimol disinhibited punished seeking, increasing lever-pressing during the "Conflict" period, while attenuating pressing during VI-15/FR5 phases. In contrast, NAcC inactivation markedly decreased output to a similar degree across all three task phases. In a separate control experiment, rats were trained on an identical task with the same schedules of reinforcement, but with no punishment. Here, BLA and NAcS inactivation reduced responding during the first phase, but did not affect responding during the FR1 schedule, suggesting that these regions make a unique contribution in situations requiring inhibition of punished reward-seeking. These results imply that BLA and NAcS are part of a circuit that suppresses reward-seeking in the face of danger, which in turn may have implications for disorders characterized by punishment resistance, including substance abuse and behavioral addictions.

Title: Prefrontal GABA regulation of sustained attention and performance of conditional discriminations

Authors: *M. AUGER, J. MECCIA, S. B. FLORESCO;
Dept Psychology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Deficits in attention are widely observed in schizophrenia, and may be an underlying factor for other cognitive impairments associated with the disorder. These attentional deficits may arise, in part, from abnormalities in either GABA or NMDA receptor signalling. In rodents,

antagonism of prefrontal GABA-A or NMDA receptors impairs attentional accuracy assessed with 3- or 5-choice serial reaction time tasks. However, what remains unclear is whether these errors arise from decreased ability to detect stimuli themselves or erroneous responses to outside distractors (i.e. false alarm responses). Here, we sought to address whether attentional impairments observed following prefrontal GABA-A or NMDA receptor antagonism result from deficits in signal detection and/or increased false-alarm responding by using the operant sustained attention task (SAT). The SAT consists of signal trials in which a brief light stimulus (500, 250, 50 ms) is presented, and non-signal trials in which no stimulus is presented. After a brief delay, subjects indicate presence vs. absence of the stimulus by pressing on one of two levers. Male Long Evans rats were well-trained on the task prior to implantation with bilateral cannulae in the prelimbic region of the prefrontal cortex (PFC). Rats were then re-trained to criterion performance, and then received counter-balanced infusions of saline or the GABA-A receptor antagonist bicuculline (12.5-50 ng) or MK-801 (6 ug). Reducing PFC GABA activity impaired attention as indexed by a reduction in the overall vigilance index, with this effect being driven predominately by increased false alarm responses. In contrast, PFC NMDA receptor antagonism did significantly affect SAT performance. As the SAT is contingent on the ability to perform conditional discriminations, a subsequent experiment assessed whether PFC GABA-A receptor antagonism affects performance of a simplified version of the task identical to the SAT in all parameters, except that stimulus duration lasted 2s and there was no delay between stimulus presentation and lever extension, reducing the attentional load of the task. Here, reducing PFC GABA activity caused a slight decrease in overall accuracy. These results indicate that PFC GABA signalling facilitates attention primarily by suppressing erroneous responses in the absence of target stimuli, and may also facilitate implementation of conditional discrimination rules. Taken together, the present findings further clarify the nature of attentional impairments that arise deficiencies in GABA and NMDA receptor function.

Title: Stimulation of dopamine D_1, D_2 or D3 receptors stimulation in the nucleus accumbens differentially alters effort-related decision-making

Authors: *C. A. BRYCE[1], S. B. FLORESCO[2];
[2]Psychology, [1]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Dopamine (DA) plays a key role in optimizing decision making processes that require evaluations of relative costs and benefits, particularly those involving effort-related costs. The nucleus accumbens (NAc) is integral for mediating these types of decisions: inactivation of this nucleus or reducing DA activity at D1 or D2 receptor sites biases choice away from larger rewards associated with a greater effort cost. Although it is well established that NAc DA is required to overcome effort costs in order to gain reward, how excessive stimulation of NAc DA receptors alters effort-related decision-making has not been explored in detail. To address this question, the present study investigated the effects of infusions of DA D_1, D_2 and D3 receptor agonists into the NAc core on effort discounting, using an operant chamber assay that required rats to choose between a low effort/low reward lever (LR; 2 pellets), and a high effort/high reward lever (HR; 4 pellets), with the effort requirement increasing over trial blocks (2, 5, 10 and 20 presses). In well-trained rats, we observed that D_1 receptor stimulation (SKF 81297; 0.2-2µg) caused a slight, nonsignificant reduction in preference for the HR option. In contrast, activation of D2 (Quinpirole; 1, 10µg), drastically and dose-dependently biased choice away from the HR option and increased choice latencies, in a manner similar to the effects of D2 antagonists and notably, acute stress. On the other hand, D3 receptor stimulation had no effect at a higher dose (PD 128907; 3µg) but slightly increased choice of the HR option at the lower dose (1.5µg). The inability of D3 agonist to reduce preference for the high effort option is notable, given that these compounds (like D_2 receptor agonists) can act on autoreceptors in the NAc to reduce DA release. These results indicate that either blocking or stimulating D2R in the NAc core biases preference away from the more rewarding but costlier option, whereas stimulation of D1R or D3R marginally reduces or increases choice of the more effortful option, respectively. The effects of D_2 receptor stimulation is unlikely to be mediated solely by reduced DA release, but instead, may be driven by a combination of factors that include excessive activation of postsynaptic D_2 receptors. Ongoing experiments aim to establish how DA receptor stimulation in the NAc shell may alter this form of decision making. Collectively these findings suggest that aberrant increases in DA D_2 receptor activity, as may occur during acute stress or certain psychiatric illnesses, can perturb certain aspects of motivation and cost/benefit decision making.

Title: Complimentary roles for the medial prefrontal and orbitofrontal cortex in mediating risk/reward decision making guided by external cues

Authors: *M. VAN HOLSTEIN, M. T. L. TSE, S. B. FLORESCO;
Psychology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: We often face decisions requiring a choice between options that vary in terms of magnitude and relative uncertainty of obtaining different rewards. Moreover, the relative amount of risk associated with any given option is often not fixed, but can also vary across situations. For example, an experienced blackjack player knows that the risk of losing a hand is higher when the dealer is showing an "ace" compared to a "6" card. Studies with humans have revealed that distinct parts of the orbitofrontal cortex (OFC) and different regions of the prefrontal cortex (PFC) are recruited to guide risky decisions. In these tasks, subjects are often presented with explicit cues that inform about the probabilities of winning a gamble. Previous research from our group used a probabilistic discounting assay to show distinct roles for the medial part of the rat OFC (mOFC) and medial PFC (mPFC) in risky decision making. In these assays, animals are presented with choice between a small/certain (1 pellet) and a large/risky (4 pellet) option and the odds of obtaining the large reward varied across blocks. We previously showed that the prelimbic region of the mPFC facilitates changes in decision biases in response to changing odds, whereas the mOFC reduces the temptation to chase after large/risky rewards. We aimed to bridge the gap between assays in rats and humans in terms of *learning* (across blocks) vs. *knowing* (using external cues) the odds associated with a risky choice. To this end, we developed an operant assay we refer to as the "Blackjack" task, which uses external cues to signal the relative risk associated with the large/risky option. Rats were trained to choose between a small/certain and a large/risky option. Prior to a choice trial, one of two tones informed the rat that the probability of obtaining the risky reward was either 12.5% (high risk) or 50% (low risk). An equal number of high and low risk trials were randomly presented over 40 trials. Under control conditions, well-trained rats selected the risky vs. certain option more on low risk trials (~70%) compared to high risk trials (~20%). mPFC inactivation reduced risky choice in a maladaptive manner, in that rats chose less risky primarily on low risk trials. This was accompanied by an overall increase in sensitivity for negative feedback. Inactivation of the mOFC also reduced risky choice on low risk trials. This effect was driven by increased reward and negative feedback sensitivity. Collectively, these data show that these regions of the frontal lobes integrate external information about the relative probabilities of obtaining rewards to promote more profitable decision making.

Title: Medial prefrontal cortex and dorsal striatum neural correlates relate to multiple aspects of delay discounting

Authors: *P. M. BAKER, S. J. Y. MIZUMORI;
Psychology, Univ. of Washington, Seattle, WA

Abstract: The medial prefrontal cortex (mPFC) and dorsal striatum (DS) are known to contribute to decision-making by signaling task relevant information including working memory, choice, prior outcomes, and expected rewards. In complex self-initiated tasks such as delay discounting, the role of these structures in signaling key task epochs such as choice, delay, agency and outcomes are poorly understood. To examine the neural responses of the mPFC and DS in delay discounting, an O-shaped maze based version of the task was utilized. Male Long-Evans rats chose to pass through one door for a single pellet delivered immediately or through an alternative door to receive three pellets delivered after a delay which increased from 5 to 20 to 40 seconds across three blocks. Each block consisted of 8 alternating forced choice trials and 8 free choice trials where both doors were available. Once animals performed the discounting task stably, they were implanted with microdrives aimed at both the mPFC and DS. Following recovery and reestablishment of stable behavior, neurons were recorded during performance of the delay discounting procedure. Partial regression analysis revealed that key task information such as whether it was a free or forced trial (agency), current length of the delay, and choice between small and large reward significantly affected individual neuron firing rates. Additionally, the location of the rat on the maze interacted with the other predictors suggesting that neurons in both the mPFC and DS were modulated by multiple task epochs as the trial progressed. The nature of these interactions suggests that the mPFC and DS are both involved in decision-making with the mPFC playing a prominent role in holding relevant information across time, while the DS seems primarily important for both choices and outcomes. This is the first demonstration of these neural correlates in a delay based discounting task in which key task elements are both spatially and temporally distinct.

Title: Hippocampal place fields respond to the expected cost of rewards

Authors: *J. DAVIS, E. C. SUTLIEF, S. J. MIZUMORI;
Psychology, Univ. of Washington, Seattle, Seattle, WA

Abstract: Hippocampus (HPC) has been implicated in decision-making as context-based features of reward have been shown to bias hippocampal place field properties. Its direct connectivity with brain structures known to be involved in determining the value of response outcomes (e.g. ventral striatum) and impulsivity related to reward-motivated behavior (e.g. orbitofrontal cortex) further implicates a role for the HPC during reward-motivated decision making. Indeed, it has been shown that the expected probability of receiving a reward biases HPC place field remapping: it seems to scale directly with the probability of receiving a reward during a probability discounting task (Tryon et al., under revision). In addition, HPC lesions increase variability in an animal's preference for large delayed rewards over small immediate rewards in a delay discounting task suggesting that the HPC is involved in cost-benefit decision making (McHugh et al., 2008). In this study, we determined whether place fields encode delay-associated costs by recording place cell activity in the CA1 region of HPC in rats as they ran a delay discounting task on an elevated T-maze. Each recording session consisted of three blocks of trials during which the rats chose between a smaller reward (1 sugar pellet) associated with a short delay (3s) and a larger reward (4 sugar pellets) associated with a longer delay (10, 20, or 40s). The delay to the small reward was held constant throughout the experiment while the long delay varied between, but not within, the three blocks. At the beginning of each block rats underwent ten forced choice trials in order to familiarize them with the delay associated with the large reward during that specific block. The rats were then allowed ten free choice trials where they chose between the small or large reward. Neural activity was correlated with reward encounters as well as the onset and end of delays. This task required rats to evaluate the cost of a decision in terms of the amount of time they were willing to wait in order to obtain the large

reward. Consistent with operant studies, the behavior analysis from 4 rats revealed the strongest preferences for the large reward when it was associated with the 10s delay, but this preference declined as the delay increased. Preliminary analysis of hippocampal place fields show evidence for encoding the cost of a reward in that place field remapping was observed across trials associated with different delays. Additionally, remapping between forced vs free choice trials was observed. This suggests that the intrinsically generated value constructs, such as the expected cost of a reward, influence spatial context coding by hippocampal neurons.

Title: Effects of stimulus size and associated reward in primate LIP and amygdala

Authors: *M. L. LEATHERS[1], C. OLSON[2];
[1]Lab. of Neuropsychology, Natl. Inst. of Mental Hlth., Bethesda, MD; [2]Ctr. for the Neural Basis of Cognition, Pittsburgh, PA

Abstract: Bigger is not necessarily better. Neurons that encode the value associated with an image should do so faithfully in the face of changes in its physical size. To assess the encoding of value across variations in image size, we monitored neuronal activity in the lateral intraparietal area (LIP) and the amygdala of monkeys making value-based decisions between images associated with rewards of different magnitudes. Images associated with 0, 1 or 2 drops of juice were presented at scales that spanned a twofold range. On each trial, two cues associated with rewards of different sizes were presented at diametrically opposed locations in the contralateral and ipsilateral visual hemifields. The monkeys made optimal choices on most trials regardless of image size. We analyzed neuronal data from trials culminating in an optimal choice in order to characterize the impact on neuronal activity of both the size of the image and the

value of the associated reward. We hypothesized that variations in image size would have less impact on the encoding of reward in the amygdala than in LIP. The main analysis focused on the effects of image size and image value on trials when the preferred option was located in the visual hemifield contralateral to the recorded amygdala neuron or in the response field of the recorded LIP neuron. The earliest signal to appear took the form of stronger firing in response to larger images in LIP. An equivalent effect appeared later in the amygdala. Value-related activity made its appearance approximately simultaneously in LIP and the amygdala. The strength of the value signal relative to the size signal was, however, markedly greater in the amygdala than in LIP. Thus, although neurons in each area were influenced by both reward magnitude and the size of the image, firing in the amygdala formed a more veridical representation of value because it was less subject to interference from size-related activity.

Title: Risky reward seeking disrupts coordination of prefrontal cortex and VTA neuronal activity

Authors: *J. PARK[1], A. DEL ARCO[1], B. YU[2], B. MOGHADDAM[1];
[1]Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Carnegie Mellon Univ., Pittsburgh, PA

Abstract: In real-life events, reward motivated actions often involve potential risk of an aversive event, i.e., punishment risk. Understanding how the brain encodes this form of risk is critical for understanding how organisms achieve behavioral goals in the face of aversive events. Neurons in the prefrontal cortex (PFC) are likely to play a role in this context because PFC is implicated in risk taking behavior as well as representation of aversive states. The dorsomedial PFC (dmPFC) is innervated by dopamine neurons in the ventral tegmental area (VTA), which are critical for processing reward related information. We hypothesized that coordinated activity between VTA and dmPFC neurons is vulnerable to punishment risk during reward-motivated behavior. We designed and characterized a task that involved actions leading to a reward with varying levels of

punishment risk in different task blocks and recorded single units and local field potentials (LFPs) simultaneously from VTA and dmPFC neurons during this task. We found that substantial proportions of single neurons in both regions encode risk, before and during the action. During risk-free actions, coherent oscillations emerged between VTA and dmPFC. This oscillation was driven by VTA, and synchronized the spike activity of neurons in both regions by LFP-spike phase-locking. During risky actions, power, coherence, and directionality of the oscillation as well as LFP-spike synchrony collapsed. Together these data characterize individual- and population-level neural representations of risk-based behavioral modulation in the VTA and dmPFC, and unravel VTA-dmPFC asynchrony as an encoding scheme for risky reward seeking.

Title: Basolateral amygdala supports the value representation and effortful choice of a preferred option

Authors: *E. E. HART[1], M. GARCIA[2], Y. ZOKEN[2], A. IZQUIERDO[2];
[1]Univ. of California Los Angeles, Los Angeles, CA; [2]UCLA, Los Angeles, CA

Abstract: Organisms are often separated from rewards by work-related costs. Rewards of higher magnitude often have higher costs, while rewards of lower magnitude typically have lower costs. The basolateral amygdala (BLA) is known to be involved in appetitive behavior, but its role in cost-benefit, effort-related choice of qualitatively different rewards (more preferred/less preferred), beyond magnitude differences (larger/smaller), is poorly understood. We assessed the effects of BLA inactivations on effort-related choice behavior, before or after exposure to choice of a preferred vs. less preferred option. Rats were first trained to lever press on a progressive ratio (PR) schedule of reinforcement for sucrose pellets. Following ~10 days of PR training, rats were implanted with bilateral cannulae in the BLA. Rats then received further PR testing until stable performance was achieved. Rats were subsequently introduced to the choice procedure: chow was concurrently available in the testing chamber while they could work for sucrose. Rats were infused with either vehicle (aCSF) or baclofen/muscimol (125ng each/hemisphere) prior to

test across 4 days. These rats were compared to a separate group of rats that reached stable choice performance before BLA inactivations. BLA inactivations had no effect on a control test of food preference, with both vehicle and inactivation groups exhibiting a strong preference for the sucrose pellets when both options were concurrently freely available. After reaching stable choice performance, BLA inactivations produced a significant decrease in number of lever presses for sucrose pellets, compared to the vehicle group. There was no effect on chow consumption. Critically, when lab chow was not concurrently available, BLA inactivations had no effect on the number of lever presses for sucrose, indicating that primary motivation in the absence of choice remains intact with BLA offline. Additionally, a test under specific satiety for sucrose pellets resulted in a main effect of satiation, yet, as expected, animals with BLA inactivations prior to satiation were less sensitive to devaluation than the vehicle group. The effects of BLA inactivations in our task are not mediated by decreased appetite, an inability to perform, a change in food preference, or decrements in primary motivation. Because animals were more sensitive to effort costs for the preferred option even with previous choice exposure, these data implicate the BLA not in the acquisition but in the performance of value-cost computations. Taken together, BLA supports the specific value and effortful choice of a preferred option.

Title: Neural correlates of positive affect in subcallosal anterior cingulate cortex and amygdala.

Authors: S. TAMANG[1], C. MOSHER[1], *P. H. RUDEBECK[2];
[1]Dept. of Neurosci., [2]Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Anhedonia is a defining symptom of depression and other mood disorders and is characterized by a loss of positive affect from rewarding events. Current theories of anhedonia emphasize two distinct deficits in positive affect: a hedonic or consummatory deficit corresponding to a loss of pleasure from receiving rewards, and an anticipation or motivation

deficit that reduces work toward rewards. Data from studies of monkeys with subcallosal ACC lesions indicate that this area is important for sustaining arousal in anticipation, but not the receipt, of rewards. However, no approach to date has been able to provide a circuit-level and mechanistic understanding of how the subcallosal ACC influences positive affect in general or reward anticipation in particular. We hypothesize that the role of the subcallosal ACC is to modulate reward-related neural activity within amygdala during reward anticipation, especially when no predictive stimuli are present, i.e. during trace intervals. To test our hypothesis, we monitored behavior and recorded autonomic responses and neural activity in Macaque monkeys' subcallosal ACC and amygdala while subjects performed Pavlovian and instrumental trace conditioning tasks where they could receive different types of juice rewards. We found that monkeys showed elevated behavioral (anticipatory licking) and autonomic (pupil size) responses in anticipation of rewards and these responses were modulated by each animal's subjective preference for the different fluid rewards. Recordings of single neuron activity and local field potentials in each of these structures revealed that the activity of neurons in subcallosal ACC and amygdala was similarly modulated by animal's subjective preferences. Furthermore, as hypothesized a proportions of neurons in subcallosal ACC and amygdala encode anticipated rewards during the trace intervals. We are now exploring how these areas interact as a functional circuit by looking at coherence of oscillations in the local field potentials recorded within and between subcallosal ACC and amygdala.

Title: Effects of ventral striatum lesions on stimulus vs. action based reinforcement learning

Authors: *K. ROTHENHOEFER, R. VICARIO-FELICIANO, R. BARTOLO, V. D. COSTA, E. A. MURRAY, B. B. AVERBECK;
NIMH, NIH, Bethesda, MD

Abstract: Learning is not a unitary process and the neural circuitry that underlies learning likely depends on the type of association being learned. For example, action-based reinforcement learning may depend on different neural circuits than stimulus-based reinforcement learning.

Prior research in our lab demonstrated that rhesus macaques (*Macaca mulatta*) with ventral striatum (VS) lesions showed behavioral deficits in tasks that required stimulus-based reward association learning. In the current study, we evaluated VS-lesioned animals' performance on a probabilistic two-arm bandit reversal learning task that comprised two distinct types of learning blocks – stimulus-based (WHAT), and action-based (WHERE). Each block was separated into an acquisition phase and a reversal phase in which the initial reward mapping was reversed. We found that, compared to controls, monkeys with VS lesions had significant deficits in making stimulus-based reward associations in the WHAT blocks. By contrast, the groups did not differ in their ability to learn action-based reward associations in the WHERE blocks. We fit a reinforcement learning model to the monkeys' choice data to evaluate their choice consistency (inverse temperature), and positive and negative learning rates. We found that, in comparison to controls, the VS-lesioned monkeys were more influenced by negative feedback (no juice reward) in the stimulus-based WHAT blocks in both the acquisition and reversal phase of learning ($p<.001$). In addition, the monkeys with VS lesions had an overall higher positive and negative learning rate across learning phases in the action-based WHERE blocks compared to the controls ($p<.001$). Furthermore, we found no statistically significant ($p = .200$) difference groups in their inverse temperature parameters in the action-based WHERE blocks. However, we found disparities between the groups' inverse temperature parameters in the stimulus-based WHAT blocks, in that the VS-lesioned animals' inverse temperature parameters were lower than those of the controls ($p<.001$). Overall, we find that the VS is implicated in learning stimulus-based reward associations but not action-based reward associations. Thus, the VS is not relevant for motivating behavior independent of the learning modality. Rather, it is specifically important for learning the motivational value of stimuli.

Title: Inhibition of drug seeking behavior by activation of somatosensory input transmitted via the dorsal column pathway to the mesolimbic reward system

Authors: S. CHANG[1], Y.-H. RYU[2], Y. GWAK[1], N. KIM[1], D.-H. KIM[1], H. KIM[1], J. LEE[1], M. KO[1], B. LEE[1], J. KOO[3], S. C. STEFFENSEN[4], E. JANG[1], *C. YANG[1], H. KIM[1];

Abstract: Animal and human studies have provided that somatosensory stimuli influence mesolimbic dopaminergic systems and can reduce drug craving and addiction. Classically, there are two main somatosensory pathways in spinal cord that carry sensory signals from peripheral receptive fields to the higher center in the brain; dorsal column (DC) and spinothalamic tract (STT) pathways. Our previous studies have shown that acupuncture at *Shenmen* (HT7) points suppresses addictive behaviors of abused drugs including cocaine, alcohol and morphine and the effects are mediated by A-fiber activation of ulnar nerve originating from superficial and deep tissue. The present study aims to investigate the spinal ascending pathway responsible for somatosensory inhibition of addiction behaviors. Here we suggest a new role of dorsal column somatosensory pathway that conveys inhibitory signals from periphery to brain reward system. Stimulation of ulnar nerve suppressed addiction behaviors such as cocaine locomotion, morphine or ethanol self-administration and the effects were completely abolished by disruption of DC pathway at the level of dorsal column, cuneate nucleus or ventral posterolateral (VPL) nucleus of the thalamus, but not STT pathway. Low-threshold or wide-dynamic range neurons in the medial portions of cuneate nucleus were excited following the peripheral stimulation. A DC lesion prevented the inhibitory effects of peripheral stimulation on cocaine-induced neuronal activation in nucleus accumbens. And, the activation of habenula neurons projecting to VTA/RMTg region was seen following the peripheral stimulation. We conclude that DC pathway contains a pathway linking external somatosensory pathway to negative reinforcing circuits in addiction.

Title: Social context shapes decision signals in primate superior temporal sulcus

Authors: *A. UTEVSKY[1], M. L. PLATT[2];
[1]Ctr. for Cognitive Neurosci., Duke Univ., Durham, NC; [2]Psychology, Neuroscience, Marketing, Univ. of Pennsylvania, Philadelphia, PA

Abstract: The superior temporal sulcus (STS) region of cortex contributes to various aspects of social cognition, including face perception, biological motion detection, joint attention, and theory-of-mind. Recent brain imaging studies have also implicated this area in establishing a social context during decision making. However, the precise neuronal mechanisms underlying the establishment of social context by STS remain unknown. To address this question, we recorded the activity of 243 neurons in the middle STS in rhesus macaques performing a reward donation task (Chang et al., 2011, 2012, 2013). Monkeys chose between two donation options in two contexts: (1) donating reward to self or to both self and a recipient monkey in the room, (2) donating reward to the recipient monkey or to no one. Critically, these two-choice options were interleaved with computer-driven "cued" trials in which the monkey was only given one option of reward donation. Consistent with our prior published studies, monkeys exhibited reliable preferences for reward donation and specific patterns varied by donor monkey and his relationship with the recipient monkey. ANOVAs with reward type (self, other, both, none) and trial type (choice, cued) as factors revealed that the activity of 31% of STS neurons was significantly modulated by reward type during the decision epoch of the trial, and 28% during the reward outcome epoch of the trial. Critically, the activity of 14% of neurons was significantly modulated during the decision epoch as a function of the interaction of reward type and trial type. Post-hoc analysis showed that all of these neurons showed higher firing rates for self and both choices than other and none choices, but did not when monkeys could not freely decide whom to reward. Our findings suggest that neuronal activity in primate middle STS may contribute to establishing a social context for decision-making by distinguishing between self-

regarding and other-regarding outcomes when this information is used to guide active, deliberate choices.

Title: Stimulation in primate caudate nucleus mediates decision-making behavior in free-choice task

Authors: *S. R. SANTACRUZ[1,2], E. L. RICH[3,2], J. D. WALLIS[3,2], J. M. CARMENA[1,2]; [1]Electrical Engin. and Computer Sci., [2]Helen Wills Neurosci. Inst., [3]Psychology, Univ. of California, Berkeley, Berkeley, CA

Abstract: Action valuation is a core element of decision-making. Reward-based action selection is a critical mechanism that allows animals to achieve goals in a variety of behaviors. The basal ganglia compose a key part of the neural substrate of action selection and goal-directed behavior, and the striatum in particular has been shown to be important for arbitrating between alternative choices. Neural activity in the caudate, or dorsomedial striatum, has been shown to be modulated by the values associated with potential choices and reward-values. When values of choices diverge from true reward-values, it is unknown how choice behavior is affected.
In this work, we applied unilateral microstimulation in the caudate nucleus of two rhesus macaque subjects to selectively mediate decision-making during a free-choice joystick task. The subjects were required to hold a cursor at a center target for a fixed interval and then move the cursor to a peripheral target to select it. In free-choice trials, two alternative targets were presented, each with a different probability of reward indicated by a different color, and the subjects were permitted to freely select either target. During instructed trials, only one of the two targets was presented. High-frequency stimulation paired with a particular choice during an instructed trial biased the subjects to select that target with a higher rate in free-choice trials irrespective of the reward likelihood. Additionally, stimulation history exerted a strong effect on monkeys' upcoming choice similar to how reward history can influence choice behavior. We argue that caudate microstimulation can differentially inflate value independent of action and

reward, and that, even though the brain has bilateral value representations, unilateral manipulations of value are sufficient to mediate choice behavior.

Title: Chemogenetic inactivation of corticostriatal projections differentially disrupts impulsive choice in rats selected for high or low trait impulsivity

Authors: *N. E. ZLEBNIK[1], J. M. WENZEL[1], M. H. PATTON[1], J. R. SMETHELLS[2], B. N. MATHUR[1], J. F. CHEER[1];
[1]Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Univ. of Minnesota, Minneapolis, MN

Abstract: Impulsive choice is characterized by preference for smaller immediate rewards over larger delayed rewards, and trait impulsive choice behavior is a determining factor in the development and persistence of drug abuse. However, the neuroanatomical substrates of impulsive choice and how they may differ in impulsive vs. controlled phenotypes are still under investigation. Emerging evidence from human and animal studies suggests frontal cortical regions exert influence over striatal reward processing areas during decision-making in impulsive choice or delay-discounting tasks. To examine how these circuits are involved in decision-making in animals differing in trait impulsive choice, we used chemogenetic tools to selectively and reversibly target corticostriatal projections during the performance of a delay-discounting task in rats previously screened for high (impulsive) vs. low (controlled) impulsivity. The prefrontal cortex (PFC) was injected with a viral vector expressing inhibitory designer receptors exclusively activated by designer drugs (Gi-DREADD), and then PFC projections to the nucleus accumbens (NAc) were selectively suppressed by intra-NAc administration of the Gi-DREADD activator clozapine-n-oxide. Inactivation of the PFC-NAc projection elicited a robust increase in impulsive choice in controlled rats without affecting decision-making in impulsive rats. This demonstrates a critical role for PFC afferents to the NAc during controlled choice behavior and suggests that maladaptive hypofrontality underlies decreased executive control in animals with high trait impulsivity. Results such as these may have important

implications for the pathophysiology and treatment of drug addiction and impulse control disorders such as attention deficit/hyperactivity disorder.

Title: Visual tactile integration in rats and underlying neuronal mechanisms

Authors: *N. NIKBAKHT[1], D. ZOCCOLAN[2], M. DIAMOND[2];
[1]Neurosci., [2]SISSA, Trieste, Italy

Abstract: Our experience of the world depends on integration of cues from multiple senses to form unified percepts. How the brain merges information across sensory modalities has been the object of debate. To measure how rats bring together information across sensory modalities, we devised an orientation categorization task that combines vision and touch. Rats encounter an object-comprised of alternating black and white raised bars-that looks and feels like a grating and can be explored by vision (V), touch (T), or both (VT). The grating is rotated to assume one orientation on each trial, spanning a range of 180 degrees. Rats learn to lick one spout for orientations of 0±45 degrees (``horizontal'') and the opposite spout for orientations of 90±45° (``vertical''). Though training was in VT condition, rats could recognize the object and apply the rules of the task on first exposure to V and to T conditions. This suggests that the multimodal percept corresponds to that of the single modalities. Quantifying their performance, we found that rats have good orientation acuity using their whiskers and snout (T condition); however under our default conditions, typically performance is superior by vision (V condition). Illumination could be adjusted to render V and T performance equivalent. Independently of whether V and T performance is made equivalent, performance is always highest in the VT

condition, indicating multisensory enhancement. Is the enhancement optimal with respect to the best linear combination? To answer this, we computed the performance expected by optimal integration in the framework of Bayesian decision theory and found that most rats combine visual and tactile information better than predicted by the standard ideal-observer model. To confirm these results, we interpreted the data in two additional frameworks: Summation of mutual information for each sensory channel and probabilities of independent events. All three analyses agree that rats combine vision and touch better than could be accounted for by a linear interaction. Electrophysiological recordings in the posterior parietal cortex (PPC) of behaving rats revealed that neuronal activity is modulated by decision of the rats as well as by categorical or graded modality-shared representations of the stimulus orientation. Because the population of PPC neurons expresses activity ranging from strongly stimulus-related (e.g. graded in relation to stimulus orientation) to strongly choice-related (e.g. modulated by stimulus category but not by orientation within a category) we suggest that this region is involved in the percept-to-choice transformation.

Col. of Med., Seoul, Korea, Republic of; [3]Dept. of electronics Engineering, Col. of Engineering, Ewha Womans Universty, Seoul, Korea, Republic of; [4]Dept. of Brain and Cognitive Sciences, Ewha Womans Universty, Seoul, Korea, Republic of

Abstract: Medial forebrain bundle (MFB) is a part of the reward system, involved in the integration of pleasure and reward. Previous studies used various stimulation parameter values for operant conditioning, but the effectiveness of each parameter value has not been

systematically studied. Our previous study investigated the optimal parameter value for operant conditioning. We fixed values for the amplitude and changed the stimulation forms such as train duration, number of stimulation, pulse interval.
Electrodes were implanted in the MFB region (AP:-2.3mm, ML:-2.0mm DV:8.6mm) of Male Sprague-Dawley rats (n=7, 270~350g). Tungsten electrodes were used for the MFB stimulation. After implantation, we conducted a self-training experiment where an electrical stimulation is sent to the MFB region via the implanted electrodes upon pressing of a lever in the Skinner box. Magnitude of the electrical stimulation was fixed between 300μA to 450 μA. We varied the frequency from 50Hz to 500Hz, the duty cycle 0.05ms-0.5ms and the total train duration 100ms-400ms. We considered individuals that pressed the lever more than 30 times per minute as addiction models.
The number of pulse and frequency did not seem to have much effect on number of lever pressures. The number of lever pressure was rather influenced by amplitude and total stimulation time.
Our study focuses on electrical stimulation parameters for behavioral control using reward stimulation of MFB, and further research will be necessary for establishment of stimulation parameters that target regions other than MFB for operant conditioning. We plan to select the optimal parameter for lever pressure, and compare between high and low burst stimulations. In addition, in order to investigate the correlation between self-stimulation training and T-maze directional control training performances, the rats will be grouped according to the number of lever pressure and will be subject to T-maze directional control training. Our study will shed light on optimization of electrical stimulation for animal behavior control and we anticipate that more efficient training for operant conditioning could be possible using optimal parameters.
This study was supported by the grant from CABMC (Control of Animal Brain using MEMS Chip) funded by Defense Acquisition Program Administration (UD140069ID)

Title: Neuronal synchrony between the anterior cingulate cortex and the amygdala reflects prosocial decision outcomes

Authors: *O. DAL MONTE, N. FAGAN, A. NAIR, S. W. CHANG;
Dept. of Psychology, Yale Univ., New Haven, CT

Abstract: Accumulating evidence suggests that neuronal coordination across multiple brain regions is important for guiding complex behaviors. Social behaviors are unique in that they require processing multidimensional information across self and others. One critical component of social processing is the computation of prosocial and antisocial decisions, and recent studies have begun to elucidate how neurons from individual brain regions such as the anterior cingulate gyrus (ACCg) and the basolateral amygdala (BLA) are engaged in social decision-making. Although strong reciprocal connections between BLA and ACCg suggest a close functional relationship, the nature of their interaction and coordination is not yet understood.
Using a modified dictator game in which an actor monkey chooses between delivering juice reward to either himself ("*Self*") or both himself and a recipient monkey ("*Both*") in one context and donating juice reward to the recipient ("*Other*") or no one ("*Neither*") in another context, we investigated the neuronal coordination between ACCg and BLA by recording single-unit activity and local field potentials (LFP) simultaneously from both regions. The actors preferred to deliver rewards to *Other* over *Neither* (mean of 65% for Other), but preferred to deliver rewards to *Self* over *Both* (mean of 70% for *Self*), providing the behavioral contexts for examining the ACCg-BLA neuronal interaction for prosocial and antisocial decisions. The time-frequency analyses of LFP signals in ACCg and BLA showed an overall robust and enhanced power associated with all reward outcomes, consistent with the function of these two brain regions in reward-guided behavior. *Self* and *Both* commonly engaged alpha and beta bands, whereas gamma band activity was associated only with *Both*. Similarly, *Other* and *Neither* showed enhanced power in the alpha band, whereas upper beta and low gamma bands were associated only with *Neither*. Field-field coherence analyses revealed strong synchronization of ACCg and BLA around the upper beta and lower gamma bands that was higher in *Other* compared to *Neither*. By contrast, synchronization between ACCg and BLA was not different in *Self* compared to *Both*. Over multiple days of testing, we found a significant correlation between the preference to donate reward to *Other* compared to *Neither* and the degree of synchrony between ACCg and BLA in the upper beta and lower gamma bands, whereas this correlation was absent for preference to deliver juice to *Self* compared to *Both*. Our results demonstrate that neuronal synchronization between ACCg and BLA carries unique signatures underlying the computations of prosocial behavior.

Title: Pathway-specific recordings of glutamatergic input to the nucleus accumbens during a reward seeking task

Authors: *S. J. REED[1], C. LAFFERTY[2], T. DAVIDSON[3], L. GROSENICK[4], K. DEISSEROTH[5], J. P. BRITT[2];
[1]Integrated Program in Neurosci., Mcgill Univ., Montreal, QC, Canada; [2]Dept. of Psychology, McGill Univ., Montreal, QC, Canada; [3]Dept. of Physiol., UCSF, San Francisco, CA; [4]Dept. of Statistics, Columbia Univ., New York, NY; [5]Dept. of Bioengineering, Stanford Univ., California, CA

Abstract: The decision to allocate effort in pursuit of uncertain reward is a function of the nucleus accumbens. This structure likely receives information concerning possible goals and action plans, information which is presumably encoded in the glutamatergic input to the nucleus accumbens from the prefrontal cortex, amygdala, hippocampus, and thalamus. To gain insight into the kind of information that is encoded in these glutamate inputs, we selectively measured pathway-specific axonal activity in the accumbens using GCaMP-based fiber photometry in mice performing a discriminative stimulus reward seeking task. Notably, thalamic input to the nucleus accumbens increased during periods of movement, cue presentations, and reward seeking. In contrast, there was a dramatic reduction in thalamic pathway activity during periods of food consumption. Optogenetic inhibition of this pathway causally promoted food consumption in satiated animals. This work highlights how glutamatergic input to the nucleus accumbens contributes to motivated behaviours. While dopamine input to the accumbens clearly influences motivational processes, fluctuations in the glutamate input directs that energy to either reward seeking or consummatory behaviours.

Abstract: The social world is an elaborate context in which much of human and animal behavior is situated. Thus, it is not surprising that social influences exert a pronounced effect on both the structure and function of the brain. However, our knowledge of the direct function of neuronal processing, on which much of translation relies, is limited to the behavioral and neurophysiological study of a single, isolated animal. To expand these efforts to social contexts our research aims to develop flexible electronics, wearable, wireless tools to record different biopotentials on behaving rats during social tasks. Our preliminary behavioral studies utilized these tools, as a "proof of concept", by examining the neural processes underlying interoception. The "interoceptive system" is likely to be instrumental in social decisions, as it plays a role in self-awareness and in self-other distinctions, in addition to spanning central to peripheral levels of the nervous system. Using our tools, integrated with typical tetrode arrays, we are exploring wireless simultaneous acquisition of neural signals of the basolateral amygdala and insular cortex, in addition to heart rate data, recorded from behaving rats during socially relevant interactions in two dyadic behavioral tasks designed to recruit the "interoceptive" system. We are also applying machine-learning approaches to develop automatic classifications of rodent behavior based on accelerometer and gyroscope data recorded using our wireless devices.

Title: The highly selective 5-HT_{2C} receptor agonist WAY163909 reduces compulsive behavior and food intake in female rhesus monkeys

Authors: *M. PEREZ DIAZ[1], L. L. HOWELL[1,2], M. WILSON[1,2];
[1]Yerkes Natl. Primate Res. Ctr., Atlanta, GA; [2]Psychiatry and Behavioral Sci., Emory Univ., Atlanta, GA

Abstract: Compulsivity has been linked to several types of addiction, a highly prevalent public health issue. It can be defined as a general inability to alter behavior with changing reinforcement contingencies. A switch from random or recreational use of reinforcers, such as drugs or highly palatable foods, to compulsive use is one of the hallmarks of addiction. Thus, compulsivity appears to be a core behavioral feature of addiction, although no one has evaluated this hypothesis directly. A highly selective 5-HT_{2C} receptor agonist, WAY163909 (WAY), has been shown to decrease food consumption and effectively reduce self-administration of psychostimulants. If compulsivity is a core feature of addiction, then activation of 5-HT_{2C} receptors should also reduce compulsive behavior. In order to test this hypothesis, we evaluated the effects of WAY (vehicle, 0.1mg/kg, 0.3mg/kg and 1.0mg/kg) on perseverative responding during a Discrimination Reversal Learning (DRL) task in rhesus monkeys (N=5). WAY increased correct responses ($p<0.05$), while decreasing perseverative responses ($p<0.05$). A proof-of-concept experiment was conducted to demonstrate that WAY reduces food consumption in our subjects. These results demonstrate the modulatory role that 5-HT_{2C} receptors play in both food consumption and compulsivity, which may inform the search for novel pharmacotherapies for treatment of addiction. In addition, we are currently measuring compulsivity using the DRL task in abstinent monkeys with an extensive history of cocaine (COC) self-administration (SA) and will determine whether their prior levels of COC intake during SA are predictive of compulsivity levels. Title: Serotonin control of self-control: 5-HT1B receptor modulation of impulsivity

Authors: *K. M. NAUTIYAL[1], V. M. MAGALONG[2], M. M. WALL[3], P. D. BALSAM[4], C. BLANCO[3], R. HEN[3];
[1]Neurosci., Columbia Univ., New York, NY; [2]NYSPI, New York, NY; [3]Columbia Univ. and NYSPI, New York, NY; [4]Barnard College, Columbia Univ. and NYSPI, New York, NY

Abstract: Impulsivity is a core feature of many psychiatric disorders including substance use disorder, pathological gambling, attention deficit hyperactivity disorder, and personality disorders. Impulsive behavior is modulated by serotonin but the mechanisms through which these effects occur are largely unknown. Given that polymorphisms in the serotonin 1B receptor (5-HT_{1B}R) are associated with impulsive behavior, and 5-HT_{1B}R knockout mice display increased impulsivity, we generated a transgenic mouse line (floxed tetO-htr1b) which allows for inducible and tissue-specific knockout of 5-HT_{1B}Rs. Using this model, we have begun dissecting the circuits through which 5-HT_{1B}Rs modulate impulsive behavior. First, the absence of 5-HT_{1B}R expression increased impulsivity in tests of behavioral inhibition - the differential reinforcement of low-rate responding (DRL) and Go/No-Go operant paradigms. This impulsive behavior this was reversed with adult rescue of the receptor, suggesting an adult mechanism of action. Tissue-specific knockouts interestingly revealed that an absence of 5-HT_{1B} autoreceptors did not significantly alter impulsivity in these tasks. However selective knockout of 5-HT_{1B}Rs from GABAergic cells throughout the brain was sufficient to recapitulate the impulsive phenotype. These results suggest that 5-HT_{1B}Rs affect impulsivity through modulation of inhibitory tone, rather than directly through alterations in serotonin levels. Furthermore, we

explored the extent to which 5-HT_{1B}R signaling influences different dimensions of impulsive behavior beyond behavioral inhibition or impulsive action. Specifically, we assessed impulsive choice, another component of impulsive behavior characterized by intolerance to delay and increased risk-taking. Using delayed discounting and probabilistic discounting tasks, we found no effect of 5-HT_{1B}R on impulsivity in these paradigms. Further analysis using an exploratory factor analysis revealed a good-fitting two-factor model to describe the behavioral data. The latent factors represented impulsive action and impulsive choice tasks as independent components, with 5-HT_{1B}R expression and sex as significant covariates. Overall, our results point to a role for 5-HT_{1B}R modulation of GABAergic signaling in the regulation of impulsivity, specifically affecting impulsive action rather than impulsive choice.

Title: Local disinhibition modulates brain functions by mediating global network state

Authors: *W. CHOI[1,2], H. LEE[1], Y. PARK[1], S.-B. PAIK[1,2];
[1]Dept. of Bio and Brain Engin., [2]Program of Brain Cognitive Engin., KAIST, Daejeon, Korea, Republic of

Abstract: Modulating global network state, such as response gain and synchronization level, of a neural network is crucial for various brain functions including memory allocation (Zhou et al., 2009) and learning. Inhibition plays a critical role in orchestrating the global network state of neural circuits (Isaacson and Scanziani, 2011). In particular, disinhibition—inhibition on inhibitory neurons—is thought to be important in facilitating learning (Letzkus et al., 2015). However, it is still elusive by what mechanism disinhibition contributes to learning. In this study, we suggest that a small number of disinhibitiory neurons can effectively control the global state of the neural network and well mediate brain functions such as learning.

Using computer simulation, we constructed a model neural network in which excitatory (E) and inhibitory (I) leaky-integrate-and-fire (LIF) neurons were locally connected to each other. We divided I cells into two subcategories—neurons that inhibit E cells and neurons that inhibit I cells—and restricted their target neurons to E and I cells, respectively. Then we examined how many neurons of each type were needed to be manipulated in order to increase the gain of the neural network to a certain level. As a result, we observed that controlling disinhibitory neurons is the most efficient way of boosting the net gain of a network; even a single disinhibitory neuron was sufficient to change the global network state.
We, then, observed the role of disinhibitory neurons in learning to see whether they were capable of controlling actual cognitive functions. To simulate learning, we used our network model in which synaptic weights were allowed to be changed in the feed-forward connections based on spike-timing-dependent-plasticity (STDP) rule. Arbitrary spike patterns were introduced to the network, and the output spike consistency was calculated as a measure of memorization. We confirmed that only a few disinhibitiory neurons could effectively control the learning process by increasing neural excitability.
Overall, our simulation results show that disinhibition is more economic and efficient way to induce changes of the global network state than direct intervention of excitatory or simple inhibitory neurons. Our study also suggests that disinhibition could manipulate the general cognitive functions in the brain.

Title: Region-dependent differences of dopamine receptors, DAT and BDNF associated to individual differences of impulsive action and vulnerability to drug reward

Authors: *R.-M. LIAO[1], C.-Y. CHUANG[2], Y.-C. CHANG[3], Y.-B. CHEN[3], S.-F. CHEN[2], P.-W. CHU[3];
[1]Natl. Cheng-Chi Univ., Taipei, Taiwan; [2]Inst. of Neuroscience, Natl. Cheng-Chi Univ., Taipei, Taiwan; [3]Dept. of Psychology, Natl. Cheng-Chi Univ., Taipei, Taiwan

Abstract: Behavioral trait of impulsivity is implicated as an important factor of the development or maintenance of drug addiction from both clinical and preclinical studies. Although impulsive action can be screened by the use of an operant behavior maintained on the differential reinforcement of low-rate (DRL) schedule of reinforcement, little is known for individual differences on DRL behavior in associated with drug reward. Here, we hypothesized that inherent variation of dopamine (DA) receptors, DA reuptake transporter (DAT) and brain-derived neurotrophic factor (BDNF) might underlie individual differences of impulsive action and vulnerability to drug reward. The rats (n=47) were first trained to press lever on a continuous reinforcement schedule and then shifted to a DRL 10-sec schedule. Following 12 daily training session, these subjects were classified into three groups as high impulse (n=12), low impulse (n=12) and the intermediate (n=23), based on the efficiency to earn reinforcer in the DRL operant paradigm. The mean values (with the maximum and the minimum) of efficiency (reinforced responses/total responses) were used in categorizing subjects into high impulse, low impulse, and the intermediate groups: 0.26 (0.20-0.32), 0.51 (0.43-0.61), and 0.36 (0.32-0.42) respectively. As compared to the high impulsive group, the low impulsive group significantly made less burst responses, and conversely, had a higher mean peak time. After DRL screening, a part of the rats in each group were tested with place conditioning by d-amphetamine (1 mg/kg), and the other part of subjects was used for biochemical assays. The intermediate group had a significant drug induced conditioned place preference (CPP). No such CPP was performed in the low impulsive group, nor was the high impulsive group. The Western blot data showed a decrement of D2 receptor in the medial prefrontal cortex and an increment of DAT in the amygdala in the high impulsive group. Together, the DRL behavioral task can be used to screen the individual difference of impulsive action in associated with the vulnerability of stimulant induced CPP and regional differences of D2 receptors and DAT.

Abstract: Our brain makes value-based decisions through an interaction between the model-based system in the prefrontal network and the model-free system in the basal ganglia network. Anatomical studies revealed that there are unidirectional projections from each subarea of the prefrontal cortex to the striatum in the basal ganglia. The lateral prefrontal cortex (LPFC), which is thought to be the center of the model-based system, strongly project especially to the caudate nucleus (Cd) in the striatum. This LPFC-Cd pathway seems to have an important role in the interaction between the two systems, such as the inhibitory control or the working memory function. So far, however, mainly due to technological constraint, no study directly elucidates what role this pathway plays on the interaction. In this study, we used a chemogenetic method that can reversibly modulate the signal transmission of a specific neural pathway by expressing the Designer Receptors Exclusively Activated by the Designer Drugs (DREADDs) through the double virus vector infection and by administering its extrinsic ligand, Clozapine-N-Oxide (CNO), to the DREADD-expressing neurons. We applied this technique to the bilateral LPFC-Cd pathway in the macaque brain. We trained the doubly-infected monkeys to learn the one-direction reward saccade task (1DR), which is a version of the memory-guided saccade task. In 1DR, one cue direction (left or right) is associated with a large amount of reward and the opposite direction is associated with a small amount of reward. The association between cue direction and reward size randomly changes block by block.We recorded local-field potential (LFP) from LPFC and Cd before and after CNO administration while the monkeys were performing 1DR. As a result, task performance gradually deteriorated after administering CNO to the doubly-infected monkeys. This effect was stronger for small reward trials than large reward trials. Moreover, we found behavioral alterations on several aspects of eye movement (e.g., poorer saccade accuracy, shorter saccade latency, and faster peak saccade velocity). These results suggested that the inhibitory control to maintain accurate and vigilant behavior was impaired after CNO administration. On the contrary, the error due to saccade to the non-cued direction was not increased, suggesting that the working memory function was not impaired. These behavioral results were consistent with the inhibitory control hypothesis about the function of the LPFC-Cd pathway. Preliminary LFP analysis, in addition, showed that CNO administration modulated the amplitude of the LFP signal over whole range of frequency bands.

Title: Monkeys become impatient after pharmacological or chemogenetic (DREADD) inactivation of ventral striatum

Authors: *M. A. ELDRIDGE, S. H. OPPLER, Jr., W. LERCHNER, B. J. RICHMOND; Lab. of Neuropsychology, NIMH, Bethesda, MD

Abstract: Single unit recording studies have implicated the ventral striatum in reward valuation and processing. We investigated whether muscimol-induced unilateral inactivation of ventral striatum would alter delay discounting and/or reward size valuation in rhesus monkey, and then assessed whether the observed effects could be replicated through neuronal silencing with an inhibitory chemogenetic system.

The monkey performed a stimulus-reward association task in which stimuli concurrently representing reward size and delay-to-reward were presented. In each trial, the monkey either accepted or rejected the offer presented; accepting the offer resulted in delivery of the reward predicted by the stimulus after the proposed wait time, refusing the offer allowed the monkey to begin a new trial with the potential for a new stimulus and different outcome. The monkey indicated choice selection by releasing a lever in one of two intervals: during the presentation of a yellow target to 'reject' or a purple target to 'accept' the outcome of a trial. If the lever was released during the red 'wait' cue, that is, if the monkey aborted the trial, an error was recorded, and the trial was repeated.

In the first phase of the study, muscimol was used to unilaterally inactivate the right ventral striatum. In three muscimol treatment sessions, the monkey received a unilateral 3 μL injection of muscimol (4 μg/μL) into the ventral striatum. For three control sessions, the same volume of vehicle was infused. In both muscimol treatment and control sessions, we observed similar accept rate patterns; the monkey was more likely to accept offers with higher reward values and shorter delays-to-reward. On muscimol treatment days, the monkey aborted significantly more trials.

In the second phase of the study, an inhibitory chemogenetic receptor - hM_4Di DREADD (Designer Receptor Exclusively Activated by Designer Drug), activated by exogenous ligand CNO - was targeted to the right ventral striatum. Systemic CNO injection (10 mg/kg) was used to induce temporary silencing. On CNO treatment days, the monkey aborted significantly more trials, similar to what happened with muscimol.

In summary, although unilateral inactivation of ventral striatum appears insufficient to alter reward evaluation, it consistently produces an elevated rate of spontaneous early responding. Thus it seems as if even unilateral inactivation of this tissue impairs response inhibition, leading to the increase of inappropriate early responses.

Title: Investigating the effect of orexin on $GABA_A$ receptor current in locus coeruleus neurons during withdrawal syndrome of morphine dependent rats

Authors: *M. DAVOUDI, S. SEMNANIAN, H. AZIZI, J. MIRNAJAFI-ZADEH; Physiol., Sch. of Med. Sci., Tehran, Iran, Islamic Republic of

Abstract: The locus coeruleus (LC) is a sensitive site for expression of the somatic aspects of morphine withdrawal. The LC nucleus receives dense orexinergic projections from the hypothlamus, and is shown to express orexin type 1 and $GABA_A$ receptors. Some studies have shown that orexin-A and GABA transmitters are involved in morphine dependence and withdrawal syndrome. In this study, the effect of orexin type-1 receptor (OX1R) at the LC nucleus on inhibitory synaptic transmission in morphine dependence and withdrawal syndrome was investigated. **Materials and Methods: Whole-cell recording**: Wistar rats (P21-P28) were anaesthetised by ether and decapitated. The brain was quickly removed and trimmed in ice-cold (1-4°C. Horizontal slices of 300 μm thickness including the LC were made at 1-4°C. The slices incubated in a holding chamber with standard aCSF. The slices were then kept at room temperature. IPSCs were recorded at a holding potential of -70 mV. Each event of IPSCs was detected and its amplitude and frequency were measured. **Results:** The data presented here show that orexin induces an effect of inhibitory synaptic transmission to the LC neurons synapses. Several observations support this conclusion. First, in vitro application of orexin-A decrease spontaneous sIPSCs frequency of LC neurons, but does not change the sIPSCs amplitude. Second, Orexin-A application decreased the eIPSCs amplitude in LC neurons. Orexin-A induced IPSCs depression in LC neurons was antagonized by SB 334867, it is mediated through OX1 receptors. **Conclusion:** This finding, for the first time, implicates evidence that there is an interaction between orexinergic and GABAergic systems in the presence of naloxone in LC. It

seems that orexin-A might either act via OX1R in LC nucleus as an external factor or affect other substances such as GABAergic currents in this brain region to play its role in morphine dependency. **Key Wordes:** Locus coeruleus, Orexin-A, GABAergic currents, Whole-cell patch clamp recordings, Orexin type-1 receptor, SB-334867, Morphine, Rat

Title: Effect of methylphenidate on response inhibition of rats.

Authors: *D.-D. ZHANG, X.-H. ZHANG;
Inst. Of Neurobio. Fudan Univ., Shanghai City, China

Abstract: Response inhibition refers to the suppression of actions that are inappropriate in a given context and that interfere with goal-driven behavior. Attention-deficit/hyperactivity disorder (ADHD) is characterized by attentional dysfunction, impulsivity, and excessive motor activity levels. Studies in patients with ADHD have confirmed deficient response inhibition and its remediation by psychostimulant treatment. Methylphenidate (MPH; Ritalin) is the most effective and widely used form of therapy for ADHD. However, effect of MPH on response inhibition in health objects remains unclear. Here, we employed the stop signal task (SST) to examine effect of MPH on response inhibition in adult rats.

Title: Glutamatergic neurons in the basolateral amygdala and infralimbic cortex regulate impulsivity via connections to the ventral tegmental area

Authors: *B. JUPP[1], R. BARLOW[2], N. ARIAS[1], Y. BAI[3,4], S. WIJAYA[1], N. COLLINS[1], B. VAN DER VEEN[1], C. MCKENZIE[1], J. ALSIO[1], J. APERGIS-SCHOUTE[4], J. NICHOLSON[2], A. PEKCEC[2], T. W. ROBBINS[1], J. W. DALLEY[1,5];

Abstract: Impulsivity is defined as a tendency for premature, unduly risky and poorly conceived actions and as a behavioral trait is associated with a number of psychiatric disorders including attention deficit/hyperactivity disorder, substance abuse and addiction, mania and antisocial behavior. The neurobiological mechanisms underlying impulsivity are thought to involve dysfunction within cortico-striatal networks and impaired modulation by monoaminergic neurotransmission. Recent studies have shown that systemic as well as directed administration of NMDA receptor antagonists to the infralimbic cortex exacerbates impulsive responding on the five choice serial reaction time task (5CSRTT). However, it is unclear whether distinct populations of striatally-projecting glutamatergic neurons contribute to this effect. Using viral (AAV2)-mediated delivery of inhibitory (hM4Di) designer receptors exclusively activated by designer drugs (DREADDs) in CaMKIIα-expressing, glutamatergic projection neurons, we investigated the contributions of glutamatergic neurons of the basolateral amygdala (BLA), prelimbic cortex (PrL), infralimbic cortex (IL), and ventral hippocampus (vHC) to impulsivity on the 5CSRTT. Since these projection pathways also innervate the ventral tegmental area (VTA), we additionally examined whether effects on impulsivity were driven by interactions in the ventral striatum (VS) or VTA. We achieved this by targeted application of the DREADDs

ligand, clozapine-n-oxide (CNO, 1μM) to specifically inhibit glutamatergic projections to these regions. We first confirmed the ability of the DREADDs approach to inhibit remote neurotransmitter release, demonstrating a reduction in glutamate efflux in the VTA of animals expressing DREADDs in the IL cortex following CNO administration. Behaviorally, we found a significant effect of inhibition of glutamatergic projection neurons from both the IL cortex ($p=0.01$) and BLA ($p = 0.03$) to enhance premature responding on the 5CSRTT, specifically via projections to the VTA, but not the VS. Suppression of PrL and vHC glutamatergic neurons produced no significant effect on impulsive responding on the 5CSRTT. These results implicate a rather selective role of glutamatergic projection neurons in both the IL cortex and the BLA in impulsivity. This modulation appears to be exerted via projections to the VTA rather than the VS. Thus, previously hypothesized contributions of top-down glutamatergic projection systems to response inhibitory control may be preferentially exerted at the level of the dopaminergic VTA rather than different sub-regions of the ventral striatum.

Title: Dysregulated NMDA co-agonist signaling in the infralimbic cortex contributes to increased impulsivity during protracted alcohol abstinence

Authors: *C. IRIMIA, M. W. BUCZYNSKI, S. A. LAREDO, L. A. NATIVIDAD, N. AVALOS, L. H. PARSONS;
Committee on the Neurobio. of Addictive Disorders, The Scripps Res. Inst., LA Jolla, CA

Abstract: Abstinent alcoholics exhibit persistent impairments in the capacity for response inhibition, and this form of impulsivity is significantly associated with heightened relapse risk. Brain imaging studies implicate aberrant prefrontal cortical function in this behavioral pathology, though the underlying mechanisms are not understood. Here, we present evidence that deficient activation of glycine and serine release in the infralimbic cortex (IL) contributes to increased motor impulsivity during protracted abstinence from chronic alcohol exposure. Levels of 12 neurotransmitters were monitored in the rat IL during performance of a challenging variant of the 5-choice serial reaction time task (5-CSRTT) in which alcohol-exposed rats exhibit excessive premature responding. Following chronic ethanol exposure, rats showed blunted task-related recruitment of IL glycine and serine release, and loss of an inverse relationship between levels of these neurotransmitters and premature responding normally evident in alcohol-naïve subjects. Intra-IL administration of the glycine transport inhibitor ALX5407 prevented excessive premature responding by alcohol-exposed rats, and this was reliant on NMDA glycine site availability. Collectively these findings provide novel insight into cortical neurochemical mechanisms contributing to increased impulsivity following chronic alcohol exposure, and highlight the NMDA receptor co-agonist site as a potential therapeutic target for increased impulsivity that may contribute to relapse risk.

Title: Neural correlates of negative occasion setting in the orbitofrontal cortex

Authors: *J. L. SHOBE, L. D. CLAAR, K. BAKHURIN, S. MASMANIDIS;
UCLA, Los Angeles, CA

Abstract: Animals can use predictive cues to resolve situational ambiguity. For instance, neutral cues can, through learning, gain powerful inhibitory control over behavior. However, it is unclear how cortical circuits generate and maintain these kinds of inhibitory signals that are capable of modulating specific behavioral outcomes. To address this, we have adopted a simplified Pavlovian feature negative (FN) conditioning paradigm. In this paradigm, it is the

pattern of temporally separated cues (rather than any individual cue) that predicts the absence of a reward delivery. Specifically, mice learn that a reward follows an odor conditioned stimulus (CS1) presented alone, but if this odor is preceded by an air puff cue (CS2) the trial is unrewarded. Mice appear to solve this task using an occasion setting strategy because we observe that on a feature negative (FN) trial, the CS2 cue enters into a specific inhibitory feature-target relationship with the CS1 cue (target cue). Thus, we hypothesize that the CS2 acquires properties that allow it to initiate an inhibitory signal that coopts working memory to selectively gate the ability of the target cue to trigger reward representations. To examine this we conducted large-scale recordings in the orbitofrontal cortex (OFC), a region implicated in working memory. We have made a number of observations that are consistent with our hypothesis. First, we found that OFC activity to the CS1 cue was significantly diminished when it was preceded by the feature cue (FN trials). Therefore, the feature cue significantly dampened the ability of the CS1 cue to trigger its reward representation. Results from a transfer test suggested that this relationship was cue specific because the feature had very little inhibitory effect on OFC activity in a novel feature-odor pairing. In this instance, the odor (in the novel pairing) was able to trigger its reward representation despite following the feature cue. These findings fit well with our behavioral observations because mice withheld reward responses on FN trials but demonstrated typical reward responses during transfer trials. Finally, we observed a modest decrease in firing rate (relative to baseline) during the working memory phase of the FN trial, indicating the feature triggers a persistent and distinct neural state. Taken together our results suggest that, within cortical circuits, cue patterning displays inhibitory gating properties consistent with occasion setting behavioral properties.

Title: Joint modeling of perceptual decision making and response inhibition

Authors: *P. MIDDLEBROOKS[1], B. B. ZANDBELT[3], T. J. PALMERI[2], G. D. LOGAN[2], J. D. SCHALL[2];
[1]Psychology, [2]Vanderbilt Univ., Nashville, TN; [3]Donders Inst., Nijmegen, Netherlands

Abstract: Decision-making in perceptual discrimination has been explained as the outcome of stochastic accumulation of evidence for the alternatives. Response inhibition in the stop-signal (countermanding) task has been explained as the outcome of a race between stochastically independent GO and STOP processes. However, models of decision-making that execute response inhibition have only recently been formulated (Logan et al. 2014 Psych Rev). Here, we present progress on a interactive stochastic accumulator model to explain performance in a novel task that jointly tests perceptual decision making and response inhibition. Macaque monkeys reported with a saccade the color of a pattern that varied in color coherence. On a minority of trials a visual stop signal was also presented after a variable stop-signal delay. On no-stop signal trials reinforcement was earned for a correct choice. On stop signal trials reinforcement was earned for inhibiting the saccade. Behavioral results indicate that perceptual choice and response inhibition function independently (Middlebrooks & Schall 2014 Atten Percept Psychophys).
We have tested the simplest interactive race model consisting of 2 stochastic accumulators for each response alternative (GO1, GO2) plus a STOP accumulator. We consider three mechanisms of choice (race, feed-forward inhibition, and lateral inhibition between GO units) and one mechanism of inhibition (lateral inhibition from STOP to GO units).
We tested four versions of parametric manipulation in each model architecture. Drift rate was allowed to vary across choice difficulty in all four versions. Starting point, threshold, drift rate, and/or non-decision time were allowed to vary across response alternatives in across the versions.
We fit the three model architectures and each of their versions to the data to determine their account of correct and error RT distributions, accuracy, and SSRT across levels of discrimination difficulty and stop-signal delays. Each model architecture accounted for both choosing and stopping performance, with little distinction between the goodness of fit. Discrimination difficulty was accounted for by variation in drift rates. Response time directional biases were accounted for by variation in starting point, threshold, drift rates, and non-decision time. Response inhibition was accounted for by late but potent inhibition of the GO units by the STOP unit.
These results show how the two major models of decision making and performance can be unified. Ongoing neuronal recordings in the frontal eye field should resolve the model mimicry to further guide model selection.

Title: Medial prefrontal cortex event-related cue signalling is necessary for inhibitory control.

Authors: *K. MANSON, S. EBNER, B. JAMAL, J. ROITMAN;
Psychology, Univ. of Illinois At Chicago, Chicago, IL

Abstract: Environmental cues associated with rewards, such as food or substances of abuse, often prompt approach and consummatory actions that are difficult to override, even when restraint would be beneficial in the short- or long-term. As such, much research has focused on the neural underpinnings of behavior driven by cues, directed at obtaining reward. However, the neural systems that underlie restraint of behavior in response to reward related cues are not well understood, but play a critical role in maladaptive, impulsive actions. We hypothesized that medial prefrontal cortex (mPFC) and its communication with nucleus accumbens (NAc) play vital roles in such behavioral restraint. Using pharmacological manipulations and a Go/NoGo task with symmetric outcomes, we found that rats' ability to restrain approach behavior on NoGo trials was substantially reduced when glutamatergic AMPA/kainate, but not NMDA, receptors were blocked in NAc, suggesting that excitatory inputs inform NAc to inhibit approach behavior. We further hypothesized that mPFC serves as a source for this excitatory input. In support of this, bilateral inactivation of mPFC activity and disconnection of mPFC communication with NAc caused an increase in NoGo errors. Additionally, we implanted multiwire electrode arrays in the mPFC and recorded the activity of single neurons and characterized firing rate responses to task cues based on cell type, categorized by specific waveform characteristics. Neurons in mPFC showed greater transient responses at the onset of cues when the animal preformed correctly on both Go and NoGo trials. These results suggest that mPFC signals the appropriate action needed for optimal performance and that NAc integrates this signal to render appropriate approach/withhold behavior.

Title: Altered hippocampal coding from misassembly of full-length Disrupted-in-Schizophrenia 1 protein

Authors: *K. KAEFER[1], H. MALAGON VINA[1], D. DICKERSON[1], J. O'NEILL[1], S. V. TROSSBACH[2], C. KORTH[2], J. CSICSVARI[1];

Abstract: Disrupted-in-schizophrenia 1 (DISC1) is a gene associated with schizophrenia and other mental illnesses. One yet unexplored role DISC1 might have in the development of mental illness is the misassembly and aggregation of DISC1 protein in the brain (Leliveld et al., 2008). DISC1 protein assembly was mimicked by transgenically overexpressing non-mutant human DISC1 in rats (tgDISC1s) (Trossbach et al., 2016), resulting in phenotypes related to a dysfunction in the dopamine (DA) system. Here we performed *in vivo* tetrode recordings of dorsal CA1 place cells in tgDISC1s exploring a familiar and novel open-field and sleeping in the following order: familiar – sleep – novel – sleep. In both open-field explorations tgDISC1 place cells had smaller field sizes and consequently higher spatial information. Improved spatial coding however was accompanied by deficits in the coding of other variables: tgDISC1 place cells showed 1) a lower coefficient of variation in spike numbers occurring in the placefield, 2) less speed modulation of their firing rate, 3) locking to a broader distribution of theta phases and no novelty-induced shift in preferred theta phase, and 4) increased reactivation in sleep after exploration of the familiar environment, but a reduction after exploration of the novel environment. In light of the DA phenotype of tgDISC1s the above results possibly suggest a DA-mediated disturbance in plasticity and novelty detection.

Title: Chronic calcineurin inhibition impairs visuospatial learning after isoflurane anesthesia

Authors: *I. A. SPEIGEL[1], J. A. FIDLER[1], C. M. MA[2], S. HESSE[1], E. K. BICHLER[1], J. L. GOOCH[3,4], P. S. GARCIA[1,4];

Abstract: There is great variability in the recovery of executive function, particularly memory, after general anesthesia. Patients with neurodegenerative diseases (e.g. Alzheimer's disease) are at greater risk for prolonged hypoactivity after anesthesia. Calcineurin (CN), a phosphatase activated by low levels of intracellular calcium, has been implicated in the pathogenesis of neurodenerative disease and has been thought to mediate isoflurane-induced toxicity in cultured neurons. CN is directly involved in GABAA receptor (GABAAR) trafficking and synaptic plasticity, by controlling GABAAR surface expression via regulatory sites on the GABAAR γ2 subunit. For decades, calcineurin inhibitors such as cyclosporine A (CSA) have been standardized therapy for organ transplantation or autoimmune diseases, but the potential for chronic use to affect the response to anesthesia is unclear.To investigate potential overlapping mechanisms of CN-mediated changes in GABAAR surface expression and isoflurane neurotoxicity, we conducted in vitro studies in primary hippocampal neuron cultures (DIV17-22) using cell-surface biotinylation, western-blot analysis, and immunostaining. We found that regardless of CSA pretreatment, one hour of isoflurane had no significant effect on β2 or γ2 subunits surface expression, nor in caspase-3 cleavage.In addition, we investigated the effect of chronic CSA treatment on post-anesthetic cognitive behavior. Adult mice ingested CSA or vehicle for 12 days prior to either 30 minutes of isoflurane anesthesia or sham treatment. Visuospatial learning was assessed via the water radial arm maze during the 3-14 days following anesthesia. Ambulation and exploratory activity were recorded via the Oxymax automated monitoring system. We found that chronic CSA significantly impaired the post-anesthetic recovery of both visuospatial learning and exploratory activity. Currently, we are undertaking experiments to characterize the changes to inhibitory network function that underlie this phenotype. Brain slices containing hippocampus and temporal cortex were harvested for

biotinylation-based measures of GABAAR surface expression. We also measured total protein expression of key GABAAR subunits as well as caspase-3 and GAD67, the GABA synthesis enzyme. Our studies suggest that under chronic CSA treatment, isoflurane anesthesia triggers the development of adverse neurological changes that impair memory and wakefulness. Therefore, we speculate that patients receiving CSA may be an at-risk group for post-anesthetic cognitive dysfunction.

Title: The long-term estrogen-induced facilitation of NMDA receptor synaptic function is mediated through altered redox state

Authors: *A. KUMAR[1], L. BEAN[3], A. RANI[2], T. C. FOSTER[2];
[1]Dept Neuroscience, McKnight Brain Inst., [2]Univ. of Florida, Gainesville, FL; [3]Neurolog. Sci., Rush Univ. Med. Ctr., Chicago, IL

Abstract: A decline in estradiol (E2)-mediated cognitive benefits denotes a critical window for the therapeutic effects of E2. Our recent results demonstrate that the window for E2-mediated benefits on cognition and hippocampal E2 responsiveness can be reinstated by upregulation of estrogen receptor alpha. Further, the beneficial effects on cognition are associated with an increase in N-methyl-D-aspartate receptor (NMDA) receptor mediated synaptic function; however the mechanisms for the increase in NMDA receptor function is unknown. Here, we hypothesized that a NMDA receptor hypofunction, starting in middle-age, will be ameliorated by an E2-induced reduction in redox state. Furthermore, the ability of E2 to influence the redox mediated NMDA receptor hypofunction will decline in the oldest animals (i.e. following closing

of the therapeutic window). We employed female Fisher 344 rats at ages that are on both sides of the therapeutic window (middle aged (MA): 12 months; aged: 20 months) whose ovaries had been removed ~ a week earlier and were injected with cyclic injections of 17β-estradiol-3-benzoate (EB, 10 μg, sc) or oil vehicle, for six to twelve weeks. Starting 48 hr after the final injection, we performed *in vitro* electrophysiological recording from CA3-CA1 hippocampal synapses, and measured total field excitatory postsynaptic potentials and NMDA receptor mediated synaptic responses. After isolating NMDA receptor mediated synaptic responses, we analyzed effect of a reducing agent, dithiotreitol (DTT) on NMDA receptor mediated synaptic transmission. Input/output (I/O) curve confirmed an EB-induced increase in NMDA receptor responses limited to MA animals ($p = 0.046$, n = 8/8 slices). The lack of an effect in aged animals is indicative that the therapeutic window was closed. Following collection of I/O curves, baseline NMDA receptor mediated synaptic responses were collected and DTT (0.5 mM) was bath applied and responses were followed for 60 minutes. An ANOVA across treatment groups indicated a trend for a treatment effect on the DTT-mediated growth of the response (EB vs Oil $p = 0.068$; 21/17 slices), which was largely due to MA animals (EB vs Oil; $p = 0.053$; n = 8/7). In fact, one group *t*-test on the percent increase in the NMDA receptor synaptic response relative to the baseline indicated that all groups (Aged-EB: 127.1 ± 8.9% of baseline, n = 13; Aged-Oil: 133.8 ± 6.8, n = 9; MA-Oil: 139.9 ± 11.8, n = 7) except MA-EB injected (109.5 ± 6.8, n = 7) exhibited a DTT-mediated facilitation of NMDA receptor response. These results suggest that, prior to closing of the therapeutic window, the E2-induced increase in NMDA receptor mediated synaptic function is due to a shift in redox state.

Title: Expression of G-protein estrogen receptor 1 (GPER1) in the hippocampus and prefrontal cortex over the oestrous cycle: Influence of ovariectomy and aging

Authors: *A. RANI[1], S. KERIC[1], L. BEAN[2], J. BARTER[1], T. C. FOSTER[1], A. KUMAR[1]; [1]Univ. of Florida Med. Col., Gainesville, FL; [2]Rush Univ. Med. Ctr., Chicago, IL

Abstract: Many of the rapid effects of estradiol are diametrically opposite to changes observed in aged memory impaired animals. Estradiol rapidly increases cell excitability and the strength of synaptic transmission. However, the effect of estradiol may decline with advanced age or prolonged estradiol deprivation, contributing to the closing of the therapeutic window. The decline in estradiol responsiveness is associated with altered expression of estrogen receptors. Evidence suggests that the orphan G protein-coupled estrogen receptor 1 (GPER1) mediates the estradiol-induced rapid increase in synaptic strength at CA3-CA1 synapses in females. The current study was designed to analyze GPER1 expression during the estrous cycle, hormonal deprivation, and senescence. We employed Western blotting to investigate expression of GPER1 in the dorsal hippocampal areas CA1, CA3, DG, and prefrontal cortex (PFC) throughout the estrous cycle in young: 3-4 months female Fischer 344 rats. Vaginal lavage was performed each day for 2-3 weeks to confirm an estrous cycle (diestrus, estrus, metestrus, proestrus). Following confirmation of estrous cycle, animals were euthanized and tissues were collected and stored at -80 for Western blot analysis. Results demonstrate that there was not a significant change in GPER1 expression in the hippocampus or the PFC across the estrus cycle (n = 5-6/cycle) of young animals. A second study examined GPER1 expression during aging in intact animals and 3-4 weeks following ovariectomy (OVX) for aged (21-24 months, n = 12) and young animals (2-4 months, n = 24-30 (all estrus cycles included as non OVX)). Western blot analyses demonstrate a significant decrease ($p<0.0001$) in GPER1 expression in the area CA1 regardless of OVX/non OVX state. A tendency for an age-related decline in the DG ($P=0.063$) was due to the fact that OVX decreased expression in young relative to non OVX young ($P<0.05$). No age-associated difference in GPER1 expression was observed in area CA3 and PFC. However, there was a tendency for expression to decrease in the PFC of young OVX vs young non OVX ($p=0.053$). These results indicate that prolonged hormone deprivation in young or advanced age may cause a decrease in GPER1 expression in different areas of the brain. Future studies will determine if these alterations in GPER1 expression contribute to impaired cognitive and synaptic function over the life span.

Title: Systemic inflammation contributes to the onset of cognitive impairment associated with senescence

Authors: *J. D. BARTER[1], A. KUMAR[2], A. RANI[2], T. C. FOSTER[2];
[1]Col. of Med. - Neurosci., [2]Univ. of Florida, Gainesville, FL

Abstract: Systemic inflammation and associated serum cytokines are thought to induce a latent neuroinflammatory response in specific brain regions. Furthermore, pro-inflammatory cytokines increase in the serum during normal aging and the level of several cytokines is correlated with age-associated cognitive impairments. Episodic memory impairments begin to emerge in middle-age and we hypothesize that systemic cytokines contributes to the onset of impaired hippocampal-dependent spatial learning and memory. For all studies, a low dose (0.25 μg/kg, ip) of lipopolysaccharide (LPS) or vehicle was injected into young (4-6 months, n=18) and middle aged (12-14 months, n=16) Fischer 344 male rats. We examined 11 cytokines by using Multiplex technology at two different time points following LPS injection, 4 hours following one injection (acute effects: young, n =8, middle aged, n = 8) or 48 hours after seven injections delivered on alternated days (chronic effects: young, n =8, middle aged, n = 8). For the chronic LPS study, learning and memory was assessed 48 hr after the fourth injection using the water maze task as described previously. The results indicate that four hours after a single LPS treatment, IL-1α, IL-1β, IL-6, 1P-10, MCP-1, GRO/KC, and RANTES levels were significantly ($p < 0.05$) elevated in blood plasma. MCP-1 and Eotaxin displayed a significant ($p<0.05$) age and treatment effect with higher concentrations in middle aged LPS injected animals. In contrast, IL-12p70 levels exhibited an age effect where young animals had significantly ($p=0.018$) elevated IL-12p70 compared to older animals. For chronic LPS treatment, the results revealed no effect of treatment on cytokine levels 48 hours after the last LPS injection, indicating that cytokine elevation was not long lasting. The behavioral results indicate a trend ($p=.16$) for spatial memory decline 48 hours after the seventh LPS injection in middle aged animals compared to middle aged rats

injected with vehicle only. This trend was not reflected in the younger animals. These results demonstrate that systemic inflammation-induced a transient increase in cytokine levels. Further, while cytokine levels decline back to baseline over a 48 hours period, these cytokines may have longer-lasting influence on the brain function and contribute to the onset of cognitive decline during aging.

Title: Up regulation of GluN2B type NMDA receptor in CA1 region of hippocampus and its influence on cognitive and synaptic function

Authors: *C. KYRITSOPOULOS, A. KUMAR, T. C. FOSTER;
Neurosci., Univ. of Florida, Gainesville, FL

Abstract: The N-methyl D-aspartate (NMDA) receptor is a critical mediator of the changes in synaptic strength that underlie learning and memory. Mounting evidence indicates NMDA receptor function declines with advanced age, and that this decrease is associated with cognitive deficits. Our previous work demonstrates that age-related impairments in episodic spatial memory are related to NMDA receptor hypofunction localized in region CA1 of the hippocampus, and aged animals are more susceptible to cognitive impairment due to a low dose of the activity-dependent NMDA receptor antagonist, MK-801. On the other hand, the idea that cell death in Alzheimer's disease is associated with over activity of NMDA receptor, provides part of the basis for the use of the low affinity activity-dependent NMDA receptor antagonists. Thus, it is important to understand how NMDA receptor function interacts with normal aging and in age-related neurodegenerative diseases. Upregulation of the GluN2B subunit of NMDA receptor can protect against cognitive decline in mice; however, it is unclear if the effects result

from increased activity during development, resulting in a "biological reserve" against aging. To determine whether enhancing NMDA receptor function in older animals can protect against memory deficits and enhance NMDA receptor mediated synaptic transmission, we are employing a viral vector-based approach to upregulate GluN2B targeted to the CA1 region of the hippocampus. Lentivirus containing a synapsin promoter to drive green fluorescent protein (GFP) followed by a self-cleaving 2A peptide and GluN2B was injected into the hippocampus of male Fischer 344 rats. Hippocampi were collected at 2 and 4 weeks post-surgery, and expression was verified for GFP and GluN2B via fluorescent microscopy and quantitative Western blotting. Examination of the *in vivo* time course indicates that expression continues to increase from 2 to 4 weeks post vector injection. The extent of expression is estimated at ~1 mm^2. Currently, young (5 mo) and older (15 mo) F344 male animals are receiving bilateral injection of lentivirus containing the GluN2B+GFP vectors or GFP alone, and 4-5 weeks following vector injection, behavior and NMDA receptor-mediated synaptic function will be assessed over the life span.

Title: Circuitry of adult- and developmentally-born neurons in the mouse dentate gyrus

Authors: *E. C. JANKE[1], C. VIVAR[2], H. VAN PRAAG[1];
[1]Neuroplasticity & Behavior Unit, Lab. of Neurosci., Natl. Inst. On Aging, Baltimore, MD;
[2]Dept. of Physiology, Biophysics, and Neurosci., Ctr. for Res. and Advanced Studies of the Natl. Polytechnic Inst., Mexico City, Mexico

Abstract: The dentate gyrus (DG) of the hippocampus consists of a large population of developmentally-born granule cells (dGC) and a smaller number of adult-born granule cells (aGC). These GC populations have distinct neuroanatomical and physiological characteristics, providing the DG with unique computational properties to process incoming information. The dGCs are positioned in the middle/outer granule cell layers (GCL) and exhibit low activity/excitability, whereas aGCs are generally located in the inner GCL and exhibit transiently increased synaptic plasticity. The aGCs are considered important for the processing of similar incoming stimuli. Analysis of the neuronal circuitry of aGCs using a combination of retroviral

and rabies virus mediated neuroanatomical tracing showed that these neurons receive preferential input from the lateral entorhinal cortex, which may promote pattern separation processes. However, less is known about the functional contribution and connectivity of dGCs. We have now used the same dual virus approach to delineate the neural circuitry of dGCs. In order to specifically label dividing cells, retrovirus expressing green fluorescent protein, avian TVA receptor and rabies glycoprotein was injected into the DG of mouse pups on postnatal day 1 (P1). Two months thereafter, these mice were injected with EnvA-pseudotyped rabies virus expressing MCherry (MCh) in the DG for retrograde tracing. One week later mice were deeply anesthetized and perfused. Preliminary histological analysis of MCh-expressing afferent cells shows that dGCs receive input from similar regions as aGCs, predominantly from the entorhinal cortex, septum, and intra-hippocampal inputs 8 weeks after cell division. Quantification and characterization of presynaptic cells from these various regions may reveal specific differences in the phenotype of the cells and proportion of input to dGCs in comparison to aGCs. Ultimately, analysis of direct inputs onto dGCs may illuminate the type of information these cells process, providing a better understanding of DG function.

Title: Attenuated late-phase Arc transcription in the dentate gyrus of mice lacking Egr3

Authors: *A. L. GALLITANO[1], A. M. MAPLE[1], R. LACKIE[2], D. I. ELIZALDE[1], S. L. GRELLA[2], D. F. MARRONE[2];
[1]Basic Med. Sci., Univ. of Arizona, Phoenix, AZ; [2]Dept. of Psychology, Wilfrid Laurier Univ., Waterloo, ON, Canada

Abstract: The dentate gyrus (DG) engages in sustained activity-regulated cytoskeleton-associated protein (*Arc*) transcription for at least 8 hours following behavioral induction. Moreover, this time course is functionality coupled to its unique role in learning and memory.

The factors that regulate this spatio-temporal pattern of *Arc* expression, however, remain poorly understood. Previous findings show that mice deficient for early growth response 3 (*Egr3*) express lower levels of *Arc* following seizure. However, the effect of *Egr3* ablation on behaviorally-induced *Arc* expression remains unknown. This is important to characterize, since the pattern of immediate early gene expression following supra-physiological stimulation often differs from the pattern induced by spatial processing. To address this, *Egr3*$^{-/-}$ and wildtype mice were placed in a novel environment and allowed to explore for five minutes. Groups of animals were sacrificed 5 minutes (m), 60m, 240m, or 480m later, and *Arc* expression in the DG was quantified using fluorescence *in situ* hybridization. Results showed that *Arc* expression at 240m and 480m after spatial exploration is selectively reduced in *Egr3*-/- mice. These data indicate that *Egr3* plays a critical role in regulating the late, protein-dependent phase of *Arc* expression in the mouse DG.

Title: Episodic-like memory and Arc expression in Goto-Kakizaki rats

Authors: *D. F. MARRONE, B. RENDA;
Wilfrid Laurier Univ., Waterloo, ON, Canada

Abstract: Diabetes mellitus is a common metabolic disorder that has steadily increased in prevalence over the past five decades. Although type I and type II diabetes differ in their pathophysiology, both types are characterized by hyperglycemia, and both types have been associated with cognitive decline and increased risk of dementia. To further investigate the link between chronic hyperglycemia and cognitive ability, here we test both memory performance and hippocampal function in the Goto-Kakizaki (GK) rat, which is selectively bred to have persistent hyperglycemia in the absence of obesity. Preliminary data indicate that GK rats show deficits, relative to Wistar rats of the same age, in performance of a what-where-when test of

episodic-like memory. Further testing is being conducted to determine if the pattern of expression of *Arc* (an immediate-early gene critical for memory function) is altered in the hippocampus of GK rats during the completion of this task, or following spatial navigation. Analysis will focus on the dentate gyrus as the most likely brain region to mediate performance in a task with high-interference stimuli. Results of these tests will help to functionally link persistent hyperglycemia to changes in hippocampal physiology.

Title: Role of CCR5 in learning and memory and in HIV V3 peptide induced cognitive deficits

Authors: ***M. ZHOU**[1], S. GREENHILL[2], S. HUANG[1], T. SILVA[1], Y. SANO[1], S. WU[1], Y. CAI[1], Y. NAGAOKA[1], M. SEHGAL[1], D. CAI[1], Y.-S. LEE[1], K. FOX[2], A. J. SILVA[1]; [1]Neurobio., Univ. of California Los Angeles, Los Angeles, CA; [2]Cardiff Univ., Cardiff, United Kingdom

Abstract: Cognitive deficits are a significant clinical problem associated with HIV infection. Although the role of CCR5 in immunity and in HIV infection has been studied widely, its role in neuronal plasticity, learning and memory, and in HIV-associated cognitive deficits is not well understood. In a reverse genetic screen, we found that a *Ccr5* null mutation results in hippocampus-dependent memory enhancements. Molecular and cellular studies indicated that the memory enhancement is caused by increases in MAPK/CREB signaling and enhanced long-term potentiation (LTP). *Ccr5* knockdown in the hippocampus of adult mice also led to enhancements in hippocampal memory, thus confirming a role for this receptor in adult plasticity and memory. These results suggest that besides its role as a co-receptor for HIV, CCR5 is a powerful suppressor for learning and memory, and that CCR5 over-activation by viral peptides may contribute to HIV-associated cognitive deficits. Consistent with this hypothesis, the HIV V3 loop peptide, known to bind and activate CCR5, caused deficits both in signaling implicated in learning and memory (hippocampal MAPK activation) and in a key cellular mechanism for

learning and memory (LTP). Accordingly, acute hippocampal injection of V3 peptide also caused memory deficits. Importantly, V3 peptide induced signaling, LTP and memory deficits were prevented by a *Ccr5* knockout. Overall, our results demonstrate that CCR5 plays an important role in plasticity and memory, and CCR5 over-activation may contribute to the cognitive deficits caused by HIV coat proteins.

Abstract: In the last few decades, there have been significant advances in the molecular, cellular and systems mechanisms underlying the storage of single memories. Real-world memory, however, involves the integration of multiple memories across time, with one memory affecting how others are processed and stored. Recent memory allocation studies suggest the hypothesis that a shared neural ensemble may link distinct memories encoded close in time. Using in vivo calcium imaging (with head-mounted fluorescent microscopes in freely behaving mice), TetTag transgenic system, chemogenetics, electrophysiology and novel behavioral designs, we tested key predictions of the memory allocation hypothesis in hippocampal networks. According to this hypothesis, learning triggers a temporary increase in neuronal excitability that biases the representation of a subsequent memory to the neuronal ensemble encoding the first memory, such that recall of one memory increases the likelihood of recalling the other memory. Accordingly, we report that the co-allocation between the hippocampal CA1 ensembles activated by two distinct contexts acquired within a day is higher than when the two contexts are separated by a week. Multiple convergent findings indicate that this co-allocation of neuronal ensembles links two contextual memories. First, fear paired with one context is transferred to a neutral context when the two are acquired within a day but not across a week. Second, the first memory strengthens the second memory within a day but not across a week. Older mice, known to have lower CA1 excitability, do not show the co-allocation between ensembles, the transfer of fear between contexts or the strengthening of the second memory. Finally, in aged animals, increasing cellular excitability and activating a common ensemble of CA1 neurons during two distinct context exposures rescued the deficit in linking memories. Taken together, these findings demonstrate that contextual memories encoded close in time are linked by directing storage into overlapping ensembles. Alteration of these processes by aging could affect the temporal structure of memories, thus impairing efficient recall of related information.

Title: Effects of isoproterenol in the dentate gyrus on spatial memory retrieval and reversal learning

Authors: *B. RENDA[1], S. L. GRELLA[1], S. M. GOMES[1], D. F. MARRONE[1,2];
[1]Psychology, Wilfrid Laurier Univ., Waterloo, ON, Canada; [2]McKnight Brain Inst. (Univ. of Arizona), Tucson, AZ

Abstract: Contextual information is represented in the hippocampus (HPC) partially through recruitment of distinct populations of neurons. We have recently shown that norepinephrine (NE) input from phasic locus coeruleus activation can induce plasticity in the HPC resulting in global remapping of these representations. We hypothesize that NE may provide a molecular switch to cause the HPC to move from a state of retrieval to a state of encoding. This hypothesis suggests that the effect of modulating NE on memory will critically depend on the stage of training. To further understand how NE modulation of hippocampal circuits affects spatial memory, we tested whether infusions of the β-adrenergic agonist isoproterenol (ISO) impaired working and reference memory retrieval (i.e. switching the system back to encoding when it is maladaptive) and facilitated cognitive flexibility thus improving reversal learning (i.e., switching the system back to encoding when it is adaptive). We employed a delayed non-match to position (DNMP) task in a 12-arm radial maze, and a spatial learning task in the Barnes maze. DNMP: Using extra-maze spatial cues, rats learned to obtain a reward from one arm of the maze (sample phase, encoding) and 10 min later were given a choice between the previously rewarded arm and a newly baited arm (choice phase, retrieval). As the distance between the arms narrowed during the choice phase, the task became more dependent on the dentate gyrus (DG) of the HPC. Bilateral DG infusions of ISO were administered prior to encoding or retrieval and choice accuracy was measured. Barnes Maze: Motivated by bright light and open space, rats used extra-maze spatial cues to learn the location of an escape hole leading to a dark escape box beneath an elevated circular platform. Immediately prior to a probe test, bilateral DG infusions of ISO were administered and memory accuracy was measured. Rats were then retrained to reduce possible extinction associated with the probe trial. Then, prior to reversal training, which lasted 5 days, rats were given another bilateral DG infusion of ISO and reversal learning was assessed during a probe test. Title: Memory enhancement increases dendritic spine turnover and clustering in retrosplenial cortex

Authors: *S. HUANG[1,2], A. FRANK[3], M. ZHOU[1,2], X. WEN[4], T. SILVA[1,2], J. TRACHTENBERG[1,2], A. SILVA[1,2];

Abstract: Dendritic spines are the postsynaptic sites of excitatory synapses on pyramidal neurons. Structural plasticity mediated by addition and elimination of dendritic spines is thought to underlie the formation of long-term memory. Here, we performed in vivo imaging of dendritic spines in mouse retrosplenial cortex (RSC) before and during learning. We report that spine turnover prior to learning predicts future learning performance in contextual fear conditioning and Morris water maze. Contextual and spatial learning lead to addition of new spines that are spatially clustered in RSC. Importantly, these newly formed clustered spines are highly stable after training ends. Remarkably, compared to wild type littermates, CCR5 mutant mice, known to have enhanced memory for contextual and spatial learning, show higher spine turnover ratio before learning as well as higher proportion of clustered new spines induced by learning. One implication of these findings is that increased spine turnover allow neurons to more efficiently sample the synaptic space during learning in order to optimize information acquisition. Once acquired, spine clustering may stabilize this information, thus strengthening memory circuits.

Title: Context-dependent Egr1 expression in the hippocampus of the Japanese Quail

Authors: *N. MILLER[1], E. GUNNING[1], D. F. MARRONE[1,2];
[1]Dept. of Psychology, Wilfrid Laurier Univ., Waterloo, ON, Canada; [2]McKnight Brain Inst., Univ. of Arizona, Tucson, AZ

Abstract: Previous work by our lab has demonstrated that the avian hippocampus expresses gene products of EGR1 (also called ZENK) in a context-dependent manner during a spatial learning task. The pattern of expression seemed to carry less spatial information than mammalian cells, but this may be a reflection of differences in behavior, rather than physiology. Examining *Egr1* expression in a non-flying species (Japanese Quail) under conditions that more closely match those employed for mammals will help to address this issue. Preliminary data show that under these conditions the pattern of *Egr1* expression in the avian hippocampus more closely resembles the pattern observed in mammals. That is, when quail were allowed to explore a single open environment twice, the vast majority of hippocampal cells expressed *Egr1* during both explorations. In contrast, when two highly distinct environments were visited the probability of the same cell expressing *Egr1* during both explorations was close to chance. Moreover, granule cells (identified by the expression of Prox1) showed a much lower probability of repeated activation than non-granule counterparts, similar to the pattern observed in mammals. Further investigation of differences in the pattern of *Egr1* expression along anatomical gradients (e.g., dorsal-ventral, rostral-caudal) will help to further clarify the comparative physiology of the spatial learning systems among these classes.

Abstract: Previous studies have demonstrated that changes in neuronal excitability determine whether a given neuron will be involved in storing a specific memory (memory allocation)[1,2]. The memory allocation hypothesis posits that the encoding of one memory may trigger a transient increase in excitability in neurons involved in storing that memory, such that for a period of time, neurons involved in storing the first memory are preferentially recruited to store subsequent memories[3]. There is now compelling evidence that demonstrates that the co-allocation of hippocampal CA1 ensembles activated by two distinct contexts acquired across five hours is higher than when they are separated by one week[4]. Furthermore, the co-allocation of memories into similar neuronal ensembles behaviorally links the two contextual memories such that 1) the recall of a given memory triggers the recall of a linked memory and 2) the encoding of one memory enhances a subsequent memory. Here, we investigate the time course of these three processes. We found that the three processes appear to follow a similar time course. Co-allocation, linking and enhancement of two contextual memories are highest when memories are acquired within the same day and begin to decrease when separated by more than one day.

Title: Norepinephrine as a memory reset signal: phasic activation of the locus coeruleus drives global remapping in the hippocampus

Authors: *S. L. GRELLA[1], J. NEIL[2], V. D. STRONG[2], I. V. ODINTSOVA[1], G. MARTIN[2], C. W. HARLEY[2], D. F. MARRONE[1,3];
[1]Dept. of Psychology, Wilfrid Laurier Univ., Waterloo, ON, Canada; [2]Psychology, Mem. Univ. of Newfoundland, St. John's, NL, Canada; [3]McKnight Brain Inst. (Univ. of Arizona), Tucson, AZ

Abstract: The locus coeruleus (LC) responds to novelty in the environment and sends a major noradrenergic projection to the hippocampus (HPC). It is hypothesized that novelty-associated activation of the LC may help to sculpt representations in the HPC, but influence of norepinephrine (NE) over HPC representations remains poorly understood. One possible mechanism is that NE may provide a “reset” signal causing the HPC to recruit distinct populations of neurons (neuronal ensembles). Thus, NE may provide a molecular switch to

dictate if hippocampal circuits should generate new representations or update existing representations to incorporate novel information. This hypothesis suggests that agonism of the NE system should cause the hippocampus to recruit a unique population even in the presence of the same stimuli an animal has just experienced. The compartmental expression of *Arc* and *zif268* allows us to test this hypothesis by mapping the activity history of individual HPC neurons as animals engage in spatial processing following manipulation of the NE system. Rats were placed in either the same context twice (A/A) or two different contexts (A/B). Prior to placement in the second context, separate groups of rats were infused bilaterally in the LC with glutamate (phasic LC activation) or clonidine (blockade of LC discharge). Additional groups were infused bilaterally with orexin A, bethanachol, and CRF (tonic LC activation). Remapping was assessed in the dentate gyrus, the CA3 and the CA1. Preliminary data show that phasic, but not tonic, LC activation can drive global remapping in the HPC, consistent with the notion of NE as a novelty "reset signal" for hippocampal mnemonic circuits from retrieval to encoding.

Title: An analysis of nrf2 expression and its effects on aging hippocampal neural stem cell function

Authors: *M. J. CORENBLUM[1], S. RAY[2], D. D. ZHANG[3], C. A. BARNES[4], L. MADHAVAN[5];
[1]Neurol., [2]Neurosci. and Cognitive Sci. Undergraduate Program, [3]Dept. of Pharmacol. and Toxicology, [4]Departments of Psychology and Neurosci., [5]Dept. of Neurol., Univ. of Arizona, Tucson, AZ

Abstract: Our recent work has examined the dynamics of neural stem progenitor cell (NSPC) function in the subventricular zone (SVZ) of aging animals (Corenblum et al., 2016). These studies have identified a critical time-period during middle-age (13-15 mos), when a marked reduction in NSPC survival and regenerative capacity occurs, and determined the reduced

expression of the redox-sensitive transcription factor, nuclear factor (erythroid-derived 2)-like 2 (Nrf2), as an important mechanism underlying this phenomenon. Given this, in the current study we analyzed the function, and Nrf2 expression, of NSPCs residing within the other major mammalian germinal niche, the dentate gyrus (DG) of the hippocampus. More specifically, using cells from seven groups of aging male Fisher 344 rats (0, 2, 9, 11, 13, 15 and 24 mos) we found that, similar to SVZ NSPCs, the proliferative capacity of cultured DG NSPCs also declined substantially during the 13-15 month critical period. However, the survival of the DG NSPCs was only compromised significantly ($p<0.05$) from the 0 to 2 mos old stage, after which it remained relatively stable throughout adulthood until old age (24 mos). Correlatively, the number of Nrf2 expressing DG NSPCs was also prominently reduced from 0 to 2 mos of age, with no further changes in Nrf2 labeled cell numbers noted across the age groups. Immunohistological assessment of hippocampal tissues from the various groups of aging animals confirmed the results from the *in vitro* analysis. Furthermore, at a behavioral level, these data correlated with a decline in spatial memory when the animals were tested via a Morris water maze task. Here it was observed that increasingly more time was taken by the animals to learn the location of the hidden platform (higher CIPL scores) with advancing age, and that the 15 mos old rats were the first adult age-group exhibiting a significant decrement in spatial memory function. Based on these results, we are currently further examining Nrf2's role in DG NSPC function using Nrf2 knock-out (Nrf2 -/-) mice, as well as tissues from young and old non-human primates. Overall, this work will provide important information on whether and how Nrf2 regulates DG NSPC activity with age.

Title: The role of medial entorhinal cortex activity in hippocampal feature selectivity and memory function

Authors: *N. T. ROBINSON, J. B. PRIESTLEY, J. W. RUECKEMANN, A. D. GARCIA, V. A. SMEGLIN, F. A. MARINO, H. B. EICHENBAUM;
Ctr. for memory and brain, Boston Univ., Boston, MA

Abstract: The hippocampus is crucial for episodic memory and certain forms of spatial navigation. Firing activity of hippocampal principal neurons contains environmental information, including the presence of specific objects, as well as the animal's spatial and temporal position relative to environmental and behavioral cues. The organization of these firing correlates may allow the formation of memory traces through the integration of object and event information onto a spatiotemporal framework of cell assemblies. Characterizing how external inputs guide internal dynamics in the hippocampus to enable this process across different experiences is crucial to understanding hippocampal function. A body of literature implicates the medial entorhinal cortex (MEC) in supplying spatial and temporal information to the hippocampus. Here we develop a protocol utilizing bilaterally implanted triple fiber optic arrays and the red-shifted inhibitory opsin JAWS to transiently inactivate large volumes of MEC in freely behaving rats. This was coupled with extracellular tetrode recording of hippocampal CA1 ensembles during an object-delay-response association task involving temporal, spatial and object related epochs, enabling assessment of the importance of MEC activity for hippocampal feature selectivity during a rich and familiar experience. We report that inactivation of MEC during a mnemonic delay selectively disrupts the existing time cell sequence structure in CA1 and the ability of individual neurons to fire in a temporally tuned manner during and following the inactivation period. Neurons with firing fields prior to the inactivation on each trial remained relatively stable. The disruption of CA1 time cell sequences was accompanied by a behavioral deficit implicating MEC activity and hippocampal temporal field sequences in effective memory across time. Inactivating MEC during the object or spatial epochs of the task did not significantly alter CA1 object selective or spatial firing fields and behavioral performance remained stable during these inactivation protocols. We observed highly object selective firing which precessed relative to local LFP theta. Our findings suggest that MEC is crucial specifically for temporal field organization and expression during a familiar and proximally rich experience. These results support a role for MEC in guiding hippocampal cell assembly sequences in the absence of salient changing stimuli, which may extend to the navigation of cognitive organization in humans and support memory formation and retrieval.

Title: Long-term stability of hippocampal ensemble sequences

Authors: *W. MAU, D. W. SULLIVAN, N. R. KINSKY, P. BIDSHAHRI, H. EICHENBAUM; Boston Univ., Boston, MA

Abstract: The mammalian hippocampus is crucial for encoding the spatial and temporal features of episodic memories. Previously published work has shown that elapsed time is tracked by sequential activity of hippocampal neurons in the absence of changing extrinsic input (MacDonald et al., Neuron 2011; Pastalkova et al., Science 2008). These internally generated sequences, comprised of "time cells", are thought to organize memory by binding temporally discontiguous events and associating features of the environment that are proximal in time. Until now, the long-term properties of these sequences and how their day-by-day stability relates to temporal coding have not been characterized. We trained mice to run on a treadmill for fixed delay periods in between laps on a rectangular track and used *in vivo* calcium imaging to observe the stability of hippocampal sequences during the delay across days. Here, we present preliminary data suggesting that the temporal tuning fields of time cells are retained for multiple days. The persistence of these responses lends credence to the idea that the hippocampus upholds sequential firing patterns for long-term maintenance and storage of temporal representations.

Title: Investigating intrinsic hippocampal circuitry during temporal encoding in spatial working memory

Authors: *R. J. PLACE[1], J. RUECKEMANN[2], H. EICHENBAUM[2];
[1]Boston Univ., Cambridge, MA; [2]Boston Univ., Boston, MA

Abstract: Interactions between the hippocampus and entorhinal cortices have been implicated in the creation of spatiotemporal trajectories used in organizing episodic memories. Both spatial and temporal properties have been observed in neurons in the medial entorhinal cortex (MEC) and hippocampus (Kraus et al., 2013; Kraus et al., 2015), but the mechanisms reponsible for generating these signals remains unclear. Here we report that transient disruptions of intrinsic hippocampal circuitry, via stimulation of the ventral hippocampal commisural (vHC), alters hippocampal temporal representations during the delay period of a spatial working memory task. Rats were implanted with a biploar stimulation electrode in the vHC along with an array of recording tetrodes in CA1. We tested memory performance using a delayed alternation T-maze paradigm, whereby rats ran on a treadmill located on the center stem of the maze during an 8s delay on each trial. After each treadmill run, the rat was rewarded for remembering its most recent trajectory and selecting the alternate route. During the treadmill run, CA1 neurons consistently fired at successive brief moments, such that “time cell” sequences spanned the entire delay. Two seconds into the delay, we stimulated the vHC with a single 1 ms biphasic pulse, which has been shown to inhibit CA1 pyramidal cell firing for 100-200 ms (Zugaro et al., 2005). In contrast to reports of place cell stability following vHC stimulation (Jadhav et al., 2012), hippocampal time cells were susceptible to the transient disruption of intra-hippocampal processing. These results suggest that mechanisms within the hippocampus may be crucial for stable temporal representation across a delay.

Title: Lateral entorhinal neurons contribute object and temporal information towards episodic memory.

Authors: *J. H. BLADON, C. LIU, J. O'KEEFE, H. EICHENBAUM;
Psychology, Boston Univ., Boston, MA

Abstract: The Lateral Entorhinal Cortex (LEC) is a central node in the episodic memory network. It provides the majority of object information into the hippocampus, and is a crucial node for relaying prefrontal information to the hippocampus. The LEC is hypothesized to buffer object and event information so that it may be properly integrated into a contextual continuum of space and time in the hippocampus. We tested this hypothesis by recording from LEC neurons in a rat performing a delayed matching task in which the rat was required to link objects across a delay. Single units showed significant object-related and object-specific coding both during the sampling period as well as during the delay. Moreover, we found that LEC units showed reliable firing rate patterns during the delay that provided significant temporal information. LEC population activity reliably held both object and time information on-line during the delay in a dynamic manner. These data confirm the hypothesis that the LEC buffers object representations by coding for both current and past objects. These data also suggest that the LEC may participate in establishing an evolving temporal context for which to bind events and experiences.

Title: The role of eEF2K /eEF2 pathway in the hippocampal circuit

Authors: *E. TAHA[1,2], C. HEISE[3], L. MURRU[3], M. PASSAFARO[3], C. SALA[3,4], K. ROSENBLUM[2,1];

Abstract: **Background:** The protein synthesis process is essential for learning and memory formation. While the initiation phase of translation is considered to be the rate-limiting step, regulation of the elongation phase via Eukaryotic Elongation Factor 2 Kinase (eEF2K) was also suggested to be important for memory and synaptic plasticity consolidation. eEF2K, known as calcium/calmodulin-dependent protein Kinase III (CaMKIII), is a ubiquitous protein kinase involved in the control of mRNA translation, whose catalytic activity is Ca^{2+}-dependent. Upon activation, eEF2K phosphorylates and inhibits eukaryotic elongation factor 2 (eEF2), leading to inhibition of mRNA translation at the level of elongation. In the present study we aim at examining the role of eEF2K/eEF2 pathway in the hippocampal circuit and memory formation.
Results: Genetic deletion of the eEF2K (knock-out, KO) in mice, which leads to a complete loss of eEF2 phosphorylation, differentially affects hippocampal-dependent memory formation. Importantly, long term trace and contextual fear conditioning are impaired in eEF2K-KO, whereas several other forms of learning and memory are normal. In addition, basal synaptic transmission is unaltered in the CA1 subregion of the eEF2K-KO mice. However, β/γ oscillations activity in the CA3 subregion and GABAergic synaptic transmission in the DG are increased in the eEF2K-KO mice. Proteomic analysis revealed that eEF2K/eEF2 pathway regulates the expression levels of several proteins, mainly cytoskeletal and presynaptic proteins. Loss of eEF2K increased the presynaptic protein Synapsin 2b (Syn 2b) and **α**5-containing $GABA_A$ receptors protein expression levels. We identified eEF2K/eEF2 pathway to differentially affect hippocampal sub-regions and neuronal subtypes.
Currently, we aim to delete specifically eEF2K expression in neuronal subtypes in the CA1, CA3, and DG of hippocampus in order to better explore its role at the circuit level.
Conclusions: Our results suggest that manipulation of the eEF2K pathway, affects specific hippocampal subregions and neuronal subtypes. This differential role of the eEF2K/eEF2 pathway provides novel insights into the intimate relationship between translation regulation and inhibition/excitation ratio in normal and diseased brain.

Abstract: Recent gene expression data in the mouse has revealed that the hippocampus contains discrete genetic subdivisions. However, it is unclear how to reconcile these genetic domains with previous data which suggested hippocampal connectivity was organized along topographical gradients. Using online gene expression data from Allen Institute, we created a full coronal and sagittal atlas map of the genetic domains in the dentate gyrus, CA3, CA1, and subiculum (Hippocampus Gene Architecture Atlas, HGAA). Then, we analyzed the connectivity of each hippocampal genetic domain using anatomical tracer data from the Mouse Connectome Project (www.mouseconnectome.org) to create a comprehensive and detailed wiring diagram of the mouse hippocampus. Overall, the distribution patterns of anterograde and retrograde labeling matched remarkably to the genetic domains outlined by the HGAA. To examine hippocampal network modularity, we performed a network analysis of intrahippocampal connectivity which revealed that the hippocampus genetic domains are organized as constituent parts of four major subnetworks. After defining the hippocampal subnetwork organization, we examined hippocampal extrinsic connectivity with cortex, thalamus, basal forebrain, amygdala, and hypothalamus. We found that each hippocampal subnetwork had unique connections with the rest of the brain, suggesting that information from each subnetwork is involved in unique functional processes. Together, our research provides a new conceptual understanding of hippocampus organization that reconciles gene expression and connectivity and lays the foundation for future functional studies with optogenetic tools.

Abstract: The finely tuned balance of inhibition and excitation in the hippocampus is essential to its role in memory and perturbations are evident in diseases such as Alzheimer's and epilepsy. The CA2 subfield is anatomically well positioned to influence hippocampal physiology and processing, but its integrative role is poorly understood. Here, we describe novel functions of CA2 in the control of hippocampal network activity. In mice with genetically-engineered chronic shutdown of CA2 pyramidal cell synaptic transmission we observed a novel pathophysiological state. On the single cell level we found increased activity in CA2 output areas, accompanied by changes in spike timing. During exploration this manifested as spatially-triggered episodes of network-wide hyperexcitability and was accompanied by the emergence of epileptiform discharges during rest. These findings demonstrate that CA2 controls the flow of information through the hippocampal circuit via subcircuit switching and identify CA2 as a locus of interest in epilepsy.

Title: Learning-induced mTORC1-dependent synaptic plasticity in somatostatin interneurons regulates hippocampal network plasticity and memory

Authors: *J. ARTINIAN[1,2], A. JORDAN[1,2], A. LA FONTAINE[1,2], M. MAURER[1,2], I. LAPLANTE[1,2], J.-C. LACAILLE[1,2];

Abstract: Long-term synaptic plasticity is a prime candidate cellular substrate for learning and memory. It has been extensively studied in principal excitatory neuron networks but to a much lesser extent in inhibitory interneurons. In the hippocampal CA1 region, excitatory synapses onto somatostatin interneurons (SOM-INs) show a cell type-specific long-term potentiation (LTP) dependent on type 1a metabotropic glutamate receptors (mGluR1a) that regulates hippocampal network plasticity, can persist 24h and requires translation via Mechanistic Target Of Rapamycin Complex 1 (mTORC1). The present study aimed at investigating the functional role of translation-dependent LTP in SOM-INs in hippocampal networks and memory, using the Cre-lox system to knock out the expression of Raptor, an essential component of mTORC1, selectively in SOM-INs (SOM-Raptor-KO mice).
We first confirmed that mTORC1 signalling was deficient in SOM-INs from KO mice, as treatment with mGluR1a agonist failed to increase ribosomal S6 protein phosphorylation, a downstream effector of mTORC1. Next we determined with whole cell recordings that SOM-INs show normal membrane properties and basal synaptic transmission, but that mGluR1a agonist-induced persistent LTP was prevented in SOM-INs from SOM-Raptor-KO mice. Thus, SOM-INs show impairment in mTORC1 signalling and persistent synaptic plasticity in SOM-Raptor-KO mice. We next investigated the behavioral relevance of mTORC1-mediated persistent LTP, and examined if contextual fear learning induces plasticity at SOM-IN synapses. We performed whole-cell recordings 24h after contextual fear conditioning and found that training induces an increase in spontaneous and minimally evoked excitatory transmission, as well as input-output function at SOM-IN synapses in WT mice. However, these learning-induced persistent synaptic changes were prevented in SOM-INs from SOM-Raptor-KO mice, demonstrating that contextual fear learning induces persistent mTORC1-dependent LTP at SOM-INs synapses. We then examined the consequences on hippocampal function of impaired SOM-IN mTORC1 activity and synaptic plasticity. Field recordings revealed a decreased LTP in the Schaffer collateral pathway of CA1 pyramidal cells in slices, suggesting impairment in CA1 network plasticity in SOM-Raptor-KO mice. At the behavioral level, SOM-Raptor-KO mice showed intact learning but impairment in long-term consolidation of contextual fear and spatial memories compared to WT mice.
Our results suggest that learning-induced mTORC1-mediated persistent synaptic plasticity in SOM-INs regulates CA1 local network activity and hippocampus-dependent memory.

Title: Cued and spatial memory acquisition, retention, and reversal following hippocampal damage and chemogenetic inactivation in rats.

Authors: *J. Q. LEE, R. J. MCDONALD, R. J. SUTHERLAND;
Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: Contemporary views on long-term memory (LTM) organization suggest that the hippocampus is involved in specific types of memory, and that its disruption before or soon after learning should cause similar, specific types of amnesia. Evidence shows that hippocampal disruption before learning causes specific anterograde amnesia (AA), while its disruption after learning results in more pervasive retrograde amnesia (RA). We propose a heterarchic concept of memory organization to account for this finding. On this view, hippocampal disruption causes dissociable AA, and more general RA due to its influence on non-hippocampal representations during learning and memory retrieval. In order to test this prediction we developed a visible two-platform discriminative water task that allows for the assessment of spatial and discriminative cue memory in parallel, and how these types of memory interact to guide behaviour. Using both permanent lesion and chemogenetic temporary inactivation approaches, we examined anterograde and retrograde memory for cue and place information, and the ability of animals to learn new cue and place associations. The results of the present series of experiments demonstrate that cue and place information are acquired in parallel, and interact to control behaviour. Our results also support that the hippocampus is involved in both cue discrimination and place memory. Together, these findings add to a growing literature suggesting that the hippocampus is involved in numerous types of memory, and that memories acquired in its presence and absence differ in important ways.

Abstract: The hippocampus plays an essential role in learning and memory. For the proper, encoding and retrieval of memories, information from a wide neural circuit bridging to the hippocampus is required. In addition to the entorhinal cortex, the major source of input, the hippocampus receives significant projections from various brain areas, such as the medial septum, nucleus reuniens, as well as other neuromodulatory systems. Here we focus on a neural circuit from hypothalamic supramammillary nucleus (SuM) to the hippocampus in the mouse brain. Although the role of SuM efferents to the hippocampus in the modulation of the hippocampal theta oscillation has long been studied, comparatively little is known about the role of the SuM-hippocampal circuit in memory encoding and retrieval on the behavioral level. By taking advantage of a recently developed SuM-Cre transgenic mouse line, we specifically expressed light-responsive channels, either channelrhodopsin-2 or archaerhodopsin, in SuM efferents, which were simultaneously labeled by the co-expressed fluorescent proteins. After brain tissue clearing by the ScaleS technique, high-resolution 3D imaging revealed strong direct projections from SuM to the hippocampal subfields of dentate gyrus (DG) and CA2. Next, we employed targeted optogenetics to test the functionality of the SuM-hippocampal circuit in various memory-related tasks. In particular, we examined whether optogenetic activation or inhibition of the SuM-DG subcircuits had different effects on the behavioral performance of the mouse in spatial working memory, fear memory, and social memory tasks. Our results showed that SuM-DG and SuM-CA2 subcircuits fulfill distinct functions in different memory tasks, indicating memory type-dependent information routing by the SuM-hippocampal projections.

Title: Nicotine disengages orbitofrontal cortex during Pavlovian Conditioning

Authors: *N. W. SIMON[1], B. MOGHADDAM[2];
[1]Neurosci., [2]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Nicotine enhances the motivational salience of environmental cues, engendering ongoing seeking of nicotine and other drugs of abuse. It is established that prefrontal cortex (PFC) regions provide information about outcome expectation during predictive cues and reward-driven behavior, but little is known about how this processing is altered during nicotine exposure. To address this, we recorded single unit activity from rat orbitofrontal cortex (OFC), a PFC subregion that encodes information about specific outcome expectancy during reward anticipation. Activity was recorded across 7 sessions of Pavlovian conditioning; each session consisted of 50 cue/reward pairings, followed by subcutaneous administration of 0.2 mg/kg nicotine, then an additional 50 trials. Before nicotine exposure, a subset of OFC neurons was selective for cue onset, and this selectivity was most pronounced on trials in which rats performed at least one conditioned response (food trough entry during the cue). After nicotine exposure, these initially cue selective neurons became disengaged by no longer changing their firing rate at cue onset. This suggests that nicotine may reduce OFC-driven outcome representation during cues, perhaps shifting motivational focus from impending outcomes to the cue itself. In support of this, nicotine caused rats to prefer a sign-tracking strategy over a more outcome-driven goal-tracking strategy. Thus, lack of OFC engagement during reward-predictive cues may be related to nicotine-induced cue salience.

Title: Differential effects of discrete subarea-specific inactivation of the rat medial prefrontal cortex on short and long-term memory of low and high aversive training

Authors: *M. E. TORRES GARCÍA, A. C. MEDINA, G. L. QUIRARTE, R. A. PRADO-ALCALÁ;
Dept. de Neurobiología Conductual y Cognitiva, Inst. de Neurobiología, UNAM, Querétaro, Mexico

Abstract: Recent studies have shown that the medial prefrontal cortex (mPFC) could be involved in memory encoding, particularly of aversive events, such as inhibitory avoidance (IA) training. Dissociable roles have been found for different mPFC subregions in mediating various memory processes, with the cingulate cortex (CgC), prelimbic (PL) and infralimbic (IL) cortex involved in the acquisition, retrieval and extinction, respectively. However, these findings are controversial. On the other hand, it has been demonstrated that enhanced training impedes the effects on memory of treatments that typically interfere with memory consolidation. The objective of the present work was to determine whether enhanced IA training also has a protective effect on short (STM) and long-term (LTM) memory in rats treated with a tetrodotoxin (TTX, sodium channels blocker) in the different subregions of mPFC. Independent groups of rats were trained in IA using two different intensities of foot-shock (1.0 or 3.0 mA). TTX (5 ng/0.5 µL) or its vehicle (NaCl 0.9%), was administered 25 min or 60 min (in the case of CgC) before the training session. Thirty min (STM) or forty-eight hours (LTM) later their retention latencies were measured. Our results indicate that PL inactivation impairs LTM in the 1.0 mA group while in the group that had been trained with 3.0 mA TTX did not produce alterations in memory consolidation. IL inactivation weakened LTM in both training conditions. CgC inactivation only impaired STM in both 1.0 and 3.0 mA training conditions. These results provide evidence that STM and LTM are served by distinct mPFC subregions: CgC mediates STM, whereas PL mediate LTM only in low training condition and IL in both training conditions. We thank Leonor Casanova, Nydia Hernández, Omar González and Ramón Martínez for technical assistance. Supported by CONACYT (237570) and PAPIIT (IN201415).

Abstract: Behavioural flexibility is critical for rapid adaptation to changing environmental conditions with direct impact on proliferation and survival. The prefrontal cortex is involved in higher-order functions such as cognitive control, memory and decision making. Specifically, the orbitofrontal cortex (OFC) plays an essential role in the formation of cue-outcome representations, reversal of learned associations, coding various statistical aspects of reward properties and may be a major player in the model-based reinforcement learning.
In addition, the interaction of the OFC with the temporal lobe, particularly during reward-driven spatial navigation tasks, and areas of the reward network has been demonstrated both anatomically and electrophysiologically. Multiple studies have investigated the role of these areas in the integration and storage of task related information and indicated the post-task replay phenomena, observed in the hippocampus, ventral tegmental area, amygdala, striatum and medial prefrontal cortex, as the electrophysiological mechanism supporting memory consolidation.
Despite the high degree of functional integration in the frontotemporal network during decision-making tasks and reward reinforcement learning paradigms, reactivation of neuronal ensembles during post-task rest has not been described in the OFC.
In this study we used a behavioral task set in a Steering Wheel Maze, which requires unidirectional locomotion along six equally spaced reward sites. Four rats were implanted with hyperdrives containing independently moveable tetrodes directed at the lateral OFC. Animals

were tested on a place-reward association task, where reward positions were changing every third training session, with each training sessions flanked by sleep episodes. We show that ensembles of putative pyramidal neurons in the OFC reactivate significantly during post-task sleep, with reactivating cells showing task-like spatiotemporal cross-correlation patterns. Furthermore, reactivation is stronger following exposure to novel spatial reward distributions as compared to familiar ones.

Title: Response strategy determines representation of outcome information in infralimbic cortex

Authors: *J. M. BARKER[1], W. B. GLEN[2], D. N. LINSENBARDT[3], C. C. LAPISH[3], L. J. CHANDLER[2];
[1]Psychiatry, [2]Med. Univ. of South Carolina, Charleston, SC; [3]IUPUI, Indianapolis, IN

Abstract: Many neuropsychiatric disorders are characterized by a shift from flexible, outcome-mediated behaviors to inflexible, persistent habits. Response strategy selection is mediated in part by corticostriatal circuitry. Previous research has implicated the infralimbic PFC (IL) in the expression of habitual reward seeking; loss of IL function restores goal-directed action in rodents that have acquired habitual reward seeking. Though IL is critical for the expression of habitual

reward seeking, though little is known about the mechanism by which IL encodes habits or mediates the transition from actions to habits. To investigate the role of IL in response strategy selection, male mice were implanted with multielectrode arrays targeting the IL and trained to self-administer sucrose. The present study took advantage of two different training schedules known to produce different response strategies - a habit-promoting schedule and an action-promoting schedule - in order to determine how the IL encodes actions and outcomes during the performance of habitual versus goal-directed behaviors within subjects. Task-dependent modulations of neural activity during key epochs of behavior were assessed that included the interval when information on action-outcome contingencies was provided (i.e., during reinforcer delivery after a lever press) as well as during periods where reward value information was available (i.e., during consumption of the reinforcer). We observed response strategy-dependent differences in neural activity in IL during lever pressing such that increases IL activity during goal-directed actions occurred during reinforcer delivery. In contrast, firing rates within IL showed increase during lever pressing under conditions where animals were seeking rewards habitually. These data suggest that habitual reward seeking is associated with a transition from IL activity during outcome information to action performance, potentially suggesting a mechanism by which IL drives habitual reward seeking.

Title: Medial prefrontal cortex to nucleus reuniens of thalamus connections are essential for the formation of long-term associative recognition memory.

Authors: *G. R. BARKER[1], L. F. WONG[2], J. B. UNEY[2], E. C. WARBURTON[1];
[1]Sch. of Physiology, Pharmacol. & Neurosci., [2]Sch. of Clin. Sci., Univ. of Bristol, Bristol, United Kingdom

Abstract: Associative recognition memory, the ability to associate an object with a location or position in a sequence, requires a neural circuit which includes the perirhinal cortex (PRH), hippocampus (HPC) and medial prefrontal cortex (mPFC) (Barker et al 07, Barker & Warburton

2011). The nucleus reuniens of the thalamus (NRe) is reciprocally connected to all three brain regions in the associative recognition memory circuit and therefore is anatomically well placed to be engaged during associative recognition memory formation (McKenna & Vertes 04, Vertes et al 06). Thus ablation of the nucleus reuniens impaired the formation of long-term but not short-term associative recognition memory (Barker & Warburton 2015), however how the nucleus reuniens interacts with the other structures within the associative recognition memory network has not yet been established. Therefore this study investigated the specific role of projections from the medial prefrontal cortex to the nucleus reuniens in associative recognition memory formation.
Projections from mPFC to NRe were targeted using a pharmaco-genetic technique which utilised an EIAV neuron-specific lentiviral vector, expressing lac-z, pseudotyped with a hybrid rabies envelope protein that enhances retrograde transport. Injection of the virus into the NRe of male Lister-Hooded rats resulted in lac-z expression in the mPFC. Infusion of a 'prodrug' Daun02 into the mPFC, via chronically implanted bilateral cannulae, inactivated the mPFC-NRe projection as Daun02 is converted to daunorubicin by beta-galactosidase, the protein product of lac-z, which inhibits neuronal firing (Koya et al 09).
Daun02 was infused into the mPFC three days before behavioural testing. The animals were run through a series of preferential object exploration tasks (Dix & Aggleton 98) which tested different types of associative and non-associative recognition memory; object-in-place, temporal order, temporal location, object recognition and object location. Associative recognition memory was tested at either a short-delay (5 min) or a long-delay (3 h), non-associative recognition was tested at a long-delay (3 h).
Inactivation of the direct mPFC-NRe projection impaired performance in the object-in-place and temporal order memory tasks at the long delay but not the shorter delay, in contrast performance in the temporal location task was not altered at the long delay. Performance of non-associative forms of recognition were not altered by deactivation of the mPFC-NRe projection.
Therefore these results demonstrate that projections from the mPFC to NRe are essential for the formation of some types of associative recognition memory.

Title: The differential contribution of primate orbitofrontal cortex and perigenual anterior cingulate cortex to contingency learning

Authors: N. HORIGUCHI[1,2], S. A. W. JACKSON[1,2], N. K. HORST[1,2], R. N. CARDINAL[2,3], T. W. ROBBINS[1,2], *A. C. ROBERTS[4,2];
[1]Psychology, [2]Behavioural and Clin. Neurosci. Inst., [3]Psychiatry, [4]Physiology, Develop. and Neurosci., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: The control of instrumental learning, whereby organisms come to associate actions with their outcomes, is supported by both a stimulus-response 'habit' system and a goal-directed action-outcome mechanism (Dickinson, 1985). Disruption to the balance between these systems is suggested to be responsible for the pathology of obsessive-compulsive disorder (OCD, Gillan & Robbins, 2014), a neuropsychiatric illness involving dysfunction in fronto-striatal circuitry. Goal-directed actions have been shown to be dependent upon contingency, defined as the difference between the probability of reinforcement given a response, and the probability of reinforcement in the absence of that response (Hammond, 1980). We have previously reported that marmoset monkeys with excitotoxic lesions of either orbitofrontal cortex (OFC) or perigenual anterior cingulate cortex (pgACC) fail to detect when one of two trained action-outcome contingencies is degraded by the non-contingent delivery of one of the potential outcomes (Jackson et al., 2016). We sought to extend these findings using localised reversible inactivations in marmosets. Marmosets were trained to respond to a stimulus on the left side of a touchscreen for delivery of reward A and, in separate sessions, to the same stimulus on the right side of the screen for reward B. Once marmosets reliably made ~10 responses per reward, they were implanted with chronic indwelling cannulae in the OFC or the pgACC. The $GABA_A$/$GABA_B$ agonists, muscimol/baclofen, were infused to inactivate, reversibly, either the OFC or pgACC during contingency degradation sessions. In the degraded session, the reward for which the marmoset was working was also delivered non-contingently on an independent schedule, thereby degrading the association between action and outcome. In the non-degraded session, the non-contingent reward differed from the contingent reward, thus leaving the action-outcome contingency intact. Under control conditions, subjects reduced responding more in degraded sessions vs. non-degraded sessions. OFC inactivation diminished the impact of non-contingent reward on overall responding whilst inactivation of pgACC, by contrast, appeared to selectively disrupt the action-outcome association. By using a novel contingency degradation paradigm that allows multiple acute pharmacological manipulations, we have revealed differences in the contribution of the OFC and pgACC to the use of action-outcome contingency information in response selection. These results have broader implications for the dysregulation of instrumental learning in OCD.

Title: Sleep spindles and single-cell reactivation in the rodent medial prefrontal cortex during context-dependent memory reconsolidation

Authors: *B. HARPER[1], A. SAMPSON[2,3], T. J. SEJNOWSKI[2,3], J.-M. FELLOUS[1]; [1]Univ. of Arizona, Tucson, AZ; [2]Howard Hughes Med. Institute, Computat. Neurobio. Laboratory, Salk Inst. for Biol. Studies, La Jolla, CA; [3]UCSD, La Jolla, CA

Abstract: Sleep spindles are 12-15 Hz oscillations observed in the mammalian neocortex during non-rapid eye movement (NREM) sleep. They are produced by the activation of thalamocortical circuitry and play a critical role in memory consolidation and reconsolidation. Reactivation has been proposed as a mechanism for this process and is thought to return a memory to a labile state in which it becomes susceptible to interference. In a rodent memory reconsolidation task, we produce or protect against this interference by changing the spatial context in which learning occurs. Animals learn to obtain rewards from a first set (Set1) of spatial locations in context A. They then learn a second, non-overlapping set of locations (Set2) in either the same context or in a different context B. Set1 recall is assessed in context A. As in previous work, we find that rats make significantly more intrusions recalling Set1 if they learn both sets in the same context as opposed to different contexts, with no difference in recall performance between conditions. This suggests that context exposure may reactivate memory for Set1 during or immediately after Set2 learning and increase the interference between the two sets. We recorded from the anterior cingulate, prelimbic, and infralimbic regions of the medial prefrontal cortex (mPFC) in adult male Brown Norway rats to investigate the relationship between spindle characteristics and memory performance. We hypothesize that a correlation exists between post-learning spindle density and intrusions during recall several hours later. Further analyses examine cell pairs that become correlated during learning and reactivate together post-learning, and we predict a correlation between reactivation during spindles and memory interference. We extract spindles using delay differential analysis, a time-domain classification framework based on embedding theory in nonlinear dynamics. This provides a low-dimensional nonlinear functional basis onto

which the data are mapped. Since this basis is built on the dynamical structure of the data, preprocessing is unnecessary, and the low dimensionality avoids overfitting. We compare the characteristics and temporal synchrony of spindles across all levels of mPFC. This study gives further insights on the role of cortical oscillations in memory consolidation and reconsolidation during sleep.

Title: Activity-dependent projection labeling reveals distinct anatomical profiling

Authors: *W. DANG[1,2], I. WINCHESTER[3], J. VU[3], M. MAYFORD[3];
[1]San Diego, CA; [2]Mol. and Cell. Neurosci., The Scripps Res. Inst., La Jolla, CA; [3]Univ. of California - San Diego, La Jolla, CA

Abstract: Recent electrophysiological evidence suggest that subcortical areas contain distinct functional populations that also project axons to different brain areas, but little is known about whether cortical regions also contain functionally- and anatomically-defined subpopulations. To approach this question using microscopy, we used activity-dependent targeting to express fluorescently-tagged synaptic proteins in populations of neurons active during fear recall. When injecting into the prelimbic area (dorsalmedial prefrontal cortex), we found that these active populations of neurons have differential projections to other brain regions compared to the constitutive labeling of the same synaptic markers, suggesting that experience-related neuronal ensembles have distinct anatomical profiles. These populations also display distinct projection profiles across groups of mice that have undergone fear conditioning and fear extinction. This data has implications on neuronal allocation of memory by a circuit bias as reflected by their projection patterns.

Title: Circuit dissection of input required for the cortical encoding of a trace fear memory.

Authors: *R. C. TWINING, M. R. GILMARTIN;
Marquette Univ., Milwaukee, WI

Abstract: Trace fear conditioning (TFC) requires a neural network that is distinct from standard delay fear conditioning. In delay conditioning, an auditory conditional stimulus (CS) co-terminates with a shock unconditional stimulus (UCS). This association is largely supported by converging auditory and somatosensory input in the amygdala. Trace conditioning differs from delay conditioning in that the CS and the shock are separated by a temporal gap. We have shown that imposing this temporal complexity renders the acquisition of associative fear dependent on both the hippocampus and the prefrontal cortex. In addition, we described a subset of neurons in the prelimbic (PL) area of the prefrontal cortex that exhibit sustained increases in learning-related neuronal spiking that bridges the empty trace interval, reminiscent of a working memory buffer. Indeed, we optogenetically silenced neuronal activity in the PL cortex specifically during the trace interval and blocked the formation of a trace fear memory. What remains unknown, however, is which subcortical inputs to the PL cortex are necessary to support TFC, when precisely they are important, and to what extent these inputs control learning-related neuronal spiking. Here we recorded single unit activity in awake-behaving rats and used optogenetic and chemogenetic techniques to selectively silence afferent input to the PL cortex during TFC to determine its control of both the learning-related bridging activity and to the learning itself. Preliminary findings suggest that silencing ventral hippocampal (VH) input to the PL cortex during the cue and trace period reduces learning related neuronal activity. Behaviorally this input plays a modulatory role in trace fear acquisition. Despite having a significant influence on neuronal cell firing in the PL cortex, the influence of silencing VH afferent input on learned fear was transient and could be overcome with more training. Ongoing studies will determine the extent to which silencing VH inputs to PL for longer durations can control prelimbic encoding and formation of a trace fear memory.

Title: Whole-brain atlas of direct input to GABAergic neurons of medial prefrontal cortex

Authors: *Q. SUN, X. LI, M. REN, P. LUO, B. LONG, A. LI, J. YUAN, Q. LUO, H. GONG; Wuhan Natl. Lab. For Optoelectronics, Hubei, China

Abstract: To play critical roles in working memory, decision making, emotion regulation and social behavior, medial prefrontal cortex (mPFC) integrates information from numerous cortical and subcortical regions through projection neurons and interneurons. Previous studies on GABAergic neurons have focused almost on local inhibited connection neglecting those neurons earning long-range input from and projecting to different areas. The inter-regional communication depends upon the subsets of postsynaptic neurons and upon what cellular the projections target. Even with recent advance in optical whole-brain imaging methods, to distinguish the circuit of single neuron in the whole brain remains many difficulties, especially for the long-range input-output networks. Here, we employed monosynaptic circuit tracing with modified rabies virus and fluorescence micro-optical sectioning tomography to acquire the whole brain inputs to GABAergic neurons in the mPFC. Combined with immunohistochemistry, we characterized the location and the properties as well as the more complete morphology of the input neurons in different brain areas. Thus, this study generated a whole brain, comprehensive, precise view of the wiring diagram of specific type neurons in the mPFC and helped us understand the circuit mechanism underlying diverse functions of mPFC.

Title: The medial prefrontal cortex (mPFC) is required for the acquisition and retention of the context preexposure facilitation effect (CPFE) in adolescent rats

Authors: *N. A. HEROUX, P. A. ROBINSON-DRUMMER, H. R. SANDERS, J. B. ROSEN, M. E. STANTON;
Dept. of Psychological and Brain Sci., Univ. of Delaware (UD), Newark, DE

Abstract: The context preexposure facilitation effect (CPFE) is a contextual fear conditioning paradigm in which learning about the context, acquiring the context-shock association, and retrieving/expressing contextual fear are temporally dissociated into three distinct phases. Previous research using the CPFE in adult rats has shown that the hippocampus is required for all three phases of learning (Matus-Amat et al., 2004). Conversely, NMDA receptor dependent plasticity in hippocampus is only required for acquiring a context representation and NMDA receptor dependent plasticity in the basolateral amygdala is only required for learning a context-shock association (Matus-Amat et al., 2007). Additionally, our lab has previously shown that the CPFE induces the expression of the transducible transcription factor early-growth-response gene-1 (*egr-1)* in the hippocampus, amygdala, and medial prefrontal cortex (mPFC) of adolescent and adult rats, suggesting that the mPFC might play a role in the CPFE (Schreiber et al., 2014; Chakraborty et al., 2016). Nothing is known about the specific role of the mPFC in mediating the acquisition and retention of the CPFE at any age. The current set of experiments were designed to assess the regional contributions of the mPFC to the CPFE by utilizing intra-mPFC infusions of the GABA-a receptor agonist muscimol prior to each phase (context preexposure, context-shock training, and retention testing). Experiment 1 found that intra-mPFC infusions of muscimol (0.5 μg/0.25 μl/side) prior to context preexposure disrupted retention test freezing to a level that did not differ from non-associative controls that were preexposed to an alternate context. Experiment 2 found that the same muscimol infusions prior to context-shock training partially disrupted retention test freezing measured 24 hours later. Finally, Experiment 3 found that the same muscimol infusions prior to a retention freezing test disrupted the retrieval and/or expression of contextual fear within the CPFE. In summary, the mPFC is required for learning or performance during all three phases of the CPFE in adolescent rats. Future experiments will examine the role of the mPFC in the ontogeny of context acquisition and contextual fear learning

within the CPFE across normal and abnormal development.[NIH grant R01 HD075066-01A1 to MES and JBR]

Title: Age and experience-dependent changes in Egr-1 expression during the ontogeny of the context preexposure facilitation effect (CPFE)

Authors: *P. A. ROBINSON-DRUMMER, T. CHAKRABORTY, N. A. HEROUX, J. B. ROSEN, M. E. STANTON;
Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: The context preexposure facilitation effect (CPFE) is a variant of contextual fear conditioning in which acquisition of the contextual representation, association of the contextual memory with an immediate footshock, and retrieval of the context-shock association are all separated by 24hrs. This temporal separation allows specific aspects of the learning experience to be isolated and the neurobiological substrates of each phase to be examined independently. Previously, our lab has shown that the CPFE is expressed at adult levels shortly after weaning on Postnatal day 24 (PD24), but is not evident in infant rats at PD17 (Schiffino et al., 2011; Jablonski et al., 2011; Robinson-Drummer & Stanton, 2014). Expression patterns of the immediate early gene known as early growth response -1 gene (*Egr-1*; Alberini, 2009; Veyrac et al., 2014) in the lateral nucleus of the amygdala (LA), hippocampus (dHPC) and medial prefrontal cortex (mPFC) is similar between adolescent (PD31; Asok et al., 2013; Shreiber et al., 2014) and adult rats (Chakraborty et al., 2016) following preexposure and context-shock training in the CPFE which suggests that plasticity in these brain regions are involved in fear learning in the CPFE. The current experiments sought to extend these findings by examining *Egr-1* expression in infant and juvenile rats (PD17 and PD24, respectively). Following a 5 min preexposure, *Egr-1*expression in the mPFC, dHPC and LA in both the Group Pre (i.e. exposed to the same context during all three phases) and Alt-Pre (i.e exposed to an alternate context during the first phase) was significantly increased relative to homecage controls (HC) at PD24.

However, at PD17 this increase was absent and there was no difference in expression between the groups. In contrast, *Egr-1*expression following an immediate footshock (1s, 1.5mA) did not differ between PD17 and PD24 rats although neither age showed the learning-related increase in mPFC expression observed previously in adolescent (Asok et al., 2013, Schreiber et al., 2014) and adult rats (Chakraborty et al., 2016). Interestingly, increased exposure to the training chamber on the preexposure day altered expression in PD24 rats such that a learning-related increase in expression between Pre and Alt-Pre animals was observed in the mPFC on the training day. Together, these results illustrate a clear maturation of *Egr-1*expression that is both age and experience dependent. In addition, the data suggest that regional activity and plasticity within the mPFC may contribute to the ontogenetic profile of the effect. Further study is necessary to elucidate the role of subregion-specific neuroplasticity in the ontogeny of the CPFE.

Title: Using the Rescorla-Wagner equation to model choice behavior

Authors: *R. M. FRANCIS[1], A. A. ORTIZ[2], L. A. ENDER[2], K. E. GREEN[2], R. A. WIRT[2], J. M. HYMAN[2];
[1]Psychology, UNLV, Las Vegas, NV; [2]Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: In order for animals to successfully exploit their available natural resources, they must rapidly update their preferences to adapt in a dynamic environment. To perform this function, the animal must continually monitor and update internal representations of these preferences. We examined this by utilizing a differential reward probability operant task, which allowed us to periodically alter the likelihood of reward following different responses. By interspersing 'choice' trials with 'training' trials, we could assess any changes in the animal's preferences for the different responses. We then used a mathematical model originally developed to describe classically conditioned behavior, and not operator controlled behavior like our current task. Using this computational model we were able to successfully replicate the animal's behavior and preferences, suggesting that choice behavior of this type is more similar to classical conditioning than it is to instrumental learning. Furthermore, the model allowed us to examine whether our subjects had any behavioral biases for the different response ports, which could possibly have

been influencing serial reversal learning. Finally, our modeled preferences were very similar to changes in anterior cingulate cortex unit firing rates when reward probabilities change.

Title: Increases in cross-hemispheric anterior cingulate cortex LFP synchrony for remote memories.

Authors: *R. A. WIRT[1], A. A. ORTIZ[1], J. M. HYMAN[2];
[2]Psychology, [1]Univ. of Nevada Las Vegas, Las Vegas, NV

Abstract: In recent years, two separate streams of research have been examining how spatial information is shared between the medial prefrontal cortex, including the anterior cingulate cortex (ACC), and the hippocampus (HC). Dual site electrophysiological recordings have revealed robust ACC-HC interactions in the theta range that are directly related to working memory performance (Jones & Wilson, 2005; Hyman et al., 2010). Separately, consolidation studies have shown an increased reliance on prefrontal activity for remote but not recent spatial memories (Ding et al., 2008). The current study examined whether electrophysiological interactions between the ACC and HC changed as memories went from recent to remote. We exposed rats to novel environments and then re-exposed them to the same environments after differing delays ranging from 1-14 days later. We recorded bilaterally from both the ACC and HC simultaneously and analyzed local field potentials. ACC-HC interactions were significantly changed in both theta and gamma bands on day 14. We also found striking increases in bilateral ACC coherence and synchrony on day 14. Since there were no corresponding increases in ACC theta or gamma power, this indicates that these interaction effects were not merely the product of stronger oscillatory drive. These findings offer compelling evidence that ACC-HC interactions change over the consolidation process. Furthermore, changes in cross-hemispheric cortical synchrony, which might be indicative of an ACC mediated readout of a remote memory, could potentially be an exciting and novel electrophysiological measure for detecting memory consolidation.

Title: What's gonna happen next? Tracking dynamic outcome likelihoods in ACC networks.

Authors: *J. M. HYMAN[1], J. K. SEAMANS[2];
[1]Univ. of Nevada Las Vegas, Las Vegas, NV; [2]Psychiatry, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Accurately calculating the probability of different outcomes is essential for optimal behavior, however, very little is known about how the brain actually performs this function. We recorded large ensembles of neurons in the anterior cingulate cortex (ACC) during a task where one of three different response ports was available on each trial. Each port had an assigned reward payout probability at the start of each session, but these were reversed midway through a session. We found that ACC ensembles were strongly affected by the port probability reversals, even though these reversals were not overtly cued and had to be surmised based on the history of recent outcomes. We used decoding analysis to assess reward predictions on a trial to trial basis. First, we examined whether cell firing rates could be used to accurately classify the two outcome states (reward and no-reward) and we found that ~45% did. Next, we compared each trial's action firing rates to these two different outcome states. Thus, an action period firing pattern more similar to the reward state would be classified as a reward prediction for the current trial. Then, for each trial we calculated how often that cell had predicted a rewarded outcome over the last four trials, allowing us to construct real time reward probabilities for each cell over the course of a session. This decoding analysis was performed on each of the three response ports. Overall, the decoded reward probabilities were very similar to the actual (experimenter-controlled) reward probabilities. When we plotted the mean outcome probabilities for the high and low likelihood ports, the lines crossed a few trials after the reversal point. We found similar patterns if we looked at the percentage of ACC neurons 'predicting' reward on each trial. At the ensemble level, signals were extracted that appeared to track the numbers of consecutive past rewarded versus non-rewarded outcomes at each port. Furthermore, we found that the firing rates of these cells were strongly influenced by recent trial outcome histories, but only for consecutive outcomes of the same type (reward or no-reward). Thus, if a trial was preceded by two or more consecutively rewarded trials, activity during the nose-poke more resembled activity exhibited during rewarded outcomes than non-rewarded outcomes whereas the converse was true if the trial was preceded by two or more consecutive non-rewarded trials. In addition to these signals, we found others related to session block (pre- and post-reversal) and the encoding of the actual

ports. Therefore, all the information necessary to accurately track outcome probabilities at different ports over trials was present in ACC ensembles.

Title: A computational model of ACC neuron outcome prediction responses

Authors: *E. H. BEDOY[1], J. M. HYMAN[2];
[2]Psychology, [1]Univ. of Nevada, Las Vegas, Las Vegas, NV

Abstract: Predicting which actions will lead to rewards is vital to survival. Neuronal recordings from the medial prefrontal cortex, including the anterior cingulate cortex (ACC), have shown clear responses that are consistent with action-outcome predictions (Hyman et al., 2013). Our lab has recently found that ACC neurons can compute highly accurate 'predictions' about the likelihood of rewarded or non-rewarded outcomes, and these 'predictions' are highly dynamic and update with changes in reward contingencies (Hyman et al., 2016). To better understand the computational environment that would engender outcome 'predictive' responses, we created a computational model that simulates neurons in the ACC as an organism is presented with successive reward and no-reward outcomes. Our recording data suggest that these ACC neurons are tracking past outcome history to predict the likelihood of rewards and no-rewards on ensuing trials. To test this, we set up a model with two interconnected neural networks; one network was activated during a reward and the other network was activated during a no-reward. This outcome activation lead to changes in synaptic strength, so that the network with more activation would be more excitable on future trials. When we ran simulations with different probabilities of reward and no-reward trials, the firing rates demonstrated that tracking past outcome history can be used to accurately predict the likelihood of rewards and no-rewards on ensuing trials.

Title: Neuronal Selectivity in higher cortical areas: What does it mean?

Authors: *N. J. POWELL[1], J. SEAMANS[2];
[1]Psychiatry, [2]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Classic electrophysiology studies identified the selectivity of neurons with specific stimuli (in the case of primary sensory areas) or specific motor outputs (in the case of primary or secondary motor neurons). However, in the case of cells recorded from more cognitive brain areas, the neural correlates of for cellular firing are more elusive. Cells in the various areas that comprise the Prefrontal Cortex (PFC) in particular have been connected to a wide range of firing correlates in a variety of species. Indeed, recently there has also been growing interest in cells that seem to represent multiple different firing correlates simultaneously (Horst and Laubach 2012, Powell and Redish 2014) and cells that respond to multiple task properties in a non-linear fashion (Rigotti et. al. 2013).

However, great care must be taken in how we identify neuronal selectivity in cognitive areas to distinguish it from the classical model of selectivity in input and output areas. In particular, many analyses do not consider all trials or instances of a particular stimulus individually, but instead concentrate on group comparisons of all instances of with a possible neural correlate vs. all laps or trials without said correlate. These analyses may obscure a considerable range of firing responses to the correlate in question, and in some cases a few laps with extreme firing may be enough to produce a finding of "selectivity" for cells that fail to respond on most instances. It is important to consider how consistently cell firing changes in response to a possible correlate before we label those cells as being selective to that correlate.

Here we consider several populations of neurons recorded from higher cortical areas (PFC and ACC) in terms of both group response statistics and in their response properties on individual trials to show that these cells are not often highly consistent in their response properties from trial to trial. In contrast, we demonstrate that other cells recorded from more primary sensory areas are significantly more consistent in their responding across trials. We will also demonstrate that some cognitive constructs (such as place fields) can be quite consistent across trials. However, despite the lack of consistent responding on an individual cell-individual trial level, it is still possible to decode meaningful information about many aspects of task structure from neuronal recordings in PFC and ACC. In light of the prevalence of population coded information, we argue that it is time to retire the concept of individual selectivity of neuronal

cells in higher cortical areas in favor of more neutral terminology reflecting their more complex population-based coding schemes.

Title: Arousal-related modulation of coordinated neural activity in the locus coeruleus, inferior colliculus and anterior cingulate cortex

Authors: *S. JOSHI, J. I. GOLD;
Dept. of Neurosci., Univ. of Pennsylvania, Philadelphia, PA

Abstract: The brainstem nucleus locus coeruleus (LC) provides norepinephrine (NE) innervation to nearly the entire brain. The LC-NE system has been linked with changes in arousal that can affect learning, attention, and other aspects of higher-brain function. Activation of the LC-NE system can reflect not just extreme fluctuations in arousal state, like fight/flight versus relaxed or awake versus asleep, but also more nuanced modulations that can influence moment-by-moment, attentive information processing in the brain. These effects are thought to involve NE-mediated changes in coordinated neural activity throughout the brain, but there is little direct evidence for such a link between moment-by-moment changes in arousal and neural dynamics. To evaluate such a link, we made paired recordings in LC and either inferior colliculus (IC) or anterior cingulate cortex (ACC) of awake, behaving monkeys while also measuring physiological arousal via pupil diameter, heart-rate variability (HRV), and electroencephalography (EEG). We targeted the IC, which is part of the ascending auditory pathway, because it receives strong LC projections. We targeted the ACC because it both projects to and receives projections from the LC.
Recordings were made while the monkey performed two different tasks. The first task simply required passive fixation on a central cue. On a randomly selected subset of trials, a startling sound was played. This task allowed us to obtain baseline measurements of coordinated activity under conditions of low arousal (no startling sound) versus high arousal (startling sound). The second task was a two-alternative forced-choice visual-oddball task in which the probability of the oddball occurring in one of two locations depended probabilistically on its previous location.

This task allowed us to examine relationships between arousal, coordinated neural activity, and task performance under various degrees of choice uncertainty.
We have preliminary data indicating that arousal is modulated during performance of both tasks. These modulations correspond to changes in the firing patterns of individual LC neurons as well as changes in pupil diameter. These firing patterns also are related to changes in spiking activity recorded in IC and ACC. Ongoing analyses will test if and how these changes include variations in coordinated activity of simultaneously recorded pairs of neurons.

Title: Muscimol inactivations of rat anterior cingulate cortex reveal its role in spatial processes in dynamic environments

Authors: *J. SVOBODA[1], V. LOBELLOVA[1], A. POPELIKOVA[1,2], N. AHUJA[1], A. BENYSKOVA[1], A. STUCHLIK[1,2];
[1]Inst. of Physiol. CAS, Prague 4, Czech Republic; [2]NIMH, Klecany, Czech Republic

Abstract: Although rodent anterior cingulate cortex (ACC) has never been considered a truly spatial structure, theories about ACC function highlighting its fundamental role in decision making, conflict detection, and cognitive control suggest that recruitment of ACC would emerge in environments which contain dynamic elements. To test this hypothesis, we evaluated performance in two spatial avoidance paradigms, Robot Avoidance Task (RAT) and Carousel maze task. Prior to each behavioral testing, male Long-Evans rats were implanted with bilateral guiding cannulae aimed at ACC (AP +2.0; ML ± 0.7). In RAT, a freely moving rat on a circular dry arena is required to keep a minimum 25 cm distance from a randomly moving programmable robot; otherwise it receives a mild foot-shock. Bilateral infusions of muscimol (compared to

saline) abolished performance of well-learned animals avoiding fast, but not slow or fixed robot. In Carousel maze, a rat placed on a slowly rotating circular dry arena is required to avoid a sector-shaped shock zone which remains stable in the reference frame of the room. Thus a rat solves a conflict of discordant spatial cues: misleading rotating arena-bound cues must be treated as irrelevant while stable room frame cues remain relevant. Bilateral muscimol inactivations of ACC impaired avoidance of a sector located in the south-east, and slowed (but not blocked) reversal learning with sector located in north-west. When the conflict was attenuated by training rats in a wading arena suppressing olfactory cues, ACC inactivations had the same deteriorating effect. Thus, the discordant cues conflict was not likely a cause of the observed deficit. Instead, as results from both Carousel maze and RAT suggest, ACC appears to be particularly important for continuous monitoring of dynamic spatial information. Title: Sex differences in the dentate gyrus and overall shape of the hippocampus in DBA mice

Authors: *W. E. GRISHAM, C. TSAI, K. INOUYE;
Dept Psychol, UCLA, Los Angeles, CA

Abstract: Sex differences with males having a higher number of granule cells in the dentate gyrus have been reported in some mouse strains (LG/J, A/J, and MA/MyJ) but not in others (Wimer & Wimer, 1985). Similarly, A/J strain males have a larger volume in the granule cell layer and a laterality difference that is not present in females (Tabibnia, Cooke, & Breedlove, 1999). We sought to extend observations to the DBA strain of mice by measuring the area of the granule cell layer of the dentate gyrus as well as the whole hippocampus.
We used images of coronal sectioned, Nissl-stained DBA mouse brains (5 males, aged 36-294 days; 5 females, aged 44-178 days) obtained from the Mouse Brain Library (http://www.mbl.org/). Each section was 30 microns thick and every tenth section was presented in these images. The Allen Brain Atlas (http://www.brain-map.org/) was used for guidance to the extent of the granule cell layer and the entire hippocampus. The cross sectional areas of the granule cell layer and entire hippocampus were measured blind using NIH ImageJ. In instances

where we had two sets of sections for a given mouse, we averaged their total areas. (In one instance, one set had far fewer sections than the other set, so we discarded it while still being blind.)
As in A/J mice, DBA males had a marginally larger granule cell layer when averaged across side. However, unlike A/J mice, there was no laterality difference in the granule cell layer of DBA mice. This sex difference in granule cells may be involved in sex differences in spatial learning. Notably, DBA/2J male mice learned a spatial escape task with shorter latencies and fewer errors than females (O'Leary, Savoie, & Brown, 2011).
Whole hippocampus area measures revealed neither sex nor laterality differences. Nonetheless, we found a significant sex X section interaction in hippocampal areas; the area of the hippocampus was smaller in females' caudal sections, suggesting a sex difference in the shape of the hippocampus. In this latter analysis, we (1) averaged the right side areas by section across all sets for each mouse, (2) similarly averaged the left side areas, (3) averaged the right and left side areas obtained in (1) and (2). The number of sections used in analyses was based on the mouse with the fewest number of sections per brain region. Similar analyses examining the areas of the granule cells revealed no such interaction between sex and section across rostral-caudal sections. The shape difference seems to involve the intermediate hippocampus, which is involved in rapid one-trial place learning (Bast, Wilson, Witter, & Morris, 2009).

Title: Estradiol regulates bioenergetics in hippocampus and striatum of young adult female rats

Authors: *W. WANG, E. C. D'AMICO, D. L. KOROL;
Dept. of Biol., Syracuse Univ., Syracuse, NY

Abstract: Estrogens enhance hippocampus-sensitive learning and memory but impair striatum-sensitive cognition. One possible explanation for these bidirectional effects is that estradiol

might differentially modulate bioenergetics across brain regions such as the hippocampus and striatum. To test this hypothesis, we used microdialysis to measure extracellular glucose and lactate concentrations in the hippocampus and striatum of three-month-old ovariectomized Sprague-Dawley rats that received either estradiol benzoate (4.5 μg/kg) or oil vehicle (s.c.) 24 and 48 hours prior to microdialysis. Microdialysis probes were used to collect dialysate samples from the hippocampus or striatum while rats were in a holding container that allowed free movement. Artificial cerebrospinal fluid prepared with six different concentrations of glucose (0.5 mM-3 mM) was infused through the probes while samples (20 μL at 1 μL/min) were collected for off-line assay of glucose concentrations. Separate groups of rats were tested for each glucose concentration. The dialysates were later measured for glucose content with an enzymatic assay. Differences between [glucose]out and [glucose]in plotted against different glucose concentrations in the perfusate generated a Zero-Net-Flux regression line. The concentration where [glucose]in = [glucose]out was taken as the extracellular concentration. Rats with estradiol treatment had significantly higher hippocampal extracellular glucose concentrations (2.44 ± 0.1 mM) than did oil-treated rats (1.86 ± 0.16 mM). In contrast, estradiol did not alter extracellular glucose concentrations in the striatum (2.75 ± 0.17 mM for oil treatments vs 2.61 ± 0.14 mM for estradiol treatments). We also measured lactate concentrations from a portion of glucose perfusate samples using lactate enzymatic assays. Interestingly, we found a treatment by brain structure interaction for lactate concentrations: after estradiol treatment, extracellular lactate levels were decreased in the striatum (0.51 ± 0.02 mM for estradiol and 0.62 ± 0.03 mM for oil) but increased in the hippocampus (0.73 ± 0.04 for estradiol and 0.64 ± 0.03 for oil). The results indicate that estradiol increases availability of substrates for energy metabolism in the hippocampus but actually decreases availability of these substrates in the striatum. With past evidence from our labs and others indicating that substrate availability modulates learning and memory, these opposing actions of estradiol on bioenergetics in these memory systems may contribute to the bidirectional effects of estrogens on different types of learning and memory.

Title: Testing the effects of testosterone and age on spatial memory in male rats using an object location memory task

Authors: *L. E. MILLER, V. C. BRADDICK, C. U. CHYR, E. C. GOINS, M. D. SPRITZER; Neurosci. Program in Biol. Dept., Middlebury Col., Middlebury, VT

Abstract: Past studies have shown a positive relationship between circulating testosterone and spatial memory in men. Testosterone declines with age in men, implicating testosterone as a cause of age-related memory loss. To test this relationship, we tested rats using the object-location memory task (OLMT), which relies on a rat's preference for novelty. Our protocol involved 4 days of habituation, during which the rat was introduced into the testing arena for 10 min each day. On testing days, rats were first exposed to two identical objects in the testing arena for 5 min. This was followed by an inter-trial interval of variable length and then a 3 min testing period, during which one of the objects was moved. Rats demonstrated good spatial memory if they investigated the moved object more than the unmoved object. Our first experiment tested the dose-dependent effects of testosterone on OLMT performance using young (2-month old) male rats and a 2 h inter-trial interval. All subjects were castrated or sham-castrated and were given daily injections of either drug vehicle (castrated and sham-castrated control groups) or one of four doses of testosterone propionate (0.125, 0.250, 0.500, and 1.00 mg/rat). Injections started 7 days before the first day of testing and continued throughout testing. Three groups (0.125, 0.500, and 1.00 mg/rat) showed significantly more investigation of the moved than the unmoved objects, whereas the other groups showed no preference. These results demonstrated a dose-dependent enhancement of spatial memory by testosterone. For our second experiment, we used young (2-month old) and old (20-month old) rats that were either castrated or sham castrated. Short inter-trial intervals (5 and 30 min) were used to ensure that the task was not too difficult for old rats. Castration had no effect on memory among the old rats at the 5 min interval but caused memory impairment at the 30 min interval. For the young rats, castrated subjects performed worse than intact subjects at the 5 min interval but, surprisingly, castrated subjects performed better than intact subjects at the 30 min interval. These results suggest that testosterone may differentially impact memory in young and old males. We are in the process of replicating this experiment with a longer (2 h) inter-trial interval. Brain tissue was collected from all subjects at the end of the second experiment to assay BDNF. We observed no significant effects of castration on BDNF, but within the hippocampus we found significantly higher BDNF among old rats than young rats. Overall, we have demonstrated that elevated testosterone can enhance spatial memory in young and old rats, but BDNF levels do not seem to explain this effect.

Title: Acute corticosterone treatment differentially affects spatial memory behavior and vesicular glutamate transporter 2 mRNA in the hippocampus of adult male and female zebra finches

Authors: *Y. V. MAKEYEVA, D. A. GARDNER, B. A. RUPP, D. J. BAILEY;
Biol., St. Norbert Col., De Pere, WI

Abstract: The stress hormone corticosterone affects hippocampal-dependent spatial memory in birds through modifications of glutamatergic neurotransmission. Glutamate is loaded into vesicles by vesicular glutamate transporter proteins (VGLUTs) prior to its exocytosis. Previous studies revealed the immunocytochemical distribution of one of these isoforms, VGLUT2, in the brains of male and female zebra finches (*Taeniopygia guttata*). Additional work found that acute (48 hr) corticosterone treatment enhanced learning in a spatial memory task and increased VGLUT2 mRNA in the dorsolateral hippocampus in females. The current experiments were designed to replicate these results and extend the findings to adult male finches. As males of this species perform better during retention trials in a spatial memory task, we hypothesized that acute corticosterone treatment would further potentiate memory function and VGLUT2 mRNA levels relative to females. Silastic capsules containing corticosterone or nothing were implanted subcutaneously in adult male and female zebra finches. After 48 hrs, birds were food-deprived and tested for spatial learning and memory function in two stages: birds had to learn the location of a cup that contained seed by reaching a predetermined criterion level, then remember the location of that cup during probe trials after an extended interval. Brain tissue from additional groups of hormone- or blank-implanted birds was collected after 48 hrs of treatment and a similar period of food deprivation (but no spatial memory test), and VGLUT2 mRNA expression in the hippocampus was measured with digoxigenin-tailed oligonucleotides. Overall, corticosterone treatment decreased the number of learning trials relative to controls, with no significant difference between males and females. In the first retention trial, corticosterone-treated males took significantly less time to reach the baited cup and made significantly fewer mistakes than blank-treated males and corticosterone-treated females. Interestingly, corticosterone treatment significantly increased VGLUT2 mRNA in the dorsolateral hippocampus of females but not males. These data suggest that corticosterone-induced potentiation of learning in female zebra finches may result from an increased transcription of

VGLUT2. Corticosterone-induced potentiation of spatial memory function in males may occur via mechanisms independent of glutamate shuttling or may not entirely depend on levels of VGLUT2 transcription. Additional studies aim to determine the signal transduction mechanisms mediated by glucocorticoid receptors that lead to modifications in VGLUT2 levels.

Title: The effects of dorsal hippocampus MEK/ERK inhibition on rapid 17beta-estradiol facilitated social recognition in female mice

Authors: *P. A. SHEPPARD[1], K. J. SELLERS[2], I. A. WATSON[3], D. P. SRIVASTAVA[2], E. CHOLERIS[1];
[1]Psychology, Univ. of Guelph, Guelph, ON, Canada; [2]Basic and Clin. Neurosci., [3]Wolfson Ctr. for Age Related Dis., King's Col. London, London, United Kingdom

Abstract: In addition to the delayed and long lasting gene-transcription regulation of steroid hormones, very rapid actions have also been described. The rapid effects of estrogens on learning and memory have been repeatedly shown. In female mice, facilitation of social recognition was found within 40 minutes of systemic administration of 17β-estradiol (E2), as well as estrogen receptor α (ERα) and G-protein coupled estrogen receptor (GPER) selective agonists (PPT and G-1 respectively), but not an estrogen receptor β (ERβ) selective agonist (DPN)(Phan et al, 2011; 2012; Gabor et al, 2015). The dorsal hippocampus mediates these effects as intrahippocampal administration of E2, PPT, or G-1 facilitates social recognition (Phan et al, 2015; Lymer, 2015). Furthermore, systemic administration of E2, PPT, or G-1 increases dendritic spine density in the dorsal hippocampus (Phan et al, 2011; 2012; Gabor et al, 2015). The mechanisms of action by which these rapid effects occur are not well understood; however, estrogenic actions on cell signaling cascades affecting synaptic plasticity and dendritic spine dynamics are thought to play a role. One candidate cascade is the extracellular signal-regulated kinase (ERK) pathway as blocking the phosphorylation (activation) of the ERK protein has been shown to block estrogen facilitated increases in dendritic spine density in cultured neurons (Sellers et al, 2015) and rapid estrogen-induced enhancements in object memory consolidation (Fernandez et al, 2008).

Whether the ERK pathway is also involved in rapid estrogenic facilitation of social recognition in the hippocampus is unknown. First we infused (0.5μL/side, 0.2μL/min) MEK/ERK inhibitor U0126 (0.1, 0.5, or 1.0μg/side) in the dorsal hippocampus of ovariectomized female mice 15 min prior to testing for social recognition. Preliminary results suggest doses of 0.1 and 0.5μg/side do not block social recognition whereas 1.0μg/side does. Then, we infused into the dorsal hippocampus the highest dose of U0126 that did not block social recognition to investigate only the ERK-dependent effects of 50nM E2 – a dose shown to rapidly facilitate social recognition in a difficult version of the social recognition paradigm. These paradigms consist of habituation trails where two female conspecifics are presented and one test trial where one conspecific is novel and the other is familiar. The paradigms are completed within 40 minutes of drug administration, thus enabling the investigation of rapid effects of estrogens.

Title: Memory-enhancing effects of 17β-estradiol in male and female mice

Authors: *W. A. KOSS, K. M. FRICK;
Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: Our laboratory has shown that 17β-estradiol (E_2) infused directly into the dorsal hippocampus of ovariectomized female mice immediately after training increases memory consolidation in the object placement and object recognition tasks. This enhancement depends on the rapid activation of numerous cell-signaling cascades in the dorsal hippocampus including the extracellular signal-regulated kinase (ERK) cascade. In males, systemic post-training injection of E_2 enhances spatial memory consolidation, but the effects of intrahippocampal E_2 infusion on memory in males are unknown, as are the signaling pathways necessary for E_2 to enhance memory formation in males. Thus, the present study compared the effects of dorsal hippocampal E_2 infusion on memory consolidation and cell-signaling in ovariectomized females and sham-operated gonadally-intact males. Males were left gonadally-intact to better relate their data to the vast majority of learning and memory literature that has used gonadally-intact male subjects.

Immediately after ovariectomy or sham surgery, mice were implanted with bilateral dorsal hippocampal cannulae and allowed a week to recover. Immediately after training in the object placement and object recognition tests, mice received bilateral vehicle or E_2 infusion into the dorsal hippocampus. Memory was tested 48 h (object recognition) or 24 h (object placement) later. E_2 enhanced memory consolidation in both sexes in both tasks. Two weeks after behavioral testing, mice were infused again with vehicle or E_2 and the dorsal hippocampus dissected bilaterally 5 minutes later. Preliminary Western blot findings suggest that although females treated with E_2 had increased phosphorylated p42-ERK levels, as shown previously, males did not. Measurement of the effects of E_2 on the activation of other signaling pathways that our laboratory has found to be necessary for E_2's memory-enhancing effects will be measured in both males and females.

Title: Estradiol mediates Wnt/β-catenin signaling in the dorsal hippocampus of female mice

Authors: *L. TAXIER, M. M. KIEFER, A. M. FORTRESS, K. FRICK;
Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: The potent estrogen 17β-estradiol (E_2) enhances learning and memory through activation of several cell signaling cascades, including mTOR, ERK, and PI3K. Previously, we demonstrated that learning robustly activates the Wnt/β-catenin signaling pathway by rapidly increasing levels of β-catenin, phosphorylated GSK3β, and Cyclin D1 (Fortress et al., 2013, JNeurosci, 33:1219-1226). Moreover, activation of Wnt/β-catenin signaling is necessary for object recognition memory consolidation in male mice. Specifically, blockade of Wnt/β-catenin signaling through dorsal hippocampal infusion of the Wnt/β-catenin antagonist Dickkopf-1 (Dkk-1) impaired object recognition memory consolidation in male mice. E_2 may modulate Wnt/β-catenin signaling through crosstalk with other pathways, such as PI3K signaling, that are similarly able to phosphorylate GSK3β and thus allow for downstream transcriptional activation. However, a role for E_2 in mediating memory formation by activating the Wnt/β-catenin signaling

pathway has yet to be elucidated. To determine whether E_2 activates Wnt/β-catenin signaling in the dorsal hippocampus, 10 week-old ovariectomized female C57BL/6 mice were infused bilaterally into the dorsal hippocampus with vehicle or E_2, and the dorsal hippocampus was dissected bilaterally 5 minutes or 4 hours later. Preliminary data indicate that E_2 rapidly activates this pathway, as demonstrated by increased levels of Wnt7a, phosphorylated GSK3β, and total β-catenin 5 minutes post-dorsal hippocampal infusion of E_2. Collectively, these data provide support for a role of E_2 in rapidly activating dorsal hippocampal Wnt/β-catenin signaling. Ongoing studies will investigate the necessity for activation of Wnt/β-catenin signaling in E_2-enhanced memory consolidation in female mice.

Title: The role of the dorsal hippocampus and medial prefrontal cortex in estradiol-mediated enhancement of object memory consolidation in female mice

Authors: *J. J. TUSCHER, A. M. FORTRESS, K. M. FRICK;
Psychology Dept., UW-Milwaukee, Milwaukee, WI

Abstract: Dendritic spine plasticity is thought to be essential for the formation and consolidation of memories. Both natural fluctuations and systemic administration of the sex-steroid hormone 17β-estradiol (E_2) can regulate spine density in the dorsal hippocampus (DH) of rodents. Recently, we found that infusion of E_2 directly into the DH also increases dendritic spine density in the DH and medial prefrontal cortex (mPFC), and that these effects depend upon rapid activation of the extracellular signal-regulated kinase (ERK) and mammalian target of rapamycin (mTOR) cell-signaling pathways in the DH. These intriguing findings highlight a previously unexplored interaction between the DH and mPFC that may have important implications for understanding how E_2 regulates memory. As such, these data led us to question whether interactions between the DH and mPFC are necessary for the E_2-induced memory enhancements that we have previously observed in hippocampus-dependent object tasks (Fernandez et al.,

2008; Fortress et al., 2013; Boulware et al., 2013). To investigate whether the DH and mPFC collaborate to facilitate object memory consolidation, we utilized inhibitory Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) to inactivate the DH or mPFC immediately after object training. As expected, we found DREADD-mediated inactivation of the DH immediately after object placement training impaired spatial memory tested 4 hours later. Ongoing studies are evaluating the extent to which E_2 infusion or inactivation of the mPFC affects spatial memory consolidation, and whether activation of the mPFC is necessary for DH-E_2 mediated enhancement of object memories. Together, these studies will provide critical insight into the estrogenic regulation of memory formation in female mice.

Title: Chronic administration of estradiol benzoate with a spatial pattern separation task reduces adult neurogenesis in the dentate gyrus in a dose dependent manner.

Authors: *S. YAGI[1], C. CHOW[2], S. E. LIEBLICH[2], L. A. M. GALEA[3];
[1]Grad. Program in Neurosci., [2]Dept. of Psychology, [3]Ctr. for Brain Hlth., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Adult neurogenesis in the dentate gyrus (DG) plays an important role for pattern separation, the process of separating similar input and forming distinct neural representations during memory encoding. The objectives of this study were to determine the effect of estradiol on adult neurogenesis and the ability for separating similar patterns. Ovariectomized female Sprague-Dawley rats received daily injection of estradiol benzoate for 28 consecutive days (from day 0 to 27). A single bromodeoxyuridine (BrdU) injection was administrated on day 1 and rats were tested in the spatial pattern separation paradigm for 14 days beginning on day 14 after BrdU. Rats were tested in a delayed nonmatching to place with radial 8-arm maze. During the sample phase, only the start arm and the sample arm were open and a rat was allowed to explore the sample arm and retrieve sugar pellets as a reward. Forty seconds after the sample phase, an additional arm, “correct arm”, opened and the rat was allowed to choose one arm from the sample arm or the correct arm. A separation pattern was 45 degrees away (similar) and the other

pattern was 135 degrees away (distinct) from the sample arm. Rats were all perfused on day 27. Chronic estradiol benzoate reduced adult neurogenesis in a dose dependent manner, whereas there was no significant effect on the ability for separating similar patterns in the radial arm maze. High estradiol benzoate reduced the density of BrdU/NeuN double labelled neurons compared to either oil treated or low estradiol benzoate. We also examined the effects of estradiol benzoate on cell proliferation in the dentate gyrus with using Ki67 immunohistochemistry. In contrast to BrdU/NeuN double labeled cell density, there was no significant effect of estradiol benzoate on Ki67 immunoreactive cell density. In conclusion, chronic administration of estradiol benzoate reduced adult neurogenesis in a dose dependent manner by reducing cell survival of newly produced neurons but did not influence the ability to separate similar patterns or altering cell proliferation in the dentate gyrus. Title: The role of membrane-bound estrogen receptors in the rapid estrogenic enhancements of learning and memory within the hippocampus

Authors: *T. KUUN, E. CHOLERIS;
Univ. of Guelph, Guelph, ON, Canada

Abstract: It has become increasingly well established that estrogens play a role in various types of learning and memory. The binding of estrogen to its receptors often mediates long-term genomic actions (Nilsson et al., 2001). It has more recently been reported that estrogens also mediate rapid actions, requiring only minutes to hours (Woolley, 2007). Specifically, systemic treatment with 17β-estradiol (E2) was shown to rapidly improve object recognition, social recognition and object place learning in ovariectomized mice within a timescale of 40 minutes after treatment (Phan et al., 2012). Recent studies have further identified the dorsal hippocampus as one site of these estrogenic enhancing effects on learning and memory (Phan et al., 2015). Whether or not these rapid estrogenic effects are mediated solely by membrane-bound estrogen receptors is unknown. The current research seeks to determine the role of membrane estrogen

receptors in the rapid effects of E2 in the hippocampus. By conjugating E2 to a large bovine serum albumin molecule (BSA-E2), the estradiol is prevented from passing through the cellular membrane and thus, from binding to intracellular receptors (Taguchi et al., 2004). Therefore, the use of BSA-E2 allows for the investigation of the role of membrane-bound estrogen receptors in the rapid nongenomic effects of estrogens on learning and memory, while ruling out the intracellular mechanisms of estrogen action. The methodology will then use the rapid versions of social recognition, object recognition and object placement paradigms (Phan et al., 2012) to test the rapid effects of intrahippocampal BSA-E2 infusions on these types of learning and memory within 40 minutes post-administration. BSA-E2 or a vehicle control, are infused via previously implanted bilateral hippocampal cannulae, 15 minutes prior to the initiation of the testing procedure. The paradigms involve two 5 minute habituations where two stimuli are presented, and one 5 minute test phase where one of the now familiar stimuli is replaced by a novel one. An investigation ratio of the preference for novel stimulus is calculated. Due to the innate inclination for mice to investigate novel stimuli over familiar ones, mice that remember the habituation stimuli show a preference for the novel stimulus at test. We expect the BSA-E2 treated mice to show investigation ratios at test that are significantly different from the those during habituations, thus demonstrating that these rapid effects of E2 are not impeded by the conjugation with BSA, suggesting the involvement of hippocampal membrane-bound estrogen receptors in these types of learning and memory. Title: Effects of agonism and silencing of G-protein-Coupled Estrogen Receptor (GPER) on hippocampal memory and underlying cell-signaling mechanisms in female mice

Authors: *J. KIM[1], J. S. SZINTE[1], M. I. BOULWARE[2], K. M. FRICK[1];
[1]Psychology, Univ. of Wisconsin-Milwaukee, Milwaukee, WI; [2]Obstetrics & Gynecology, Med. Col. of Wisconsin, Milwaukee, WI

Abstract: The G-protein-coupled estrogen receptor (GPER) is a novel membrane estrogen receptor expressed in areas of the brain including the hippocampus. Although, we previously demonstrated that the ability of 17β-estradiol (E_2) to enhance hippocampal memory depends on rapid activation of extracellular-signal-regulated kinase (ERK) in the dorsal hippocampus (DH), little is known about the role of GPER in mediating the effects of E_2 on memory or cell signaling. Therefore, the present study examined whether activation of GPER mimics the effects of E_2 on ERK signaling and hippocampal memory. Post-training DH infusion of the GPER agonist G-1 enhanced object recognition and spatial memory in ovariectomized female mice, whereas the GPER antagonist G-15 impaired memory, suggesting that GPER activation, like E_2, promotes hippocampal memory formation. However, unlike E_2, G-1 did not increase ERK phosphorylation, but instead significantly increased phosphorylation of c-Jun N-terminal Kinase (JNK) in the DH. Moreover, DH infusion of the JNK inhibitor SP600125 prevented G-1 from enhancing object recognition and spatial memory, but the ERK inhibitor U0126 did not. These data suggest that GPER enhances memory via different cell-signaling mechanisms than E_2. This conclusion was supported by data showing that the ability of E_2 to facilitate memory and activate ERK signaling was not blocked by G-15 or SP600125, which demonstrates that the memory-enhancing effects of E_2 are not dependent on JNK or GPER activation in the DH. Together, these data indicate that GPER regulates memory independently from E_2 by activating JNK signaling, rather than ERK signaling. As a next step, we are currently determining the necessity of GPER for hippocampal memory using short-interference RNAs (siRNAs) to silence GPER expression in the DH. We determined the spread of the Accell short-interference RNAs (siRNAs) using Accell FAM (6-fluorescein amidite)-labeled non-targeting control siRNA. Mice received bilateral DH infusion of FAM-labeled control siRNA and the brains were cut on a cryostat 2, 4, and 7 days later. FAM-labeled siRNA fluorescence was detected in the DH, mostly in the CA1 and part of the dentate gyrus, on day 2 and 4, but not day 7. Infusion of GPER-targeting siRNA suppressed GPER mRNA expression significantly compared to control-non-targeting siRNA infused mice at day 2. Also, levels of GPER protein were reduced 4 days later in mice infused with GPER-targeting siRNA. The effects of hippocampal GPER silencing on learning and memory consolidation are currently being investigated. Collectively, these data provide new insights into the role of GPER in regulating hippocampal function.

Title: Male and female BDNF Val66Met mice feature a "pre-stress" transcriptional signature in CA3 neurons.

Authors: *J. MARROCCO, G. H. PETTY, M. B. RÍOS, J. D. GRAY, J. F. KOGAN, E. M. WATERS, E. F. SCHMIDT, N. HEINTZ, B. S. MCEWEN;
The Rockefeller Univ., New York, NY

Abstract: Brain-derived neurotrophic factor (BDNF) promotes neural plasticity as well as the establishment of long-term memories. Abnormalities of BDNF levels have been associated with behavioral impairment and altered mental status. Also, BDNF mediates the effects of gonadal hormones, which, along with transcriptional regulation, critically contribute to the establishment of sex differences. The discovery of the single nucleotide polymorphism BDNF Val66Met suggested a novel predictor to identify populations at greater risk of affective disorders. Heterozygous carriers (+/Met) are of considerable clinical value with a frequency as high as 40%, depending on the ethnicity. The disparity in affective disorders, which is higher in women than in men, indicates the necessity to include both sexes in neuroscience studies. We wanted to assess the brain transcriptional signature characteristic of heterozygous $BDNF^{+/Met}$ mice both in naïve animals and in response to an acute challenge. We used a $BDNF_{Met}$ knock-in mouse ($BDNF^{+/Met}$), which recapitulates the pathological human hallmarks, and their matched wild type $BDNF^{+/+}$. We focus our study on the CA3 region, a BDNF-enriched hippocampal area that displays sex-dimorphism in response to stress. We generated a Bacterial Artificial Chromosome mouse in which the EGFP-L10a ribosomal protein is expressed under a promoter for a CA3-selective gene. Genetically-targeted translating ribosome affinity purification allowed for the isolation of the CA3 area. RNA-sequencing analysis revealed that stressed $BDNF^{+/+}$ and unstressed $BDNF^{+/Met}$ showed similar transcriptional changes when compared to unstressed $BDNF^{+/+}$, although both differed with respect to sex. In particular, epigenetic markers such as DNMT1 and DNMT3a were equally dysregulated in stressed $BDNF^{+/+}$ and unstressed $BDNF^{+/Met}$. Yet, one marker of acute stress, c-Fos, was not increased in unstressed $BDNF^{+/Met}$ mice, indicating that $BDNF_{Met}$ carriers featured a “pre-stress” transcriptional phenotype. Gene ontology based clustering of equally dysregulated genes displayed a sex-dimorphic enrichment score of the pathways. $BDNF^{+/Met}$ females showed a poor discrimination index in the object placement test whereas cognitive performance was intact in $BDNF^{+/+}$ regardless of acute stress. Estrus cycle status modulated anxiety-like behavior in $BDNF^{+/Met}$, demonstrating that sex hormones critically modulate the behavioral phenotype of $BDNF_{Met}$ carriers. Together, these data suggest that the transcriptional response in the hippocampus may predict the increased vulnerability to neuropsychiatric disorders of $BDNF_{Met}$ carriers.

Title: Effects of fluoxetine & clozapine on learning and memory, depressive behavior, and androgen levels of male rats

Authors: *M. E. RHODES[1], C. SLEDZIK[2];
[1]Psychol Dept, [2]Psychology, McDaniel Col., Westminster, MD

Abstract: Schizophrenia very often occurs comorbid with depression, which can necessitate the use of both antipsychotics and antidepressants for treatment. The present study investigated the effects of co-administration of clozapine (an antipsychotic) and fluoxetine (an antidepressant) on depressive behavior, learning and memory, and androgen levels of male rats. Rats were randomly assigned to one of four groups: vehicle-vehicle, vehicle-clozapine, vehicle-fluoxetine, or clozapine-fluoxetine. Rats were administered the assigned drug regimen once daily for five weeks. After one week of drug administrations, behavioral tests were conducted once per week and order of testing was counterbalanced among rats to avoid order effects. All rats were tested in the forced swim, Y-maze, and object recognition tasks. One week following completion of behavioral testing, brains were collected for measurement of androgen concentrations in the hippocampus. Fluoxetine decreased depressive behavior in the forced swim test; there was no effect of clozapine in this task. In both learning tasks, clozapine decreased performance, but the co-administration of fluoxetine attenuated these effects. Clozapine and fluoxetine, alone and together, significantly altered androgen levels in the hippocampus. Together, these data suggest that some of the negative side-effects (clozapine) and therapeutic effects (fluoxetine) may be due, at least in part, to their actions to alter androgen levels.

Title: Previous midlife estradiol treatment results in increased nuclear ERα expression in the hippocampus of aging ovariectomized rats

Authors: *K. L. BLACK[1], R. C. SPRINGER[1], N. E. BUMGARTNER[1], J. A. GELLER[1], J. M. DANIEL[2];

Abstract: Work from our lab has demonstrated that previous midlife estradiol treatment improves memory in ovariectomized female rats months after hormone exposure has ended. Furthermore, midlife estradiol exposure results in lasting increases in levels of estrogen receptor alpha (ERα) in the hippocampus, an effect that mediates the memory enhancements. Traditionally, ERα acts as a nuclear receptor, initiating genomic effects including increased transcription of certain genes. More recently, ERs have been localized to the membrane. Activation of membrane ERα could result in non-genomic, rapid acting effects. The goal of the current work is to determine where ERα is localized following midlife estradiol treatment. Middle-aged rats were ovariectomized and implanted with hormone capsules containing either estradiol or vehicle. Forty days later, capsules were removed. One month after hormone treatment ended, rats were killed and hippocampi were dissected and processed for subcellular fractionation. Hippocampal lysate was homogenized and separated into cytosolic, membrane, and nuclear compartments using the protocol included with a commercially available kit. All samples (cytosolic, membrane, and nuclear) were further processed for western blotting. Using a subset of samples, we verified that there was negligible contamination between subcellular compartments. Western blotting for ERα was then performed. Previous estradiol treatment resulted in lasting increases of nuclear protein expression of ERα compared to vehicle-treated rats. There were only trace amounts of cytosolic ERα, regardless of hormone treatment. We found no differences in membrane ERα protein expression. Results demonstrate that in the aging female hippocampus, lasting increases in ERα protein expression following midlife estradiol treatment are due to increases in nuclear-localized ERα.

Title: Sex differences in levels of myelin basic protein in the orbitofrontal cortex of adult rats results from action of ovarian hormones during puberty.

Authors: *J. DARLING[1], A. H. NGUYEN[1], S. A. RIOS[1], J. M. DANIEL[1,2];
[1]Neurosci. Program, [2]Psychology, Tulane Univ., New Orleans, LA

Abstract: Previous work from our lab has revealed that adult female rats have increased levels of myelin basic protein (MBP), a marker for myelination, in the orbitofrontal cortex (OFC) as compared to adult males. However, this sex difference in MBP in the OFC was not seen in prepubertal rats. In a follow-up experiment, we examined adult circulating levels of gonadal hormones for activational influence on this sex difference in myelination and found no impact. Therefore, we hypothesized that exposure to a rise in gonadal hormone levels during puberty mediates a sex difference in MBP in the OFC of rats. To test this hypothesis we compared the impact of gonadectomy prior to and after puberty on levels of MBP in the OFC of adult male and female rats. 36 rats (18 males, 18 females) were used in this experiment. One third of rats (28d of age) underwent gonadectomy prior to puberty, one third of rats (90d of age) underwent gonadectomy in adulthood, and one third of rats received sham surgeries (at either 28d or 90d of age). At 4 months of age, animals were killed and OFC were dissected and processed for western blotting. Consistent with our previous results, intact female rats had increased levels of MBP in the OFC than did males and there was no impact of adult gonadectomy on levels of MBP. A significant decrease in MBP in the OFC was found in female rats gonadectomized prior to the onset of puberty while no such effect was seen in males. These results indicate that exposure to gonadal hormones during puberty organizes and significantly increases adult levels of MBP in the OFC in female rats as compared to males. Future work will examine the ability of gonadal hormones acting during the pubertal period to influence previously described sex differences in OFC-dependent behaviors in adult rats.

Title: Previous exposure to estradiol in ovariectomized female mice results in lasting increased expression of estrogen receptor alpha and maintenance of estrogen receptor-dependent gene transcription in the hippocampus

Authors: *K. J. POLLARD[1], H. WARTMAN[1], J. M. DANIEL[2];
[1]Neurosci., [2]Psychology, Tulane Univ., New Orleans, LA

Abstract: The long-tern effects for the brain and memory of short-term use of estrogen therapy following surgical or natural menopause in women are unknown. We have previously found that a 40-use of continuous estradiol exposure in aging ovariectomized female rats improves hippocampal dependent memory and increases hippocampal expression of the estrogen receptor alpha (ERα) up to 7 months after treatment has ceased. Furthermore, an increased hippocampal expression of ERα alone is sufficient to elicit memory enhancement in rats. However, the cellular functions through which ERα mediates memory enhancement in absence of circulating estrogens remain unknown. We hypothesize that ERα continues to act as a nuclear transcription factor to elicit these effects. The goal of the current work is to first replicate our previous findings using mice and then utilize ERE-LUC transgenic mice to determine if and how long estrogen receptors act as nuclear transcription factors in the hippocampus after termination of previous estradiol exposure or cessation of ovarian function. In experiment 1, wild-type C57BL/6 mice were trained to criterion on the radial arm maze (RAM) task, OVX and treated for 40 days with continuous estradiol or vehicle, and tested on the RAM between two and four weeks after termination of treatment. Experiments 2 and 3 were conducted with transgenic ERE-LUC mice that express the firefly luciferase protein under transcriptional control of the estrogen response element (ERE). In experiment 2, mice were OVX and treated as in experiment 1. Hippocampi were harvested four or seven weeks following termination of estradiol or vehicle treatment. For comparison, mice in experiment 3 were simply either OVX or sham OVX and hippocampi were harvested four weeks after surgery. Hippocampi were analyzed for the presence of the luciferase reporter gene, which is indicative of ERE-dependent gene transcription. From these three experiments we determined that previous estradiol exposure increases the hippocampal expression of ERα protein and enhances hippocampal dependent memory in OVX female mice. We also determined that ERE-dependent gene transcription occurs at near intact levels four weeks after either ovariectomy alone or termination of previous estradiol treatment. Data from the seven week time point are pending. These results suggest that ERα can improve memory by initiating ERE-dependent gene transcription in hippocampi of female mice lacking circulating estrogens. The mechanisms through which this occurs are still under investigation.

Title: Rapid effects of 17β-estradiol in the paraventricular nucleus on social recognition in female mice

Authors: *P. PALETTA, K. ALI, E. CHOLERIS;
Univ. of Guelph, Guelph, ON, Canada

Abstract: Essential for social species is being able to identify others based on information obtained from previous encounters. This ability is referred to as social recognition and is important for the development of social bonds, dominance hierarchies, and various other aspects of social life. Both estrogens and oxytocin (OT) facilitate social recognition. When the estrogen receptor alpha (ERα), OT, and the oxytocin receptor (OTR) are each knocked out social recognition is impaired. In addition, estrogens can rapidly facilitate social recognition (Phan, et al., 2012). This suggests that both estrogens and OT are needed for social recognition. A model was developed (Choleris, et al., 2003) that suggests that estrogens bind to the estrogen receptor beta (ERβ) located on OT neurons in the paraventricular nucleus (PVN) of the hypothalamus and facilitates the production and release of OT. OT reaches the medial amygdala where estrogens bind to ERα to facilitate the production of OTRs. OT-OTR binding in the medial amygdala then facilitates social recognition. The purpose of this research is to determine whether this model accurately depicts estrogens/OT regulation of social recognition within the rapid time frame of estrogen effects. First we need to determine whether 17β-estradiol in the PVN can facilitate social recognition. This is tested by ovariectomizing (OVX) female, CD-1 mice, to control circulating estrogens and inhibit social recognition, then infusing 17β-estradiol (25nM, 50nM, and 100nM) in the PVN through implanted bilateral cannulae prior to testing in a “difficult” social recognition paradigm where social recognition in OVX mice is typically not found. The paradigm begins 15 minutes after the infusion of 17β-estradiol. The mice are presented with two stimulus mice (habituation phase) and, after a delay, with two mice again (test phase), one from habituation and a novel stimulus mouse. This “difficult” paradigm with low performance in the control mice allows for the detection of enhancing effects of treatment. In addition, the paradigm takes place within 40 minutes of treatment to assess the rapid effects estrogens have on social recognition. Since mice have a natural inclination to investigate novelty, if at test they investigate the novel mouse more than the familiar mouse, it would suggest that they recognize the previously encountered familiar mouse. It is expected that 17β-estradiol infused into the PVN

will recover social recognition while the control mice will still be impaired. This would prove that estrogens in the PVN facilitate social recognition and we can next determine if this facilitation occurs through an interaction with OT. Funded by NSERC.

Title: Destructive circuit remodeling mediates neurogenesis-induced forgetting

Authors: *A. GUSKJOLEN, J. EPP, L. RESTIVO, S. JOSSELYN, P. FRANKLAND;
Sick Kids Hosp., Toronto, ON, Canada

Abstract: The production and maturation of new neurons in the dentate gyrus of the hippocampus provide a physical substrate for new learning[1]. However, computational models also predict that the addition of new neurons should lead to degradation of previous acquired information (i.e., forgetting)[2,3,4]. Consistent with this possibility, our lab recently demonstrated that high rates of neurogenesis cause forgetting of hippocampal-dependent information learned one month earlier[5]. Our current model of neurogenesis-induced forgetting is based on the idea that as newborn neurons mature and form synaptic connections, they necessarily remodel the circuitry upon which hippocampal memories are dependent. This 'destructive remodeling' of the circuit likely reduces the probability that a given environmental cue will reactivate the specific pattern of neural activity that mediates successful memory retrieval[6]. If this model is correct, then inhibiting the synaptic integration of newborn neurons into the surrounding circuit should alleviate the forgetting phenotype. To test this hypothesis, we have developed multiple transgenic mouse lines in which the integration of new neurons is selectively disrupted. In one such line, we deleted the Rho GTPase Rac1 from neural progenitors using a cre-loxP strategy. This deletion does not affect the proliferation (Ki67+ cells) or survival (DCX+ cells) of newly generated neurons. However, deletion of Rac1 reduces synaptic integration as indicated by decreased dendritic growth, arborization, and mushroom spine development[7]. To test the idea that forgetting depends upon integration of new neurons, we then trained these mice in a contextual fear conditioning task. Following training, half the mice were allowed free access to a running wheel for a month and the other half were housed conventionally. Whereas post-training

running increased hippocampal neurogenesis and induced forgetting in control mice, conditional deletion of Rac1 prevented running-induced forgetting. Since the integration, rather than production, of new neurons is altered in the Rac1-deficient mice, these results suggest that forgetting is mediated by circuit remodeling caused by the synaptic integration of recently generated hippocampal neurons. Critically, deleting the Rac1 gene from mature CaMKII+ forebrain neurons did not block the forgetting phenotype, thereby establishing the cellular specificity of this effect. Furthermore, this effect was not driven by an anxiogenic alteration, as behavior in the open field and elevated plus maze was unchanged. This set of experiments helps elucidate the mechanism underlying neurogenesis-induced forgetting.

Abstract: Schizophrenia is a devastating neurodevelopmental disorder that affects about 1% of the population. The etiology of schizophrenia is quite complex with numerous genetic and non-genetic risk factors. The vast majority of research to date has focused on understanding the genetic components of schizophrenia, which has come at the expense of identifying and exploring non-genetic risk factors that may act alone or in concert with genetic factors to cause schizophrenia. Of the currently known non-genetic risk factors, one of the most prevalent is exposure to the parasite toxoplasma. Toxoplasma infection leads to a 2.6 fold increase in

schizophrenia rates in offspring, which is an odds ratio similar in magnitude to many of the genetic risk factors. Therefore, toxoplasma is clearly an important contributing risk factor but there is no model system to study schizophrenia associated with toxoplasma infection. In order to develop a toxoplasma infection based model of schizophrenia we injected mice at either postnatal day (p) 10 or p60 with a type III (CEP) strain of *T. Gondii.* 8 weeks later we examined the mice for chronic changes to schizophrenia-related behaviors including pre-pulse inhibition (PPI) of the acoustic startle response and locomotor sensitization. The results of these behavioral tests show that mice infected with *T. gondii* demonstrate impaired prepulse inhibition without changes in the startle response, which suggest deficits in sensorimotor gating. In addition, *T. gondii* treated mice exhibited a disrupted locomotor response to cocaine sensitization. These abnormalities in sensorimotor gating and drug sensitivity are indicative of cognitive and positive symptoms of schizophrenia. Therefore, our results further support the involvement of *T. gondii* in neuropsychiatric disorders such as schizophrenia, and also lends credence to this paradigm as a viable animal model for these disorders.

Title: Learning regulates the mRNA demethylase FTO and mRNA methylation

Authors: *B. J. WALTERS[1], V. MERCALDO[2], C. J. GILLON[3], M. YIP[2], R. NEVE[4], P. W. FRANKLAND[2], S. A. JOSSELYN[2];

Abstract: Translation of mRNA into proteins is vital for memory formation. The necessity of translation is evidenced by local, spine-specific mRNA translation in response to synaptic stimulation and the detrimental effects on memory produced by translational inhibitors. Although

the role of translation in memory is well accepted, the actual mechanism that underlies local control of translation is poorly understood. In this study, we explored whether mRNA methylation, a novel regulator of translation, is involved in memory formation. RNA can be heavily modified, with the most abundant modification being methylation of adenine (m6A). The potential to locally control translation makes m6A particularly enticing as a regulator of synaptic activity, where local control of translation in synapses is vital for synaptic plasticity. Here, we provide the first direct exploration of mRNA methylation in memory. We demonstrate that associative learning dynamically regulates the RNA demethylase *Fto* and mRNA methylation in area CA1 of the dorsal hippocampus. Notably, isolation of synaptosomes from the hippocampus of trained mice shows preferential removal of FTO from the synaptic fraction after training, suggesting that a major function of FTO during memory occurs at the synapse. Finally, we knocked-down FTO from the dorsal CA1 of mice using either CRISPR/Cas9 or traditional shRNA and observed an improvement in memory. These studies represent the first attempt to link epitranscriptomics (the study of mRNA modifications) to memory formation and demonstrates the importance of RNA modifications in memory.

Title: Identification of an inhibitory hippocampal-thalamic pathway that mediates remote memory retrieval

Authors: *G. VETERE, F. XIA, S. A. JOSSELYN, P. W. FRANKLAND;
Program In Neurosci. & Mental Hlth., Hosp. For Sick Children, Toronto, ON, Canada

Abstract: Systems consolidation requires time-dependent reorganization of brain regions that are necessary for memory retrieval. Analysis of a fear memory functional network (Wheeler et al. 2013) revealed that remote memory recall involves an increase in functional connectivity between thalamic, hippocampal and neocortical brain regions. Most interestingly, further analysis of this remote memory network revealed a unique pattern of negative functional connections between the anterodorsal thalamic nucleus (ADn) with the rest of the network. This

led us to hypothesize that inhibition of the ADn may be necessary for remote memory retrieval. Using an optogenetic approach, we virally infused an adeno-associated virus (AAV) carrying the excitatory opsin, channelrhodopsin-2 (ChR2), in the ADn of wild-type mice, and trained them in a standard contextual fear conditioning paradigm. When we excited ADn CaMKII+ neurons during remote memory recall 28 days post-training, we found that ADn activation impaired reduced conditioned freezing, suggesting that ADn inhibition is necessary for successful memory retrieval. Next, we examined the anatomical connectivity, and found that in addition to functional connections, ADn is also structurally connected with hippocampal and neocortical regions that are highly implicated in memory consolidation, such as CA3, prelimbic, and anterior cingulate cortex. In particular, we identified strong inhibitory projections from the CA3 to the ADn that could potentially mediate the inhibition of ADn during remote memory recall. To test this, we bilaterally infused a cre-recombinase-dependent AAV carrying the inhibitory opsin, archaerhodopsin (eArch), in the CA3 of VGAT-cre mice, and implanted optrodes in the ADn. This allows us to specifically inhibit GABAergic projections from the CA3 to the ADn. When we inhibited these projections during the remote memory test, mice showed reduced freezing levels. These results indicate that CA3 inhibition of the ADn is necessary for memory retrieval. Here, we show for the first time, that remote memory recall engages and requires a unique negative functional and structural connection from the CA3 to the ADn.

Title: Establishment of a contextual fear learning paradigm in zebrafish

Authors: *J. W. KENNEY[1], I. C. SCOTT[2], S. A. JOSSELYN[1], P. W. FRANKLAND[1]; [1]Neurosciences and Mental Hlth., [2]Developmental & Stem Cell Biol., The Hosp. for Sick Children, Toronto, ON, Canada

Abstract: Adult zebrafish are a useful vertebrate model organism for studying memory due to their genetic accessibility, low cost, and potential for high-throughput analysis. However, there

are few robust, rapidly acquired, one-trial learning paradigms that have been established in zebrafish. Such a paradigm would be useful for facilitating the in-depth analysis of mechanisms involved in memory formation and forgetting. Towards this end, we developed a contextual fear conditioning task in zebrafish that has numerous similarities to the contextual fear paradigm extensively used in rodents. Exposure of fish to a series of mild electric shocks results in a shock-number and -intensity related reduction in locomotor activity. Upon re-exposure to the conditioning tank a day later, fish continued to demonstrate a decrease in locomotor behavior relative to baseline and is absent in un-shocked fish. Furthermore, we find that the decrease in locomotor activity is robust, lasting at least 2 weeks, and is specific to the tank in which the fish were shocked. Finally, we find that various strains of fish, such as the AB, Tu, and TL strains, all demonstrate robust learning of this paradigm, but differ with respect to extinction of the memory. We believe this paradigm will prove useful in the study of learning and memory due to its robustness, rapid acquisition, and consistency across fish strains. In addition, the task is similar to the widely used contextual fear conditioning paradigm in rodents, thereby allowing straightforward comparisons to a considerable body of experimental findings that we can now extend by exploiting the extensive molecular genetic toolbox of zebrafish. Title: Neuronal allocation to a hippocampal engram

Authors: *S. PARK[1], E. E. KRAMER[2], V. MERCALDO[2], A. J. RASHID[2], N. INSEL[3], P. W. FRANKLAND[2], S. A. JOSSELYN[4];
[1]Sickkids Hosp., Toronto, ON, Canada; [2]SickKids Hosp., Toronto, ON, Canada; [3]sickKids Hosp., toronto, ON, Canada; [4]sickKids Hosp., Toronto, ON, Canada

Abstract: The dentate gyrus (DG) is important for encoding contextual memories, but little is known about how a population of DG neurons comes to encode and support a particular memory. One possibility is that recruitment into an engram depends on a neuron's excitability (Han *et al*, 2009; Zhou *et al*, 2009; Choi *et al*, 2011; Sano *et* al, 2014). Here we manipulated excitability by overexpressing CREB in a random population of DG neurons and examined whether this biased their recruitment to an engram supporting a contextual fear memory. To directly assess whether neurons overexpressing CREB at the time of training became critical components of the engram, we examined memory expression while the activity of these neurons was silenced. Chemogenetically (hM4Di, an inhibitory DREADD receptor) or optogenetically (iC++, a light-activated chloride channel) silencing the small number of CREB-overexpressing DG neurons attenuated memory expression, while silencing a similar number of random neurons not overexpressing CREB at the time of training did not. As post-encoding reactivation of the activity patterns present during initial experience is thought to be important in memory consolidation, we investigated whether post-training silencing of neurons allocated to an engram disrupted subsequent memory expression. We found that silencing neurons 5 min (but not 24 h) following training disrupted memory expression. Together these results indicate that the rules of neuronal allocation to an engram originally described in the lateral amygdala are followed in different brain regions including DG, and moreover, that disrupting the post-training activity pattern of these neurons prevents memory consolidation.

Title: Energy drink consumption during pregnancy affects hipocampal synaptophysin expression, spatial learning but not memory in the offspring of Wistar rats

Authors: *N. A. MOY LÓPEZ[1], M. F. PINTO-GONZÁLEZ[2], J. A. AGUILAR-MORENO[2], K. A. MOKAY-RAMÍREZ[2], E. O. QUINTERO-MARTÍNEZ[2], M. CANDELARIO-GONZÁLEZ[2], O. GONZÁLEZ-PÉREZ[2], J. L. COLLÁS-AGUILAR[2], J. GUZMÁN-MUÑIZ[2];
[2]Lab. of Neurosciences, [1]Univ. of Colima, Colima, Mexico

Abstract: Energy drink (ED) use and popularity has increased over the years due to its effects on metabolic and cognitive processes. Nowadays, the beverage has been distributed in some countries as Mexico without regularizations about its consumption during pregnancy. Additionally, there is a lack of studies about the relationship between ED consumption during pregnancy and brain development in fetuses. Therefore, the aim of the study was to analyze the effects of ED consumption during pregnancy on spatial learning and memory and hipocampal synaptophysin expression in the offspring of Wistar rats. In this study, we used commercial energy drink. It was given at free access to female Wistar rats during pregnancy and lactancy as experimental group (EG), while rats from control group (CG) consumed only water. The pups were evaluated on postnatal 28 on spatial learning using the Morris Water Maze (MWM), while spatial memory was evaluated in P42. Brain tissue was extracted to analyze the expression of synaptophysin in CA3 and DG hipocampal areas. Significant differences were only found in spatial learning, where EG pups showed an improved performance in MWM compared with CG pups ($t=2.21$, $df=89$, $p=0.03$). Synaptophysin expression in CA3 was lower in EG pups ($U=2$, $P<0.01$). Similar results were found in DG, where synaptophysin expression was also lower in EG pups than CG pups ($U=0$, $P<0.01$). Also, a significant prevalence of low weight gain was found in EG pups. According to this, synergy between ED ingredients can enhance learning processes when consumed during prenatal development. However, synaptophysin expression may indicate changes in neuronal communication that not necessarily affects spatial learning and memory, adding a low weight gain that could be an indicative of metabolic malfunctions that lead to future health problems. Thus, ED consumption should be avoided during pregnancy not only for its caffeine content but for the combined effect of its ingredients.

Title: Brevican regulates learning by gating parvalbumin interneurons in an activity-dependent manner

Authors: E. FAVUZZI, R. DEOGRACIAS, A. MARQUES-SMITH, C. WINTERFLOOD, C. FERNANDES, *B. RICO;
King's Col. London, London, United Kingdom

Abstract: Experience-dependent plasticity in the brain requires a balanced interplay between excitation and inhibition. Parvalbumin (PV) basket cells constitute the most abundant subpopulation of inhibitory neurons and have been shown to be critical for the regulation of plasticity and learning. In the cerebral cortex PV cells are enwrapped by the perineuronal net (PNN), a complex of extracellular matrix molecules that has been shown to regulate synaptic plasticity. However, little is known about the precise mechanism by which individual PNN proteins regulate PV cells to ultimately trigger plasticity in complex cortical networks. We found that transcripts of the chondroitin sulphate proteoglycan Brevican, one of the most enigmatic PNN proteins, are expressed in astrocytes, oligodendrocytes and in the majority of PV basket cells. Indeed, PV cells expressed both the secretable and the GPI-Brevican isoforms. Using super-resolution microscopy, we showed that Brevican was flanking the excitatory synapses made onto PV cells. Loss of Brevican caused a decrease in the density of the excitatory boutons during synapse maturation and a substantial change in the PV intrinsic properties. Furthermore, we demonstrated some of the molecular mechanism behind these defects and found that Brevican expression was dynamically regulated by activity. Finally we showed that the lack of Brevican has singular impact in some aspects of learning and short-term memory. Our findings uncover the mechanism by which the PNN protein Brevican regulates the maturation of excitatory synapses and modulates the properties and function of PV cells to orchestrate plasticity in the neural circuits. These results further reveal the different molecular programs underlying learning and memory.

Title: Development- and experience-dependent plasticity in the dorsomedial habenula

Authors: *P. KOPPENSTEINER, C. GALVIN, I. NINAN;
Dept. of Psychiatry, New York Univ. Langone Med. Ctr., New York, NY

Abstract: Of the two major subdivisions of the habenula, the medial and lateral nuclei, the medial habenula is the least understood in terms of synaptic transmission, intrinsic properties and plasticity. The medial habenula (MHb) is composed of glutamatergic neurons which receive the majority of their inputs from the septal region and project predominantly to the interpeduncular nucleus (IPN). To understand the synaptic transmission, we studied both glutamatergic and GABAergic synaptic transmission in the dorsal region of the medial habenula (dMHb). While glutamatergic transmission dominates during early development, an attenuation of glutamatergic transmission and an enhancement of GABAergic transmission occur during development leading into adulthood. Furthermore, as reported previously, $GABA_A$ receptor-mediated transmission is excitatory in the adult dMHb, which is consistent with the reduced expression of the K-Cl co-transporter KCC2. Given the potential role of the dMHb in fear behavior, we examined whether fear conditioning affects synaptic transmission and excitability in dMHb neurons. Fear conditioning caused a reduction in GABAergic transmission without affecting glutamatergic transmission. Furthermore, we observed a suppression of the excitability of dMHb neurons following fear conditioning. Given that the medial habenula is upstream of the median raphe nucleus which is believed to be involved in the consolidation of fear memory, the decrease in GABAergic transmission and excitability in dMHb neurons following the fear learning might play a role in the strengthening of fear memory.

Title: Maternal folic acid supplementation affects structure and function during early and postnatal development of the nervous system

Authors: *K. A. MOKAY-RAMÍREZ, E. O. QUINTERO-MARTÍNEZ, M. F. PINTO-GONZÁLEZ, J. A. AGUILAR-MORENO, J. GUZMÁN-MUÑIZ, O. GONZALEZ-PEREZ, N. A. MOY-LÓPEZ;
Neurosci., Univ. of Colima, Colima, Mexico

Abstract: Folic acid (FA) plays an important role in the development and maturation of the central nervous system (CNS). For pregnant women, FA supplementation and fortification is implemented with doses depending on their health state, administration periods and gynecological and obstetric history. In addition, CNS indispensably requires a certain amount of FA, due to its intervention on DNA (deoxyribonucleic acid) production and replication. Furthermore, motor and cognitive processes can also be influenced by external factors, such as maternal nutrition before and during gestation. In this study, we evaluated the effect of maternal food supplementation with FA on motor, cognitive and neural development of Wistar rat pups. For this porpoise, supplementation of 0.2mg of FA per day was given one week pre-conception and one week during gestation to the short fortification scheme group (SFS), meanwhile, long fortification scheme group (LFS) received FA from one week pre-conception until the end of pregnancy. Control group consumed only a balanced diet. Also, mobility of pups was evaluated ad postnatal 27 (P27) using the open field test (OF), while spatial learning and memory were evaluated with the Morris water maze (MWM), 1 trial per day during 7 days for learning at P28, and only trial for memory at P42. Brain tissue was extracted for synaptophysin analysis in CA3, dentate gyrus and fimbria from the hippocampus. In 7 days of MWM, no significant differences were identified in spatial learning between groups [$F_{(3, 55)}=1.13, p=0.34$]. However, when we excluded the days 1 and 2 of habituation, significant differences were found in all groups [$F_{(3, 55)}=1.1, p=0.02$]. In all cases, LFS group presented an improved learning performance. Spatial memory evaluation showed similar results, where LFS group indicated better results in this test. As for motor skills analysis, OP showed that groups treated with an FS traveled a greater distance compared to the control group [$F_{(3,55)}=15.52$, $p<0.01$]. No significant effect was found on speed [$F_{(3,55)}=0.97, p=0.41$], which could indicate an anxiolytic effect. On the other hand, immunological analysis showed significantly more expression of synaptophysin only on hipocampal CA3 [$F_{(3,36)}=3.511, p=0.025$]. This results indicate that maternal consumption of food enriched with FA positively affected the hippocampus-dependent learning and memory, neuronal plasticity and motor skills of Wistar rat pups, especially to pups with LFS. It is reasonable to think that FA supplementation could help to enhance fetal development, for which FA doses should be adequate to the woman needs and nutritional status before and during the whole pregnancy.

Title: The role of mossy cells on hippocampal-dependent learning and memory

Authors: *K. KOLARIC[1], S. WOODS[1], C. JUNG[4], R. MCINNES[5], C. HOUGHTON[2], R. SZALAI[2], Z. BASHIR[3], D. ATAN[1];
[1]Sch. of Clin. Sci., [2]Sch. of Engin., [3]Sch. of Physiol. and Pharmacol., Univ. of Bristol, Bristol, United Kingdom; [4]Univ. of Toronto, Toronto, ON, Canada; [5]McGill Univ., Montreal, QC, Canada

Abstract: The hippocampal dentate gyrus (DG) is essential to cognition, learning and memory. Sensory information about the environment arrives from the entorhinal cortex (EC) via the perforant pathways to granule cells (GCs) in the DG, the so-called gateway to the hippocampus. GCs are responsible for coding similar EC inputs into distinct output patterns in a process called pattern separation. Pattern separation ensures that catastrophic interference between recall of similar memories does not occur.
Mossy cells are the principal glutamatergic cells of the DG hilum. They are directly excited by GCs and also feedback onto GCs via a direct excitatory projection to GC dendrites and an indirect inhibitory projection via hilar interneurons. Although integral to the DG and the process of pattern separation through their disparate projections, the net impact of MCs on GC activity is largely unknown.
PRDI-BF1 and RIZ homology domain containing 8 (PRDM8) is a member of the PR/SET domain transcription factor family. PRDM8 is expressed in MCs and GCs in the developing and mature DG. We have found that *Prdm8*$^{-/-}$ mice have deficits in spatial learning and memory associated with the specific absence of MCs. Electrophysiological recordings of field excitatory post-synaptic potentials (fEPSPs) from GC dendrites in hippocampal transverse slices in response to 5Hz, 20Hz and 50Hz subthreshold stimulations of the medial perforant pathway (MPP) have shown that MCs provide frequency-dependent inhibition of GC activity. We found that MPP-GC signal transmission was depressed in adult *Prdm8*$^{-/-}$ mice and litter-matched controls (aged 8-10 weeks) to a comparative level after 5Hz stimulations. However, 20 and 50Hz stimulations resulted in weaker depression of MPP-GC signal transmission in *Prdm8*$^{-/-}$ versus wildtype animals, an effect that could be recapitulated in wildtype mice in the presence of picrotoxin, a γ-aminobutyric acid A receptor ($GABA_AR$) antagonist. Using a variant of the object recognition task to test pattern separation (van Hagen et al., 2015), we have further characterised

the learning and memory deficits caused by absent MCs and the observed altered transmission in *Prdm8*$^{-/-}$ mice.
These findings suggest that the net impact of MCs is frequency-dependent inhibition of GC activity via their indirect projection to hilar interneurons. These data further our understanding of the role of MCs in hippocampal-dependent learning and memory.

Title: Burst-like stimulation of the locus coeruleus leads to thalamo-cortical activation and hippocampal suppression: implication for competing networks

Authors: *O. ESCHENKO[1], R. M. NEVES[1], M. YANG[1], N. LOGOTHETIS[1,2];
[1]Max Planck Inst. for Biol. Cybernetics, Tuebingen, Germany; [2]Ctr. for Imaging Sciences, Biomed. Imaging Institute, Univ. of Manchester, Manchester, United Kingdom

Abstract: Diffusely projecting noradrenergic (NE) neurons of the brainstem nucleus locus coeruleus (LC) regulate excitatory/inhibitory balance in their multiple forebrain targets. The net effect of LC activation depends on the amount of NE released and mediated by different types of adrenergic receptors. It has been long recognized that a predominant effect of NE in cortex is suppression of spontaneous firing, which increases a signal-to-noise ratio of sensory transmission. However, we have recently reported that a brief phasic activation of LC transiently increases gamma power and spike probability in the prefrontal cortex (PFC). Research on NE effects in hippocampus mainly focused on synaptic plasticity. The vast experimental evidence shows that NE release in hippocampus creates a temporal window of heightened synaptic plasticity, but both potentiation and depression effects have been documented. Here, we recorded simultaneously extracellular activity in multiple cortical and subcortical projection targets of LC including sensory and associative thalamic nuclei, hippocampus, sensory cortex and PFC in the urethane-anesthetized rat using high-density multi-electrode arrays. We quantified the effects of LC phasic activation (direct electric current: 0.5mA, at 50-100Hz for 100-200 ms) on neural activity using band-limited power (BLP) analysis. Briefly, a wide-band (0.1Hz-8kHz) signal was band-pass filtered in different frequency ranges; the BLP for each band was normalized to pre-stimulus values and the magnitude of power modulation was extracted over 1s post-stimulus

period. Power increase/decrease in the gamma frequency range was indicative for excitatory/inhibitory net effect, respectively. The LC stimulation produced remarkable dissociation between thalamo-cortical activation and strong suppression of neural activity in hippocampus. The neuromodulatory effects were transient and lasted for 1-3 s post-stimulation. This result suggests that LC phasic activation in response to salient stimuli potentiates broadcasting within thalamo-cortical circuit, while suppresses potentially competing hippocampal-cortical network, which support 'off-line' information processing. Present results also consistent with our recent findings that LC stimulation at times of hippocampal ripples after learning reduced the efficiency of 'off-line' memory consolidation, possibly by activating a competing thalamo-cortical network and therefore causing interference for hippocampal-cortical communication.

Title: Interaction between parasympathetic and sympathetic pathways on prediction of noradrenergic activity by pupil size.

Authors: *V. BRETON-PROVENCHER, M. SUR;
Picower Inst. for Learning and Memory, MIT, Cambridge, MA

Abstract: Pupil diameter has been used as a predictor of brain arousal. However, little is known about the neuromodulators responsible for pupil-mediated brain state, and to what extent pupil size can predict these neuromodulatory tones. Here we recorded the activity of noradrenergic (NA) neurons by using both functional imaging of NA axons in the cortex, and by single unit

recordings in the locus coeruleus (LC) of awake mice. We show that pupil dilation predicts an increase of correlated NA activity both at a single cell and population level. The increase in LC-NA firing rate is linearly correlated with the amplitude of dilation events. This coherence between NA and pupil signals peaks in the low frequency range (10^{-2} to 10^{-1} Hz). Direct activation of LC-NA neurons by optogenetics further demonstrates the causal relationship between NA and pupil dilation. We are currently investigating the interaction between the pathways governing light mediated pupil constriction and internal state driven dilation. Altogether, our results show that pupil diameter can be used as a tool to track noradrenergic tone in the brain.

Title: Monitoring large populations of locus coeruleus single units reveals the heterogeneous and non global nature of the norepinephrine neuromodulatory system

Authors: *N. K. TOTAH[1], R. M. NEVES[1], S. PANZERI[2], N. K. LOGOTHETIS[1,3], O. ESCHENKO[1];
[1]Max Planck Inst. for Biol. Cybernetics, Tuebingen, Germany; [2]Neural Computation Lab., Inst. Italiano di Tecnologia, Rovereto, Italy; [3]Ctr. for Imaging Sciences, Biomed. Imaging Inst., Univ. of Manchester, Manchester, United Kingdom

Abstract: Cognitive theories assume that the locus coeruleus (LC), a brain stem neuromodulatory nucleus, broadcasts a redundant signal to the entire forebrain due to synchronized activity of a homogeneous population of diffusely projecting norepinephrine (NE) neurons. Until recently, technical challenges limited recordings to 1-2 LC single units, which was insufficient for characterizing the diversity of LC cell types and their ensemble activity patterns. We recorded as many as 75 single units simultaneously in the urethane-anesthetized rat using a high-density multi-electrode array and analyzed 11893 unit pairs. To assess input-output specificity of LC units, we electrically stimulated 15 forebrain LC projection sites and analyzed

evoked orthodromic and antidromic LC spiking. Using noise and cross correlation analyses, we assessed the heterogeneity of unit activity with respect to input-output circuits. Our results revealed 2 cell populations differing by spike width (Type 1: 461±14μs, Type 2: 1076±9μs) and rate (Type 1: 1.6±0.06Hz, Type 2: 0.84±0.04Hz). NE identity was confirmed for both types by a α2 agonist. Spontaneous noise correlations were weak and did not depend on linear distance, but Type 1 units exhibited higher correlations with one another (pair of Type 1's: 0.138±0.007, Type 2's: 0.049±0.001, mixed Type1/2 pair: 0.038±0.002 in 200ms bins). Evoked noise correlations were also weak (Type 1: 0.155±0.009, Type 2: 0.051±0.006, Type 1/2: 0.040±0.008, in 750ms window after five 5mA, 0.5ms, 30Hz foot shocks). Consistent with weak noise correlations, the majority (77%) of pairs did not have any significant spike count change at any cross-correlelogram bin (-2 to +2s). Some pairs were correlated (from 0 to +50ms or +1.0 to 1.5ms) or anticorrelated (+1.0 to 2.0ms). We defined projection targets for 65 of 205 units. 53% of those projected to only 1 forebrain site and the remainder projected to multiple (up to 8) sites. Both cell types projected widely to the forebrain. Unit pairs projecting to thalamus had significantly higher noise correlations (0.198±0.015) than pairs with diverging projections (0.132±0.011). PFC input to the LC was area-specific: PL stimulation decreased and IL increased spiking (PL: 9% of units dec., 3% inc; IL: 1% dec., 14% inc.). PFC stimulation also decorrelated LC activity (200ms before / after stimulation in PL: 0.063±0.005 / 0.050±0.005 and IL: 0.053±0.006 / 0.038±0.007). Thus, we found 2 LC cell types differing in spike width, rate, and noise correlation; however, overall correlations were weak. These findings challenge the prevailing view that LC cells are physiologically similar and are homogenously driven to provide a global signal.

Abstract: The adaptive gain theory (AGT) hypothesizes that the locus coeruleus-norepinephrine (LC-NE) system regulates the balance between exploiting available rewards vs. searching for alternative sources of reward. According to AGT, opportunities for reward elicit phasic burst responses that facilitate decisions to exploit such rewards. When utility, or opportunity for reward wanes, LC tonic baseline firing increases, causing disengagement from a task in favor of searching for alternative sources for reward. However, there has been little causal examination of these predictions. We tested predictions of AGT using a patch foraging task for rats, in which rats must repeatedly make decisions to harvest reward from a patch, which depletes with each harvest, or to leave the patch to travel to a new, full patch, which requires the cost of time and effort. We examined how frequently rats decided to travel to a new patch and used a logistic model to estimate rats' subjective value of staying in the patch vs. leaving the patch compared to optimal behavior (i.e. bias towards staying in the patch too long or leaving too early), as well as how correlated rats' decisions were to this subjective value (i.e. how noisy rats' decisions were). AGT predicts that increased tonic NE should promote disengagement from the task, causing rats to leave patches more frequently, not due to a change in subjective value or decision bias, but by increasing decision noise. We tested this hypothesis using selective DREADD stimulation of LC-NE neurons and pharmacological inhibition of NE via the $alpha_2$ agonist clonidine. As predicted by AGT, DREADD stimulation of LC-NE neurons caused rats to leave patches more frequently, with no change to decision bias, and increased decision noise. Clonidine, at a moderate dose (10 ug/kg) caused rats to leave patches less frequently, but not at a higher dose (20 ug/kg). Regardless of dose, clonidine reduced decision noise, but also changed rats subjective value of leaving the patch. Future studies will include additional pharmacological manipulations. Overall, these findings indicate that tonic LC-NE activity regulates the balance between exploiting available rewards vs. searching for alternative sources of reward. Title: Direct comparison of hippocampal and rhomboid/reuniens inputs to medial prefrontal cortex

Authors: *P. J. BANKS, Z. I. BASHIR;
Univ. of Bristol, Bristol, United Kingdom

Abstract: It has long been known that communication between hippocampus and medial prefrontal cortex (PFC) is crucial for various cognitive processes including working memory and long-term associative recognition memory. These regions are connected by a direct glutamatergic projection which when disrupted impairs cognition. Additionally hippocampus and PFC are both reciprocally connected to the midline thalamic nuclei (MTN) consisting of the nucleus reuniens and rhomboid nucleus. It is thought that the MTN may play a crucial role in contributing to synchronous oscillatory activity between hippocampus and PFC. As the PFC is not directly connected to hippocampus it is thought that the MTN may be a key node for feedback from PFC to hippocampus. Additionally many hippocampal neurons project to both PFC and MTN neurons, thus the output of these hippocampal neurons may be transmitted both directly to PFC neurons and in a modified form via the MTN. Whilst we have some understanding of the physiological properties of the hippocampal-PFC synapse, such as short- and long-term plasticity, the function of NMDA receptor mediated transmission and modulation by neuromodulators including acetylcholine and dopamine, nothing is known of transmission from MTN to PFC. Here we combine electrophysiological and optogenetic approaches to allow study of hippocampal and MTN synaptic inputs in modified coronal PFC slices, allowing direct comparison of these paths onto the same layer 5 PFC pyramidal neurons. Using short bursts (10 stimuli) of synaptic stimuli ranging from 5 to 100 Hz we show that there are significant differences in the degree of short-term plasticity between these synapses, with MTN inputs to PFC undergoing more short-term depression than hippocampal inputs at low frequencies and greater short-term facilitation at higher frequencies. Interestingly although NMDA receptor mediated transmission plays a crucial role in temporal summation of hippocampal-PFC transmission (Banks et al 2015, *PNAS*), we did not observe any difference in the NMDA receptor-mediated components of hippocampal and MTN inputs to PFC. Furthermore we show that hippocampal and MTN inputs are differentially modulated by cholinergic receptor activation, with carbachol (10 μM) inducing a profound depression of hippocampal input whilst leaving MTN inputs virtually unaffected. We have thus embarked upon investigating alternative pre- and postsynaptic mechanisms for these pathway differences.

Title: Performance of a touchscreen-based visual discrimination task is restored with electrical stimulation of the ventral tegmental area (VTA) in rats sedated with isoflurane

Authors: J. D. KENNY[1], N. E. TAYLOR[1], J.-Y. YANG[2], K. Y. VLASOV[1], J. T. LEE[1], J. A. GUIDERA[1], J. PEI[1], E. N. BROWN[1], *K. SOLT[1];
[1]Anesthesia and Critical Care, Massachusetts Gen. Hosp., Boston, MA; [2]Caltech, Pasadena, CA

Abstract: INTRODUCTION: Electrical stimulation of the VTA restores the righting reflex in anesthetized rats. It is unknown whether it also restores cognitive function. In this study rats were trained to perform a visual discrimination task to test if VTA stimulation restores task performance during isoflurane (ISO) sedation.
METHODS: Male Sprague-Dawley rats (n=8) were first trained to perform a visual discrimination task in a modified chamber with ports for gas in/outflow and sampling. Two images were presented on a touchscreen, and rats were trained to touch the correct image for a food reward. After >85% correct responses for at least 3 consecutive days, the rats underwent stereotaxic implantation of VTA stimulation electrodes, and recovered to their baseline performance levels 3 weeks after surgery. After establishing that task performance was reliably lost with 0.5% ISO, once a week (for 5 weeks) the rats underwent VTA stimulation during sedation with 0.5% ISO. In week 3, the D1 dopamine receptor antagonist SCH-23390 (0.5 mg/kg ip) was administered before VTA stimulation. **Figs. A** and **B** show the protocols for anesthesia and stimulation, respectively. After completing all the experiments, histological analysis revealed that the electrode tip was in the VTA in 5/8 animals. Only these animals were used for analysis.
RESULTS: The trials completed by each rat are shown in **Fig C** (black circles= correct responses, white=incorrect). At 0.5% ISO, all rats were heavily sedated and performed no trials. However, with VTA stimulation 5/5 rats performed the task despite 0.5% ISO (weeks 1,2,4,5). SCH-23390 (week 3) reversibly abolished the task performance induced by VTA stimulation. As shown in **Figs. D** and **E**, VTA stimulation restored task performance but not mean accuracy.
CONCLUSIONS: At a dose of ISO insufficient for loss of righting (0.5%) the ability to perform a visual discrimination task was lost, suggesting that this many be a useful endpoint to determine anesthetic-induced loss of cognitive function. VTA stimulation restores task performance but not accuracy, an effect likely mediated by dopamine.

Title: Functional role of inhibitory superior colliculus neurons in target selection

Authors: *J. ESSIG[1], A. B. WOLF[2], G. FELSEN[3];
[1]Neurosci. Program, [2]Med. Scientist Training Program, [3]Physiol. and Biophysics, Univ. of Colorado Sch. of Med., Aurora, CO

Abstract: The superior colliculus (SC) is a midbrain structure critically involved in selecting targets for orienting movements. Multiple cell types are found comingled within the SC, but how these cell types function together to underlie target selection is not well understood. Approximately one-third of SC neurons are GABAergic and these cells have been proposed to mediate inhibition between competing motor plans. However, while GABAergic SC neurons have been studied *ex vivo*, their activity has not been directly examined in behaving animals. We have recently begun to examine GABAergic activity in the SC during head-fixed and freely-moving behavioral paradigms, each of which requires the mouse to select and initiate a leftward or rightward orienting movement in response to a stimulus cue in order to receive a water reward. In these contexts, the activity of principal output neurons of the SC increases as contralateral movements are selected. Given that GABAergic neurons are thought to inhibit these output neurons, we predict that the activity of GABAergic neurons will decrease during the selection of contralateral movements. We selectively expressed channelrhodopsin-2 (ChR2) in GABAergic neurons of the intermediate and deep (motor output) layers of the SC by injecting an AAV-mediated Cre-dependent ChR2 construct unilaterally into the SC of GAD2-Cre mice. The specificity of ChR2 expression to GABAergic neurons ultimately enables us to optically identify these cells *in vivo* so that we can record, and selectively manipulate, GABAergic activity during behavior. This approach will allow us to test whether and how GABAergic activity in the SC mediates competition between the circuits responsible for discrete motor plans. This is the first study to examine GABAergic activity in the SC *in vivo* and provides a platform for future studies to delineate how specific GABAergic cell types contribute to the functional circuitry underlying target selection.

Title: Nucleus Reuniens infusions of muscimol, but not procaine, produce impairments on choice accuracy & perseverative behavior using a T-maze paradigm

Authors: *T. D. VIENA, S. B. LINLEY, R. P. VERTES;
Ctr. for Complex Systems and Brain Sci., Florida Atlantic Univ., Boca Raton, FL

Abstract: Nucleus reuniens (RE) of the midline thalamus is an important part of a brain circuit linking the medial prefrontal cortex (mPFC) with the hippocampus (HF) and whose inactivation has been shown to alter spatial working memory (SWM), goal directed actions, and behavioral flexibility (see Vertes et al., 2015). Infusions of muscimol into RE has been shown to produce impairments in SWM at short delays (Layfield et al., 2015). However, the disruption of the HF, the mPFC, or their interactions has been shown to alter SWM at much longer delays - about to 5 min (Jones and Wilson, 2005; Lee and Kesner, 2003). We presently examined the effect of reversibly inactivating RE on SWM and behavioral flexibility by comparing the actions of saline, the GABA agonist, muscimol, and procaine infused into RE using various delays. Long Evans rats were implanted with guide cannulas targeting RE and were trained to alternate between arms of a modified T-maze at delays of 30 s, 60 s, or 120 s (at the start of each trial) which were presented in a pseudorandomized order. When an incorrect choice was made, rats were allowed to continue to make choices until a successful choice was made. Once performance reached a level of 80% correct on two consecutive days, rats were given infusions of the various substances over several days. Two doses of muscimol were used: 0.250 and 0.500 mg/ml. A dose of 0.250 mg/ml muscimol significantly impaired choice accuracy and produced an increase in perseverative responses (repeated re-entry into the previously rewarded goal arm) across all delays. A dose of 0.500 mg/ml muscimol also produced impairments in choice accuracy across all delays, but only resulted in perseverative behaviors at the shortest delay (30 s). Interestingly, RE infusions of procaine failed to alter behavior at any of the time delays, and it is presently unclear why that was the case. As indicated above, the perseverative behavior following infusions of muscimol was very pronounced in that rats continued to make unsuccessful/unrewarded choices even when allowed to correct their behavior on repeated trials. This inability to inhibit a previously successful but now inappropriate choice is similar to the perseverative deficits seen with lesions/inactivation of the dorsal or ventral hippocampus (Dallard, 1976). The present results contribute to a growing body of research indicating that RE serves a pivotal modulatory role in the exchange of information between the mPFC and HF for spatial working memory, and further that selective RE input to the mPFC is critical for executive functions and behavioral flexibility as demonstrated by the compulsive behavior resulting from RE inactivation.

Title: The mediodorsal thalamus regulates prefrontal function and E/I balance through modulation of PV interneuron activity

Authors: *B. R. FERGUSON[1], W.-J. GAO[2];
[1]Neurobio. and Anat., [2]Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: The prefrontal cortex (PFC) was originally defined by its projections from the mediodorsal thalamus (MD). However, how the MD is regulating local circuit activity to optimize medial PFC (mPFC) dependent behaviors, such as working memory, remains elusive. Data from primary sensory cortices indicate that thalamocortical activation of excitatory versus inhibitory cellular populations is distinct, with stronger activation of local GABAergic interneurons, an important property in feed-forward inhibition. Additionally, we previously demonstrated that decreasing MD afferent activity with DREADDs reduces inhibitory post-synaptic currents (IPSCs) in mPFC Layer V pyramidal neurons, concurrent with impairments in working memory performance. We hypothesize that the critical intermediaries between MD glutamatergic afferents and excitatory pyramidal neurons in the mPFC are local parvalbumin (PV) expressing fast-spiking (FS) interneurons. Further, under normal conditions, MD afferents provide stronger drive to PV interneurons, to help maintain the proper E/I balance. To explore this, we utilized pharmacogenetic downregulation of MD neuronal activity, and examined the consequences for excitatory versus inhibitory neurons in the mPFC. Following MD inhibition, we observed a downward shift in the resting membrane potential and action potential threshold in both Layer V FS interneurons and pyramidal neurons. Although both neuronal populations show no alterations in spiking output, we saw a specific increase in input resistance only in FS interneurons, suggesting less open channels. We also observed a shift in the E/I balance towards excitation, due to a specific loss of the evoked IPSC amplitude. Ongoing studies involve seeking

to rescue the E/I balance and proper circuit function with pharmacogenetic upregulation of mPFC PV activity.

Title: Sensory coding in the vestibular thalamus discriminates passive from active self-motion

Authors: ***A. DALE**, K. E. CULLEN;
Physiol., McGill Univ., Montreal, QC, Canada

Abstract: Successful navigation of the world requires precise coordination of voluntary actions in combination with accurate perception of the motion experienced both as a result of these actions and due to external events. Linear accelerations as well as rotations of the head are sensed by the vestibular labyrinth in the inner ear, and this information is eventually transmitted through the thalamus to contribute to a representation of spatial orientation and speed in a given direction. Interestingly, early central processing of both linear and angular self-motion differentiates between motion that is passively applied versus self-generated. To date, vestibular thalamic responses to externally generated motion have been well characterized (e.g., Meng et al. 2007); however, the important question remains: are passive and active movements distinguished in ascending vestibular pathways? We addressed this question by recording from n=45 neurons in the ventral posterior lateral thalamus (VPL) of rhesus monkeys (*Macaca mulatta*) that were sensitive to passive, whole-body rotations and/or translations in the horizontal plane, and did not respond to eye movements or visual stimuli. We characterized responses to both whole-body and head-on-body motion, and then compared these to responses of the same neurons during monkeys' self-generated head-on-body movements with matching trajectories. We found that neurons showed robust and comparable modulation to passive whole-body and head-on-body rotations and/or translations (the latter with preferred directions spanning 360 degrees). However, these same neurons showed a dramatic reduction (>80%) in firing rate modulation when monkeys generated voluntary motion to rotate and/or translate their heads in to space. Interestingly, we further found that VPL neurons were even more selective for passive motion relative to active motion than neurons at the first central stage of vestibular processing

(vestibular nuclei: Carriot et al. 2013). Thus, taken together, these results suggest that thalamocortical vestibular pathways specifically signal unexpected self-motion to higher-order processing areas for the subsequent computation of self-motion and spatial orientation in order to ensure perceptual stability and accurate motor control.

Title: A novel type of cortical input to the thalamic reticular nucleus

Authors: *N. HADINGER[1], M. M. HALASSA[2], L. ACSADY[1];
[1]Lab. of Thalamus Res., Inst. of Exptl. Medicine- Hungarian Acad, Budapest, Hungary; [2]The Neurosci. Inst. Depts. of Psychiatry, New York Univ., New York, NY

Abstract: It has become increasingly clear that thalamic circuits are not uniform, with some nuclei primarily relaying subcortical inputs to cortex (first order) and others mediating cortico-cortical interactions required for a wide range of cognitive functions (higher order). While, in both cases, inhibition plays critical roles in gating thalamic output and shaping overall network activity, little is known about the microcircuits underlying different types of inhibitory control. The thalamus receives inhibitory inputs from the thalamic reticular nucleus (TRN), a group of GABAergic neurons that are segregated into subnetworks each establishing reciprocal connections with a particular thalamic nucleus. Thalamic nuclei also receive excitatory input from topographically aligned cortical Layer 6 pyramidal neurons (L6) which is often thought to be modulatory in nature. Higher order nuclei receive additional inputs from Layer 5 (L5) which are faster, stronger and more precise than ones from L6. While it is commonly assumed that the TRN only receives L6 inputs, making L5 corticothalamic inputs purely excitatory, here we report a novel pathway from L5 frontal cortex to well-defined TRN subnetworks. This pathway enables rapid and robust thalamic inhibitory control by frontal cortical circuits.
We performed selective and conditional anterograde tracing in the L5-specific Rbp4-Cre mouse, which revealed dense, topographically-organized terminal clusters in the anterior and ventral

TRN arising selectively from the primary motor (M1), secondary motor (M2), cingulate and prelimbic cortices. Retro-anterograde viral tracing from the brainstem showed that L5-TRN terminals were the collaterals of classical, corticofugal, L5 fibers. At the electron microscopic level, L5 terminals established asymmetrical synapses with TRN somata and proximal dendrites. L5 and L6 (L6 labelled using Ntsr1-Cre) terminals from a given cortical region innervated the same TRN regions. Optogenetic activation of L5 pyramidal cells both in Thy-1 and RBP4 L5 specific mouse lines elicited actions potentials in juxtacellularly recorded and labeled TRN cells with short latency, high fidelity and little jitter. Of note, TRN cells were able to follow cortical stimulation up to 60 Hz.
The data suggest that frontal cortical control of certain TRN neurons and the corresponding thalamic targets is distinct from previous reports. This specialized L5-TRN projection may allow precise temporal coordination of frontal cortico-thalamic circuits, even when both areas are engaged in rapid firing and high frequency oscillations underlying certain cognitive functions.

Title: Thalamic gating of fronto-parietal interactions: a computational model

Authors: *J. JARAMILLO[1], X.-J. WANG[1,2];
[1]Neurosci., New York Univ. Ctr. for Neural Sci., New York, NY; [2]NYU-ECNU Joint Inst. of Brain and Cognitive Sci., NYU Shanghai, Shanghai, China

Abstract: The higher order thalamic nuclei are hypothesized to mediate cortico-cortical communication in the brain. A prominent example is the primate pulvinar, believed to play an important role in attention and confidence. However, little is known precisely how the pulvinar contributes to flexibly gating cortico-cortical communication. For instance, as interconnections between principal excitatory neurons in the thalamus are absent, how is the interaction between two cortical areas instantiated in the pulvinar? What may be the role of the inhibitory reticular thalamic nucleus (RTN)? In this computational study, we designed and implemented a three-

module architecture that includes the dorsal pulvinar, the parietal, and prefrontal cortices. Using a firing-rate description for each of the areas, we first show that the pulvinar acts as a gate that determines the effective connectivity between the two cortical modules. Direct and indirect (through the RTN) corticothalamic projections modify the gain of thalamic relay neurons and this gain in turn modulates the connectivity between the cortical modules. We study the function of this malleable connectivity between prefrontal and parietal cortex in the context of decision-making, conflict resolution, and working memory. Next, we show that a similar thalamo-cortical architecture can account for the representation of confidence in the parietal cortex (Kiani and Shadlen, 2009) and in the pulvinar (Komura et al, 2013). In this architecture, we propose that a dynamic cortico-thalamic switch that includes the RTN (Crandall et al., 2015) contains the necessary computational elements to transform an implicit cortical representation of confidence into an explicit representation in the pulvinar. Our modeling results suggest that the pulvinar can flexibly control cortico-cortical connectivity for attentional tasks and is also part of a distributed thalamo-cortical circuit that represents confidence.

Title: CREB over expression in dorsal CA1 ameliorates memory deficits in aged rats

Authors: *X.-W. YU[1], D. M. CURLIK, II[2], M. M. OH[1], J. C. P. YIN[3], J. F. DISTERHOFT[1]; [1]Feinberg Sch. of Med., Northwestern Univ., Chicago, IL; [2]Behavioral Sci., York Col. of Pennsylvania, York, PA; [3]Genet., Univ. of Wisconsin-Madison, Madison, WI

Abstract: Humans and animals often display learning and memory impairments as they age, however the underlying mechanisms of these impairments are poorly understood. Identifying the molecular pathways that mediate these impairments will allow us to design therapeutics to prevent or reverse these deficits. Increasing activity of the transcription factor cAMP response element-binding protein (CREB) in young adult rodents has been shown to facilitate their behavioral performance and increase intrinsic cellular excitability - both of which are impaired in

normal aged animals. To test if increasing CREB activity would ameliorate age-related cognitive deficits, we overexpressed CREB in CA1 of dorsal hippocampus using an adeno-associated viral vector. Young and aged rats both received CREB or control virus, then received Morris water maze training. CREB overexpression in aged animals ameliorated the deficits in long-term memory seen in control animals, while surprisingly; young animals were unaffected by CREB overexpression. Concurrently, cells overexpressing CREB in aged animals were found to have a reduced post-burst afterhyperpolarization i.e., increased excitability. These results indicate that activation of CREB signaling is a potential therapeutic for age-related cognitive deficits.

Title: Severity of age-related memory impairment correlates with pilocarpine-induced c-fos expression across cortical structures

Authors: *M. KOH, R. P. HABERMAN, M. GALLAGHER;
Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: Age-dependent changes in coordinated neural activity of cortical and subcortical structures alter functional connectivity of brain networks important for cognition. Poorer memory performance in aging has recently been linked to increased neural excitability in the hippocampus. Here, we ask whether changes in the excitability of cortical areas connected to the hippocampus are also associated with memory decline seen in aging. We assessed cortical and hippocampal responses of aged rats with and without memory impairment to a low dose of the cholinergic agonist pilocarpine. Aged Long-Evans (24 mo-old) and young controls (6 mo-old) rats were behaviorally characterized for memory performance in a water maze protocol. Aged rats that performed on par with young controls were designated as memory-unimpaired, and those that performed beyond the young normative range were considered memory-impaired. Several weeks after cognitive assessment, rats were administrated a low-dose pilocarpine (25 mg/kg) intraperitoneally in the home cage to induce neural activation. No age differences in behavioral/peripheral response to the drug treatment were observed. Rats were perfused 1 hr

after injection and their brains were processed for mRNA expression of the immediate-early gene c-fos, used here as a marker for neuronal activity. Aged rats with memory impairment showed higher c-fos expression than young and memory-unimpaired aged rats in the CA3 of the hippocampus, frontal, orbitofrontal and parietal cortices. A similar trend of expression was observed in the retrosplenial but not the anterior cingulate cortex. Interestingly, c-fos expression in the CA1 of the hippocampus showed no differences between memory-impaired aged rats and young controls, but instead was significantly lower in memory-unimpaired aged rats consistent with the recent findings of increased tonic inhibition in the CA1 in those rats. Across the full spectrum of individual differences, c-fos expressions in the hippocampus and cortical regions were strongly correlated with memory function such that aged rats with the worst memory deficit exhibited the strongest c-fos activation. These data extend the findings that tie age-associated cognitive impairment to greater neural excitability in specific cortical networks important for cognitive function, and support a need to consider the impact of hippocampal-cortical communication.

Title: Three-dimensional analysis of newborn neuron network integration

Authors: *A. E. BRANCH[1], N. SAH[2], C. VIVAR[2,3], H. VAN PRAAG[2], M. GALLAGHER[1]; [1]Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD; [2]NIH, Baltimore, MD; [3]Dept. of Physiology, Biophysics, and Neurosci., Ctr. for Res. and Advanced Studies of the Natl. Polytechnic Inst., Mexico City, Mexico

Abstract: The medial temporal lobe (MTL) circuit underlying the formation of episodic memory is sensitive to modification by a variety of physiological and environmental factors, such as aging and exercise. Voluntary wheel running enhances both the number of new neurons and afferent connectivity of adult generated neurons in the dentate gyrus (DG) (Vivar, et al. 2016). Running was shown to recruit input to newborn DG neurons from brain areas relevant to

contextual and spatial-temporal information processing, changes that appear to have relevance for memory computations performed by the MTL. The widespread connectivity of the new neuron network and the sparse number of cells it contains present a challenge for identifying and reconstructing how such networks integrate new neurons into complex circuits. However, these same features of new neuron integration are especially amenable to new technologies for whole brain clearing and imaging, which allow for improved detection of sparse populations of cells and their connections. To investigate this network, both newborn neurons and their upstream afferents were labeled in young adult male C57B1/6 mice housed with or without a running wheel using a dual-virus tracing system. This began with retroviral labeling of newborn neurons with nuclear GFP, TVA receptor, and rabies glycoprotein, which was followed one month later by trans-synaptic retrograde tracing of monosynaptic inputs with an EnvA-pseudotyped rabies virus carrying cytoplasmic mCherry. Brains from these animals were cleared with the iDISCO method and imaged with the LaVision Ultramicroscope to generate 3D projections of the newborn neuron network under these conditions. This set of tissue will allow for validation of the use of 3D morphometric analysis on the network properties including the number, regional distribution, and connectivity profiles of labeled newborn neurons. We intend to extend this analysis to the investigation of aging on newborn neuron integration into MTL networks.

Title: Epigenetic regulation of medial prefrontal cortex transcription associated with aging and impaired executive function

Authors: *T. C. FOSTER[1], L. IANOV[1], A. RIVA[2];
[1]Dept Neurosci., Evelyn F. and William L. McKnight Brain Inst. Univ. Florida, Gainesville, FL;
[2]Bioinformatics Core, Interdisciplinary Ctr. for Biotech. Res., Univ. of Florida, Gainesville, FL

Abstract: The medial prefrontal cortex (mPFC) of rodents is involved in executive function and the mPFC transcriptional profile is altered over the course of aging. Further, transcriptional changes are associated with impaired performance of attentional set-shifting behavior. While it is understood that the transcriptional profile of the mPFC differs with aging and cognitive impairment, studies are needed to identify the mechanism of transcriptional regulation of these target genes. To address this question, the current study investigates DNA methylation of cytosines in guanine-cytosine dinucleotides (CpG) as a possible epigenetic regulator of mRNA. Young (5-6 months) and aged (17-22 months) male Fischer 344 rats were behaviorally characterized on a set-shifting task, a mPFC dependent behavior. The mPFC was isolated bilaterally and, for one hemisphere, RNA expression was determined using next generation sequencing (RNA-seq: Ion Proton). For the other hemisphere, whole genome bisulfite sequencing (WGBS) was implemented. Multiplex sequencing of WGBS libraries was performed in an Illumina NextSeq 500, and a high-performance pipeline for differential methylation analysis was employed. The pipeline includes quality trimming, alignment, DNA methylation base calling and statistical comparison across aging and cognitive impairment in hypo and hypermethylated sites and regions. The results for RNA expression (Ianov et al., Frontiers in Aging Neuroscience, *in press*) indicated a correspondence of transcription with age-related changes identified in the dorsolateral PFC of aging humans, including expression of genes linked to synaptic function. Moreover, cluster analysis indicated increased expression of genes linked to inflammation. In contrast, impaired set shift behavior was associated with increased expression of genes linked to transcription and synaptic activity/plasticity. Here we will report on the DNA methylation status of these target genes. Currently, we are focused on CpG methylation state of genes identified by RNA-seq as differentially expressed due to age or cognitive status.

Abstract: Hippocampal-dependent episodic memory declines with advancing age in a number of species, including humans and rodents. This collaborative effort across McKnight Brain Institutes examines region-specific hippocampal transcription profiles (i.e., CA1, CA3 and the dentate gyrus, DG) that may help explain differential susceptibility to impairment in specific cognitive domains over the lifespan of the rat. Young (5-6 months) and aged (17-22 months) male Fischer 344 rats were trained on a spatial episodic memory task, and hippocampal regions CA1, CA3 and DG were collected for transcriptional profiling ~2 weeks after behavioral testing. In this regard, next-generation sequencing technology is a powerful tool for examining complex processes, such as aging, by monitoring the parallel expression of thousands of genes. However, the technique requires verification of differentially expressed genes. In many cases, a subset of genes is confirmed using RT-PCR. We have taken advantage of two different next-generation platforms to confirm differential expression associated with aging and cognitive decline. RNA-seq was implemented using the Illumina HiSeq2500 and the Ion Proton. Illumina was used to generate seed lists of genes that were differentially expressed across age or cognitive function in each hippocampal subregion. The gene lists were then retested using the Ion Proton platform for validation of the results. Age effects: Across regions, aging was associated with an increase in expression of genes for gene ontology clusters linked to immune responses (FDR $p<0.05$). The DG region showed the highest number of gene changes related to the age of the animal, including the greatest number of distinct genes, consistent with the idea that the DG may be more vulnerable or responsive to aging. Cognition-related genes: The results suggest that the CA1 region was the most sensitive to cognitive impairment, with 45 up-regulated and 49 down-regulated genes in impaired animals. Clustering was observed for genes linked to Ca^{2+} signaling (FDR $p<0.05$) with decreased expression of *Hpca, Dclk2, Prkca*. Likewise, a decrease was observed for genes associated with Ca^{2+} entry (*Neto1, Prickle2*) and release of Ca^{2+} from intracellular Ca^{2+} stores (*Adra1d, Homer3, Itpr1*). An increase was observed for the Ca^{2+} pump (*Atp2b4*) in aging. In addition, altered expression was observed in genes linked to synaptic function (e.g., *Gabra5, Nptxr)* and K^+ channels (*Hcn4, Kcnk1, Kcnab2*). Together, these results suggest that impaired performance of aged animals is linked to the regulation of Ca^{2+} and synaptic function in region CA1.

Title: Transcriptional differences among hippocampal subregions

Authors: ***M. DE BOTH**[1], L. IANOV[2], M. K. CHAWLA[1], A. RANI[2], A. J. KENNEDY[3], I. PIRAS[1], J. J. DAY[3], A. L. SINIARD[1], A. KUMAR[2], J. D. SWEATT[3], T. C. FOSTER[2], C. A. BARNES[1], M. J. HUENTELMAN[1];

Abstract: Subregions of the hippocampal formation have been suggested to possess varying vulnerabilities to aging and disease-related pathologies, but the underlying molecular mechanisms of these differences are not well understood. RNA-sequencing allows an unbiased comparison of transcriptional differences between hippocampal subregions and can therefore potentially identify the underpinnings of the differential regional susceptibility. Here, we apply RNA-seq to adult rat hippocampal subregions CA1, CA3, and DG to investigate the transcriptional differences among them. Male Fischer 344 rats (n=34) were aged to 5-6 months ("young") or 17-22 months ("old") and tested with the Morris Water Maze to identify "good" and "bad" performing individuals. Two weeks after cognitive testing, hippocampal subregions CA1, CA3, and DG were isolated. RNA-sequencing was conducted in replicate by two different laboratories on two different platforms, the Illumina HiSeq 2500 at the University of Arizona and the Ion Proton at University of Florida. Pair-wise differential expression was conducted among the three regions, between young and old rats, and between rats with good and bad cognitive performance. While the study design allows the investigation of transcriptional changes associated with aging or cognitive decline, here we present subregion-specific expression regardless of age or performance. To identify subregion-specific levels of expression, a gene must be significantly different from both of the other regions using both sequencing platforms. Region-specific level of expression can be up-regulated, down-regulated, or fall between expression in the other two regions. Overall, we identified 1068 genes exhibiting a region-specific level of expression in CA1, 1200 genes in CA3, and 2532 genes in DG. These genes likely play a key role in the development and aging of the distinct hippocampal subregions.

Abstract: Next generation RNA sequencing (RNA-Seq) provides the ability to construct an unbiased whole transcriptome map, digitally quantify transcript levels, and interrogate splice form abundance. It has been widely established that in response to neuronal activity, specific RNA species redistribute within one hour or less to the dendrites where local translation can occur. Much is left to be discovered about the function of these dendritic mRNAs, however, evidence suggests that they play a key role in synaptic plasticity and transmission, the dysfunction of which is indicated in many neurological disorders including Alzheimer's disease. We propose that the creation of a complete catalog of activity-regulated transcripts will enable a hypothesis-driven investigation of neurological disease with a focus entirely on activity regulated genes. In this study, we utilized RNA-Seq to identify transcripts from small amounts of total RNA (~1ng) obtained from laser-capture microdissected (LCM) regions of the hippocampus (dentate gyrus, CA1, and CA3) of 6 month old Fisher344 rats. The cell soma and corresponding neuropil regions were compared in caged control (CC) animals and maximal electroconvulsive shock (MECS) treated animals sacrificed at 10 minutes, 30 minutes, 1 hour, 2 hours, 4 hours and 24 hours post treatment. In a previous pilot study with one time point we sacrificed animals at 60

min post MECS and utilized an analytical approach to identify those transcripts that were differentially compartmentalized within each hippocampal subregion in CC animals, the "resting state", and in response to MECS treatment, the "induced state". Following MECS treatment, we found a significant difference in the expression of several immediate early genes like *Arc*, *Homer1*, *Egr1* and *Fos* in the different hippocampal regions. RNA sequencing is a valuable tool for identifying and quantitating differentially-compartmentalized RNAs. Further understanding of the activity regulated transcriptome will likely offer valuable insight into the biology of the neuronal environment and may provide new avenues to treat neurological disease.

Title: Arc mRNA induction thresholds following electro-convulsive shock treatment may be regulated by dendritic Ca++ plateau potentials

Authors: *M. K. CHAWLA[1,2], C. NGUYEN[1,2], G. S. SADACHAR[1,2], D. T. GRAY[1,2], M. J. HUENTELMAN[1,4], C. A. BARNES[1,2,3];

Abstract: Immediate-early genes (IEGs) are rapidly and transiently induced following excitatory neuronal activity. The rapid RNA response is blocked by tetrodotoxin, indicating a role for electrical excitation in induced mRNA responses (Cole et al., 1990). Using the IEG *Arc* (Lyford et al., 1995) which is selectively synthesized at active synapses, we have previously shown that there is a sharp threshold of activation in granule cells between 65 and 77 mA current (65 mA = 2.8 %, 77 mA = 85%). Here we investigate whether other subregions of the hippocampus (CA1 and CA3) exhibit a similar abrupt threshold for burst spiking activity. F344 rats (5-6 mo old) were divided into 6 groups. Five groups received electroconvulsive shock treatment of varying

intensity (20, 40 65, 77 and 85 mA) using a UGO Basile ECT unit (1sec, 100Hz, 0.5ms square wave pulse). A sixth group did not receive shock. Five minutes following treatment, brains were rapidly extracted and quick frozen. Sections were cut and fluorescence *in situ* hybridization was performed as described previously (Chawla et al., 2005) using the full length *Arc* cDNA. Confocal images were acquired using a Leica SP5 microscope equipped with 405 nm and 543 nm lasers, with a 40x oil immersion lens. Images were obtained of proximal, distal and medial CA1 subregions of the hippocampus and *Arc* mRNA-positive cells were counted. Compared to the granule cells there is more *Arc* mRNA positive pyramidal cells at the lower current intensities (20 and 40 mA conditions) with ~ 20-30% of pyramidal cells having a lower threshold for *Arc* induction up to 65 mA. And similar to the granule cells there is a sudden threshold crossing between 65 and 77 mA where there is a dramatic increase in *Arc* transcription. **Proximal CA1**, 0 mA = 8.35%, 20 mA = 15.8%, 40 mA = 23.4%, 65 mA = 17.4%, 77 mA = 72.1% and 85 mA = 75% *Arc* mRNA-positive cells. **Middle CA1**, 0 mA = 10.9%, 20 mA = 22.5%, 40 mA = 24%, 65 mA = 26%, 77 mA = 71% and 85 mA = 71% *Arc* mRNA-positive cells. **Distal CA1**, 0 mA = 11%, 20 mA = 25%, 40 mA = 30%, 65 mA = 27.4%, 77 mA = 70.1% and 85 mA = 70% *Arc* mRNA-positive cells. Indeed, recent observations in CA1 pyramidal neurons suggest that a supralinear summation of electrical activity occurs when entorhinal layer III input to distal CA1 dendrites crosses a threshold to produce a Ca^{++} plateau potential. These plateau potentials appear to drive burst firing, characteristic of CA1 place cell discharge (Milstein and Magee, SfN Abstr, 2014). Our data suggest the possibility that similar plateau potential processes may regulate both the *in vivo* patterned firing that occurs when granule and pyramidal cells express place fields and when these cells express *Arc* mRNA. We are currently collecting the same data from the CA3 region.

Title: Activation of neuronal populations in young and aged rat Lateral Entorhinal Cortex during track-running behavior with odors

Authors: *A. COMRIE[1,2], J. P. LISTER[1,4], M. K. CHAWLA[1,2], C. A. BARNES[1,2,3];
[1]Evelyn F. McKnight Brain Inst., [2]Divison of Neural Systems, Memory and Aging, [3]Departments of Psychology, Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ; [4]Dept. of Pathology and Lab. Med., UCLA, Los Angeles, CA

Abstract: The hippocampus is known to show biological changes with age that are related to changes in memory processes. For example, in aged rats, the CA1 region of the hippocampus fails to show accurate map retrieval upon revisiting a familiar environment (Barnes et al., 1997). The distal part of CA1 receives major inputs from Lateral Entorhinal Cortex (LEC) layer III. In contrast to the well-studied Medial Entorhinal Cortex (MEC), LEC neurons do not show substantial spatial selectivity in their firing patterns (Deshmukh and Kneirim, 2011). Rather, LEC is thought to be involved in non-spatial memory, such as encoding object and odor information. The role of LEC in odor discrimination and how the corresponding neural activity may change with age remain unknown. In this study we aim to discover if LEC neuronal populations are active in response to distinct odors during track running, and whether age-related changes in activation patterns may provide faulty input to the hippocampus that may explain remapping in older animals. To test this, 24 young (9 months) and 24 aged (24 months) male rats were trained to run in alternating clockwise and counterclockwise laps on a circular track in a constant spatial environment. One behavioral group (A/A) experienced the same set of 6 odors mixed with sand in ramekins in the same order around the track during two run sessions separated by 20 minutes. A second group (A/B) also experienced two run sessions, but the odor stimuli were all distinct between the two time points. A positive control group underwent Maximal Electroconvulsive Shock (MECS), and a negative control group was sacrificed from their home cages (CC). The mRNA of immediate-early gene *Arc* is localized to distinct cellular compartments based on the time since neuron activation. We use cellular compartment analysis of temporal activity by fluorescence *in situ* hybridization (catFISH; Guzowski et al., 1999) and confocal microscopy to visualize this time-dependent subcellular distribution of *Arc* mRNA. This method enables us to identify neurons activated during the first, second, or both running sessions in LEC. Preliminary data from LEC averaged across both treatments and age groups confirm that the track-running behavior with odors elicits 26% neural activation in comparison to low resting *Arc* expression (2%) for CC animals. With additional animals added to treatment conditions and age groups we will be able to determine if LEC encodes odor information that can discriminate between the A/A and A/B conditions, and if population representation of odor stimuli in LEC changes across the lifespan.

Title: Aged rats failed to integrate conflicting spatial reference frames

Authors: *A. W. LESTER[1,2], A. J. KAPELLUSCH[1,2], R. T. SCREEN[1,2], C. A. BARNES[1,2,3];
[1]Evelyn F. McKnight Brain Inst., [2]Divison of Neural Systems, Memory and Aging,
[3]Departments of Psychology, Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: As with older adults, aged rats show robust impairments on a number of different spatial navigation tasks. There is some evidence that these navigation impairments are accompanied by a bias away from using an allothetic-based (i.e., external cue) navigation strategy towards relying on an idiothetic-based (self-motion) strategy (Rosenzweig et al., 2003). To test the degree and timing with which aged animals utilize these two forms of spatial information, a novel behavioral arena has been developed that allows for complete and immediate control of all visual cues in the environment in order to put idiothetic and allothetic reference frames in direct conflict. The arena is composed of a circular track with a 360 degree panorama of visual cues projected on the walls. Identical feeders are spaced every 10 degrees along the perimeter of the track and animals learn to run to only one of them for food reward. By instantaneously rotating the cues we were able to characterize how quickly and accurately aged animals utilize allothetic feedback to navigate to a new rotated feeder location. Behavioral data collected from six young (9 – 15 mo) and six aged (24 - 30 mo) animals revealed that immediately following cue rotation aged rats were significantly more likely to navigate to either the exact original (idiothetically aligned) or rotated (allothetically aligned) feeder locations. Young rats, by comparison, were more significantly more likely to stop at multiple feeders, particularly those half-way between the original and rotated reward location. These findings suggest that when spatial reference frames are put into conflict young rats settle on a strategy which combines the two sources of spatial information, while aged animals adhere more rigidly to only one spatial reference frame. Previous studies have shown that when spatial reference frames are put into conflict the place cells of the same CA1 network can anchor to entirely different reference frames, while CA3 place cells will align coherently with only one reference frame (Lee et al., 2004). The behavior we observe may be a consequence of the reported hyperexcitability and excessive pattern completion of aged CA3 principle cells driving an all-or-none shift to one or the other reference frame. If this is the case we expect that

electrophysiological data from downstream CA1 place cells will match our behavioral findings and that CA1 place fields of aged animals will tend to snap to one or the other reference frames coherently as a population while those of young animals well show more variability in terms of which reference frame they anchor to.

Title: Age-related reduction in signal-to-noise ratio of sharp-wave ripple oscillations following behavior in aged rats

Authors: *D. T. GRAY[1,2], J.-P. WIEGAND[1,2], L. A. SCHIMANSKI[1,2], S. L. COWEN[1,2,3], C. A. BARNES[1,2,3,4];
[1]Evelyn F. McKnight Brain Inst., [2]Divison of Neural Systems, Memory and Aging, [3]Dept. of Psychology, [4]Departments of Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: The consolidation of episodic memories relies on the transfer of information from hippocampal networks to cortical networks, and much of this information is thought to be transferred during hippocampal sharp-wave ripple events in periods of rest. During normative aging, we have recently shown that the rate of ripple occurrence decreases, and the mean frequency of ripple events is reduced by roughly 19 Hz prior to and following behavior on a spatial eye-blink conditioning task (Wiegand et al., 2016). To extend these recent findings, here we present an age-comparison of spectral power in the local field potential before and after performance on a spatial eye-blink conditioning task. Specifically, the time periods analyzed

were: sharp-wave ripple events, the 50 ms immediately preceding and following ripple events, and quiet inter-ripple periods. In young rats, the spectral power in the 80-200 Hz frequency band during ripple events was greater in the post-behavior rest period compared to the pre-behavior rest period, although in aged rats the ripple power was not different between the rest epochs. During the inter-ripple periods spectral power was significantly lower in young rats during post-behavior rest relative to pre-behavior rest, and again the power in aged rats did not differ between rest epochs. No changes were noted between rest epochs for the 50 ms immediately preceding and following the ripple events for either age group. The observations that ripple power increases and inter-ripple power decreases following behavior only in young rats may suggest a mechanism for increased signal-to-noise in these young animals. The signal-to-noise ratios were examined by computing the ratio of the summed squared magnitudes of the 80-240 Hz spectral power of ripple events relative to inter-ripple periods. This analysis showed an increase in the signal-to-noise ratio of ripple events during post-behavior rest relative to pre-behavior rest in young animals, while aged rats did not show a change in signal-to-noise ratio following behavior. Increases in the signal-to-noise ratio of ripple oscillations in rest periods following behavior may increase the efficacy by which ripple oscillations transfer information during memory consolidation. The absence of this signal to noise ratio increase in older animals suggests less efficiency in consolidation processes carried out in hippocampal networks.

Title: Expectation of large reward elicits bursts of beta-band oscillations in the aged rat amygdala

Authors: *R. D. SAMSON[1,2], L. DUARTE[1,2], C. A. BARNES[1,2,3];
[1]Evelyn F. McKnight Brain Inst., [2]Divison of Neural Systems, Memory and Aging,
[3]Departments of Psychology, Neurol. and Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: With aging, older adults tend to use strategies that differ from those used by young adults to solve decision making tasks. This is often accompanied by the recruitment of larger brain areas, inter-hemispheric bilateralization or added brain structures, which can be interpreted as compensatory mechanisms for less effective brain networks. It has been suggested that this process is facilitated through synchronized oscillations that occur between distant brain areas, presumably enabling connections that allow more optimal performance. Because the aging process is known to alter circuit properties that may impact brain oscillations, the present study examined how network changes in the basolateral complex of the amygdala (BLA), known to support reward-based decision making, may be altered in aged rats. To examine this problem, we trained young and old rats to perform three different versions of a decision making task. Two of the tasks were versions of discrimination problems in which either the reward magnitude (reward magnitude discrimination) or the probability of receiving a reward (probability discrimination) was manipulated. The third task version was a probability discounting task in which rats had a choice between a small/certain reward and a large/uncertain reward (probability discounting). In the BLA of old, but not young rats, we found task-specific increased oscillatory power in the beta range (15-30Hz) after lever presses as the animals reached the goal location. Periods of high-power beta were minimal at first, but developed over training days in the aged rats. Within a daily session, the incidence of beta epochs was greater for the early trials and less evident by the end of the session. Both the incidence and power of beta epochs were affected by tasks that involved differing reward magnitudes. Indeed, beta power was significantly greater after pressing for the large reward option. Thus, our results suggest that aging impacts BLA networks in a way that promotes the emergence of beta band activity when learning or deciding between differently sized rewards. Furthermore, we found a correlation between beta incidence and how often the small/certain reward was selected in a session, for both the reward magnitude discrimination and probability discounting tasks. Thus, increased beta oscillations in the BLA of aged rats may reflect compensatory mechanisms which promote a more exploratory type strategy to solve certain reward-based decision making tasks.

Abstract: Cognitive aging is known to alter reward-guided behavior, implicating dysfunction of prefrontal cortical circuits, including the orbitofrontal cortex (OFC). It has been reported that there is a decline in OFC volume with age, which correlates with performance on a reward devaluation task (Burke et al., 2014) in bonnet macaques. The basolateral amygdala (BLA) volume, however, does not change with age, nor correlate with performance. In the present study, the integrity of the uncinate fasciculus (UF), the primary white matter tract between the BLA and OFC is examined using high angular resolution diffusion imaging (HARDI) along with anatomical T1- and T2-weighted imaging. The number of tracks between the BLA and OFC and fractional anisotropy (FA) were calculated and performance measures were obtained in a modified Wisconsin General Testing Apparatus in a group of 11 healthy adult female bonnet macaques (10 to 31 years). Specifically, monkeys were tested on a delayed response (DR) working memory task, reversal learning task (RL, affective shifting) and delayed nonmatching-to-sample (DNMS) with interference task. HARDI scans were acquired using a single shot EPI sequence with a diffusion weighting of b = 1000 s/mm^2 in 51 diffusion directions and with an isotropic resolution of 1.4 mm. Data pre-processing involved corrections for distortions due to eddy currents using FSL, field inhomogeneity corrections using TORTOISE followed by local PCA-based denoising. Diffusion data were then registered with anatomical T1 images using a rigid body transformation. Gray matter volumes corresponding to BLA and OFC were identified previously (Burke et al., 2014). Gray matter, white matter and CSF were segmented, and the interface of the white matter and the BLA boundary was used for seeding the streamlines. Mrtrix3 was used for probabilistic tractography to identify tracks between the BLA and the OFC. Exclusion masks were identified to eliminate tracks that cross between the hemispheres or continue posterior to the BLA. Binary masks were created using track density images to extract the mean FA values along the UF for each animal. There were no statistically significant differences between age groups in mean FA values along the UF, nor were there significant relationships between mean FA values and performance on any of the behavioral tasks. The number of tracks (normalized by the seed volume), however, did significantly correlate with the DNMS task with interference, such that animals with a lower number of tracks performed more

poorly. These data suggest that disruptions in the interaction between the OFC and the BLA may contribute to certain age-related cognitive deficits.

Title: Age-related attentional control and set shifting impairments arise independently in macaque monkeys

Authors: *K. M. ANDERSH[1,2], D. T. GRAY[1,2], A. C. SMITH[1], S. N. BURKE[4], A. GAZZALEY[5], C. A. BARNES[1,2,3];

Abstract: Goal-directed behaviors provide the behavioral flexibility necessary for selecting appropriate responses when similar stimuli are encountered in different contexts. The cognitive processes that provide this flexibility have been collectively described under the category of executive functions. Executive function can be segregated into at least 3 separate components: inhibition of prepotent responses, set shifting, and attentional control and monitoring. In humans, partially non-overlapping neural networks in the prefrontal cortex underlie the different components of the executive function network. For example, orbitofrontal and striatal networks have been shown to underlie set shifting, while dorsolateral prefrontal and medial prefrontal networks have been shown to underlie attentional control processes. At the behavioral level, age-related impairments in inhibition, set shifting, and attentional control arise independently of one another, suggesting that the separate neural networks that underlie these behaviors are also altered independently with age. To test whether different executive functions are similarly affected independently in the macaque, young (n = 6) and aged (n = 7) monkeys were tested on a

set shifting and attentional control task in a Wisconsin general testing apparatus. The results show that aged monkeys were deficient on both tasks, but the impairment scores between the two paradigms did not correlate, suggesting that set shifting-impaired animals were not necessarily impaired on the attentional control task and *vice versa*. These results suggest that, like in humans, different components of executive function in aged monkeys are impacted by normative aging independently. Furthermore, these data argue against the suggestion that the age-related deficits in attentional control seen in aged humans arise due to differences in exposure to technology, relative to young, which may negatively impact their ability to perform computerized tasks. All monkeys in the current study were exposed equally to all aspects of the task environment, suggesting that the detrimental effects seen in the aged individuals are in fact due to differences in attentional control processes.

Title: Cell counts of midbrain dopamine neurons in memory-impaired aged non-human primates

Authors: *W. PYON[1,2], D. T. GRAY[1,2], K. M. ANDERSH[1,2], M. R. PERMENTER[4], J. A. VOGT[4], C. A. BARNES[1,2,3,4];

Abstract: The midbrain dopamine complex is a collection of nuclei found in the ventral mesencephalon. These nuclei contain dopaminergic projection neurons that innervate multiple forebrain regions, including the prefrontal cortex, ventral hippocampal formation, and striatum. Among other functions, dopamine neurons are thought to provide reward prediction error signals critical to reinforcement learning, and modulate frontal cortical networks underlying working

memory. Dysfunction in dopaminergic networks has been implicated in several brain pathologies. During normative aging, deficits in mental operations that require dopamine are common. While our understanding of alterations in the midbrain dopamine complex across the primate lifespan is limited, it is evident that degradation of dopaminergic innervation in the rodent prefrontal cortex plays a key role in age-related cognitive decline (Allard et al., 2011). Furthermore, it has previously been shown, by our laboratory and others, that aged macaques require more trials than younger monkeys to learn delayed nonmatching-to-sample (DNMS) and reversal learning (RL) tasks, which assess object recognition and working memory functions, respectively. The aged monkeys included in this experiment have been previously shown to be impaired on both the DNMS and RL tasks (Comrie et al., 2015). To test whether alterations in the mesencephalic dopamine complex relate to learning impairments in the macaque, we have identified coronal sections of tissue containing regions of the midbrain dopamine complex in monkeys ranging in age from 8-32 years. The numbers of tyrosine hydroxylase-positive neurons in A8, A9, A10 nuclei will be quantified using unbiased stereological sampling techniques. Dopaminergic neurons in this region of the midbrain have been shown to project to the prefrontal cortex and hippocampus, both regions understood to play key roles in learning and memory processes. Furthermore, we will quantify the numbers of GAD67-positive neurons and calbindin-positive neurons in the same sections as we assess TH. Immunohistochemically-classified cell numbers will then be correlated with DNMS and RL learning scores to identify if and to what extent changes in dopaminergic circuits underlie age-related impairments on working memory and object recognition tasks.

Inst., [5]Dept. of Psychology, [6]California Natl. Primate Res. Ctr., [7]Ctr. for Neurosci., Univ. of California, Davis, Davis, CA

Abstract: Identifying primate hippocampal subfields *in vivo* using structural MRI imaging relies on variable anatomical guidelines, signal intensity differences, and heuristics to differentiate between regions, and lack a clear anatomically-driven basis for subfield demarcation (Yushkevich et al., 2015). Recent work, however, has begun to develop methods to use *ex vivo* histology or MRI to better inform subfield demarcations of *in vivo* images (Iglesias et al., 2015, Adler et al., 2014). For optimal results, though, *ex vivo* and *in vivo* images should be matched to the same subjects, with the goal to develop a neuroanatomically-driven basis for *in vivo* structural MRI images. Here, we address this issue in young and aging rhesus macaques (young n=2 and old n=2) using *ex vivo* Nissl-stained sections in which we identified the dentate gyrus, CA3, CA2, CA1, subiculum, presubiculum, and parasubiculum using morphological cell properties (30 μm thick sections spaced at 240μm intervals and imaged at 161 nm/pixel). These were merged with *in vivo* structural MRIs (0.625 x 0.625 x 1 mm) from the same subjects via iterative rigid and diffeomorphic registration resulting in probabilistic atlases of young and old rhesus macaques. These methods will inform subfield differentiation by identifying features of the MRI images that correspond to histological properties in the same animals, useful for work in both young and aging primates. Furthermore, we believe that this approach may be helpful in developing a phylogenetically-driven "ground truth" for more accurate identification of hippocampal subregions in human brains.

Title: Spatial reorientation in aged mice

Authors: *K. LAKHANI[1], R. K. YUAN[2], I. A. MUZZIO[3];
[1]Dept. of Biology, Neurosciences Inst., The Univ. of Texas At San Antonio, San Antonio, TX; [2]Dept. of Psychology, Univ. of Pennsylvania, Philadelphia, PA; [3]Dept. of Biology, Neurosciences Inst., Univ. of Texas at San Antonio, San Antonio, TX

Abstract: Spatial reorientation — regaining one's bearings when lost — is crucial for survival. Navigators keep track of their bearings by using internal (idiothetic) self-motion cues and external (allothetic) sensory cues. Idiothetic and allothetic cues are usually complementary, signaling the same spatial position and orientation. However, during disorientation, the internal sense of direction (idiothetic information) is disrupted, and the navigator must use allothetic cues to reorient. Behavioral findings in situations with no contextual ambiguity have shown that navigators regain their bearings by relying on spatial geometry, often ignoring non-geometric cues even when they are informative (Cheng, 1986). Using a novel 2-chamber paradigm, we recently demonstrated that in situations of contextual ambiguity, animals use the non-geometric cues in the environment only to identify the chamber where they are located (context recognition), relying instead on spatial geometry to retrieve their facing direction (heading retrieval) (Julian et al., 2015). We have also recently found that in young adult animals, these distinct cognitive processes are differentially represented in the hippocampus. Even though age-related deficits in place and route learning have been demonstrated in several species, at present it is unknown how aging affects reorientation. Here we trained disoriented aged male C57BL/6 mice to find a reward consistently hidden in one out of four cups placed in the corners of a rectangular environment. The chamber contained a distinctive visual cue that signaled a unique facing direction within the chamber, and the reward was consistently placed at the right or left of this cue (position counterbalanced across animals). We found that aged mice ignored the geometry of the layout and instead used the non-geometric feature to find the reward, making fewer errors than young adult animals. To further determine if aged animals could use geometric cues, we also tested the aged mice in the same task in the absence of non-geometric cues. In this situation, aged mice performed at chance levels, corroborating that aged animals could use the cue as a beacon to find the reward but failed to use the geometry of the chamber. Furthermore, when aged mice were tested in our novel two-chamber reorientation paradigm, performance was highly variable, with some animals using the cues for context recognition and other failing to identify the context. These data suggest that reorientation strategies differ in young and aged adult animals. We are now recording from hippocampal CA1 cells in aged disoriented mice to examine the cellular correlates underlying reorientation in aged mice.

Title: Effects of sleep deprivation on place cell activity in young and aged adult mice performing the object-place recognition task

Authors: *R. K. YUAN[1], I. A. MUZZIO[2];
[1]Psychology, Univ. of Pennsylvania, Philadelphia, PA; [2]Biology, Neurosci. Inst., Univ. of Texas at San Antonio, San Antonio, TX

Abstract: Both sleep architecture and cognition have been shown to undergo changes with aging. Moreover, there is evidence that sleep may play a role in memory consolidation, since cellular ensembles active during learning become reactivated during sleep, and sleep deprivation has been shown to cause learning impairments. Here, we examined changes in sleep characteristics and cellular activity in young and aged male adult C57BL/6 mice that were sleep-deprived after training in a hippocampus-dependent object-place recognition task. Animals were habituated to a novel environment in which they subsequently explored an array of 3 objects, over the course of 3 consecutive training sessions. Immediately after the last training session, animals were sleep deprived for 5 hours using an automated sleep deprivation system consisting of a cylindrical enclosure with a continuously rotating bar. The following day, animals were reintroduced to the environment for a single test session in which one object was displaced. We found that relative to controls, young sleep deprived animals exhibited lower preference for the displaced object, along with lower peak firing rates and less global remapping from the third training session to the displaced object test session. Surprisingly, these trends were reversed in the aged adult mice. Aged sleep deprived mice showed a stronger preference for the displaced object than aged controls, and also displayed more global remapping and higher peak firing rates during the test session. We examined patterns of REM and NREM during the 5 hours of recovery sleep occurring immediately after sleep deprivation. Relative to controls, young sleep-deprived animals exhibited an increase in overall amount of NREM and number of REM bouts, though not overall REM. Meanwhile, aged sleep-deprived animals showed an increase in overall REM and more consolidation of NREM sleep relative to controls. Our preliminary findings suggest that mice may encode object displacement through global remapping, and that sleep deprivation in young mice and normal aging both result in reduced remapping that corresponds with impaired performance. Interestingly, an acute period of sleep deprivation in aged adult mice

appears to result in improved sleep consolidation, which corresponds with changes in hippocampal representations that may underlie enhanced recognition of object location.

Title: Age-related impairments in memory in rats are accompanied by decreased lactate production by astrocytes in the hippocampus and are rescued by intrahippocampal lactate infusions

Authors: *B. HAMLING, L. A. NEWMAN, D. L. KOROL, P. E. GOLD;
Biol., Syracuse Univ., Syracuse, NY

Abstract: These experiments determined whether age-related decreases in lactate production in the hippocampus are important for memory impairments in aged rats. Extracellular lactate is largely derived from glycogenolysis and glycolysis in astrocytes and can be used to supplement glucose as a neuronal energy substrate. The availability of lactate may be particularly important with regard to age-related memory impairments because of our prior evidence that extracellular glucose levels measured in the hippocampus of aged rats are markedly decreased during memory tests. Here, male Fischer 344 rats showed age-related impairments on a spontaneous alternation task used to assess spatial working memory. In a separate group of rats, biosensor probes were placed in the hippocampus to measure extracellular lactate levels while the rats were tested on the spontaneous alternation task. During testing, lactate levels increased by 128 ± 25 μM in young rats but only by 48 ± 17 μM in old rats. To determine whether the loss of lactate was important to the age-related memory impairments, lactate (100 nmol) was infused into the hippocampus 15 min prior to testing on the alternation task. The intrahippocampal infusions of lactate reversed the age-related deficits, resulting in alternation scores higher than those of saline-injected old rats (57 ± 5% vs. 37 ± 7%) and even higher than those of saline-injected young rats (45 ± 4%). Together, with past evidence that glucose levels are also depleted during memory testing in aged rats, the findings suggest that age-related memory loss may reflect

impaired bioenergetic capacity in the aged hippocampus. Moreover, the apparently complete rescue of working memory in aged rats by lactate infusions shown here, and by glucose treatments shown previously, indicate that the aged hippocampus can function well if the bioenergetic capacity is restored. We are currently assessing whether aging is accompanied by impaired and preserved bioenergetics of brain areas associated with other attributes of learning and memory.

Title: Aged rats that are unimpaired in spatial learning successfully engage a behavioral response and CA3 gene expression when cues in a familiar environment are changed

Authors: *R. P. HABERMAN[1], D. MOORE[1], A. LOURENCO[1], G. RAO[2], J. J. KNIERIM[2], M. GALLAGHER[1];
[1]Dept Psychol & Brain Sci., [2]Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: Preserving cognitive function is critical to achieving a high quality of life in elderly individuals. Mechanisms of successful brain aging are under study in our laboratory in a rat model of cognitive aging in which individual differences span a range of outcomes including impairment and preserved memory function relative to young adult rats. Here we compared behavior and gene expression in aged rats characterized for preserved cognitive spatial ability and in young adult rats in response to change within a familiar environment, using a paradigm that engages the encoding properties of hippocampal neurons (Monaco et al. Nat Neurosci. 17: 225, 2014). After initial behavioral characterization for cognitive status, age unimpaired and young rats were acclimated to performance on a circular track in an environment with both local and global cues. On test day, half the rats in each age group encountered an altered environment in which cues were rotated in opposite directions to create a mismatch between local and global cues (mismatch condition). For the other half of subjects, the cues were left unchanged (no-change condition). We assessed behavioral evidence that rats detected the cue mismatch by measuring attentive head scans, episodes during track running when the rat stops and surveys the environment. In both young and aged unimpaired rats, head scans significantly increased on the

test day in response to the mismatch rotation relative to the previous day. As expected, no increase was observed in either age group in the no-change condition. Supporting that behavioral outcome, in both age groups we found increased CA3 expression of neuroligin1, a synaptic plasticity gene, in the mismatch condition relative to no-change. These data add support for the characterization of individual differences in aging such that some aged individuals maintain cognitive functions and underlying neurobiological mechanisms on a par with younger adults.

Title: Verifying the Octodon degus as a non-transgenic model of Alzheimer's Disease

Authors: *P. A. ANGELI[1], A. M. SPIEGEL[2], R. P. HABERMAN[1], A. G. PALACIOS[3], P. R. RAPP[2], M. GALLAGHER[1];
[1]Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD; [2]Lab. of Behavioral Neurosci., Natl. Inst. on Aging, Baltimore, MD; [3]Ctr. Interdisciplinario de Neurociencia de Valparaíso, Univ. de Valparaíso, Valparaíso, Chile

Abstract: Current rodent models of Alzheimer's Disease (AD) based on the genetics of early onset familial AD have contributed substantially to understanding the pathophysiology of this disease. However, these models do not develop the complete brain pathology of the disorder including progressive neurodegeneration. The *Octodon degus*, a large rodent native to South America, recently emerged as a potential candidate for a natural model of AD. Two previous studies have documented neurobiological evidence for AD in degu, including age related accumulation of Aβ containing inclusions and tau protein phosphorylation that negatively correlate with performance on cognitive tasks. Our research attempts to further validate the degu

as a model for AD that includes the neuropathological hallmarks together with neurodegeneration. Two series of coronally sliced sections from 19 degus aged 7-96 months (kindly provided by Dr. Palacios) were immunohistochemically processed for NeuN or for doublecortin (DCX). NeuN was used as a marker for all neurons, and DCX was used to identify newborn neurons, which decrease progressively with age in many species. We focused our initial neuron counts on CA1 because it is the hippocampal subregion where neurodegeneration is first observed in AD. Stereological methods were used to obtain estimates of total NeuN positive neurons in this subfield. In the degu, we did not find a significant difference in total cell counts between young and aged groups or a correlation with age. Exhaustive counting in matched sections was used to compare DCX positive cell counts in the dentate gyrus of the same subjects. Relative DCX counts confirmed a significant decrease in neurogenesis between young and aged animals (students t-test: $p<0.0001$) and a strong negative correlation with age (Pearson's: $r=-0.839$, $p<0.0001$). These results show that there are age-dependent changes in the hippocampus of degus consistent with that of other rodent species. However, no evidence for age-dependent neuronal loss in CA1 was observed in these degus. Our data suggest that in the presence of naturally occurring AD-like pathology, degus may more closely resemble asymptomatic Alzheimer's, a clinical condition in which AD-like pathology occurs without dementia or neurodegeneration. Further studies are currently examining AD pathological markers in the cohort described above.

Title: A multiple memory systems approach to age-related changes in cognition: Differential modulation of BDNF in hippocampus and striatum in rats

Authors: *R. S. GARDNER, L. A. NEWMAN, P. E. GOLD, D. L. KOROL;
Biol. Dept., Syracuse Univ., Syracuse, NY

Abstract: Distinct types of learning and memory map well onto dissociated neural circuits consistent with a multiple systems perspective. Learning to navigate an environment by relying on the arrangement of spatial cues (place learning) requires an intact hippocampus; in contrast, learning a fixed route or sequence of movements (response learning) requires an intact striatum. The hippocampus and striatum also interact and under certain conditions compete to control behavior. Thus, study of a single form of memory or neural structure may lead to an incomplete understanding of structure-function relationships. Importantly, older adults demonstrate a greater reliance on response navigation than do younger adults, suggesting a shift with age in the dominant learning strategy. This shift is also observed as deficits in place navigation among old vs. young rats accompanied by unaffected or improved response navigation. Here, we augment this prior work to further characterize age-accompanied changes in memory systems by measurement of brain derived neurotrophic factor (BDNF) in hippocampus and striatum among young (3 month) and old (24 month) F344 rats trained on place and response tasks. BDNF is implicated in age-related changes in learning and memory and modulates both hippocampal- and striatal-dependent performance. We found that levels of mature BDNF in the hippocampus were higher in old compared with those in young rats, an effect most pronounced among place-trained rats. In contrast, levels in the striatum were largely comparable across conditions. Interestingly, these results parallel data from our lab demonstrating alterations across the lifespan in energy substrates associated with learning, i.e., glucose and lactate. Specifically, training-induced increases in extracellular glucose and lactate are attenuated in hippocampus but not in striatum among old compared to young rats. Altogether, these results verify that age-related changes in learning and memory are not all-encompassing and suggest site-specific changes to both BDNF signaling and bioenergetics in aging. Characterization across the lifespan of distinct forms of BDNF (pro vs. mature) with a high degree of spatial resolution (permitting cellular vs. extracellular localization) in addition to expression levels of BDNF receptors will further enhance our understanding of changes to learning and memory that accompany aging.

Title: Light treatment enhances memory and adult neurogenesis in circadian disrupted and aged rats.

Authors: *R. J. SUTHERLAND[1], M. FIDA[2], C. BYE[2], M. WANG[2], J. M. SUTHERLAND[3], R. J. MCDONALD[2];
[1]Univ. Lethbridge, Lethbridge Alberta, AB, Canada; [2]Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada; [3]NeuroInvestigations, Inc, Lethbridge, AB, Canada

Abstract: Irregular light-dark cycles (circadian disruption) can trigger adverse effects that include the cognitive and motivational domains in humans and rats. Several studies have found that in normal aging circadian disruption is common and may contribute to age-related adverse outcomes. Here we exposed rats with continuous access to running wheels to two weeks of phase-shifting (3 hr/day phase advance), the two weeks were separated by a one week re-entrainment phase. This procedure is known from previous work to generate several adverse effects. We confirmed that circadian disruption, even after 6 days of re-entrainment, tends to reduce long-term retention of spatial memory measured in the Morris water task and also reduced adult hippocampal neurogenesis measured by number of Ki67, doublecortin and BrdU labeled cells. We found that 30 min/day of light treatment (Litebook) at the beginning of the light phase during re-entrainment improved spatial memory retention and enhanced adult hippocampal neurogenesis. No reliable effects were observed on social or food motivation. In a second experiment we measured spatial memory and adult hippocampal neurogenesis in 12 month old male and female rats. We provided 6 weeks of continual access to running-wheels or 30 min/day of light treatment or combined running wheel and light treatment. Both adult hippocampal neurogenesis and memory showed a reliable trend for benefit from both treatments.

Title: Age-related spatial long-term memory deficits can be overcome with spaced training

Authors: *S. MCQUOWN, D. ELOW, G. ANDERSON, R. JOHNSON, K. BAUMGAERTEL, M. PETERS;
Dart Neurosci., San Diego, CA

Abstract: Hippocampal function and spatial memory has been shown to decline in response to normal aging across multiple species, including humans. C57Bl/6 mice are the most commonly utilized strain for characterizing gene effects on memory, but the effect of age on memory in this genetic background is poorly understood. Here, we characterized the effects of normal aging on contextual fear memory and spatial memory in the Barnes Maze. Aged 21-22 month old mice were unimpaired in short-term contextual memory, but showed significantly less freezing than young 3 month old animals in a 24 h long-term memory test, as well as in tests of contextual discrimination. This impairment of memory retention coincided with reduced training-induced immediate early gene (IEG) expression and reduced hippocampal CREB levels. Because training parameters and CREB gene-dosage interact to control memory retention in invertebrates and vertebrates alike, we reasoned that spacing of trials should result in improved memory in age-associated memory impairment. In young mice, training for 1, 2 or 4 trials with a 1 min intertrial interval (ITI) over 4 days resulted in similar levels of 24 h memory. With 2 days of training, however, 24 h memory was improved when trials were spaced by a 10 min ITI rather than massed together. Aged mice that received 2-trial training with a 1 min ITI had significantly impaired spatial memory when compared to young mice, but this impairment was overcome by introduction of a 10 min ITI. Our results provide behavioral and neurogenetic evidence for a role of CREB in age-associated memory impairment.

Title: Enhanced learning and memory from chronic dietary supplementation with quercetin and PS-DHA is associated with increased IL-10 expression and reduced mtDNA in the hippocampus of aged C57BL/6J mice.

Authors: *S. D. PEREZ[1,5,8], K. DU[2,5,6], S. RUBAKHIN[9,3,6], L. WANG[9,7,6], Q. WU[10,6,7], J. H. BAXTER[12,6,7], J. RHODES[4,11,3,6];

Abstract: A possible correlation exists between cognitive function and dietary habits in the elderly population; but comparative assessment of nutrient deficiency or supplementation and its effects on learning and memory function is not clear. We investigated the effects of various micronutrients on learning and memory tasks, neuronal plasticity, energetic and neuroimmune status in the aged hippocampus. 18 month-old C57BL/6J mice were fed 8 distinct diets, of various concentrations of select micronutrients, essential vitamins and minerals. After 16 weeks, mice were tested on behavioral tasks to measure learning and memory. The number of immature neurons (DCX^+) in the hippocampal dentate gyrus (DG) was determined. Gene expression of molecular markers of mitochondrial biogenesis (Ppargc1α, Sirt1, Tfam), mitochondrial content (amount of mtDNA) and neuroinflammatory markers (IL-10, Alox15, Ptgs2, IL-1β, IL-6 and Tnf) were assessed by RT-PCR of brain sections containing hippocampus; and tissue incorporation of selected nutrients was measured by ultrahigh performance liquid chromatography and mass spectrometry. The diet supplemented with RRR d-alpha tocopheryl acetate, citicholine, 5-methyltetrahydrofolic acid, Quercetin and the n-3 fatty acid PS-DHA, improved performance on the active avoidance learning and memory task compared to the other diets. Also, increased IL-10 expression and attenuated the age-related change in mtDNA content in the hippocampus. Although the mechanisms remain unknown, we conclude that chronic supplementation of diets with multiple micronutrients including quercetin and PS-DHA can improve learning and memory in aged mice. These observations support the hypothesis that

cognitive benefits of wholesome diets are partially mediated through antioxidant and anti-inflammatory activities of combined micronutrients.

Title: Synaptic distribution along the basal dendrites of CA1 pyramidal cells in the behaviorally characterized, aged rat

Authors: *T. F. MUSIAL[1], S. A. MULLEN[1], G. AYALA[1], N. J. CORBETT[1], M. D. ANTION[2], C. WEISS[2], J. F. DISTERHOFT[2], D. A. NICHOLSON[1];

Abstract: Learning and memory is an instrumental function enhancing the ability of many higher organisms' ability to thrive in a dynamic environment; however, many species experience disruptions in this domain as they age, which can be exacerbated by pathological factors in diseases such as Alzheimer's disease and frontotemporal lobe dementia. However, a substantial proportion within these aged populations will experience decline in normal memory function in the absence of such pathology. The specific mechanism underlying the decline in normal aging, however, remains elusive. Many of the cognitive domains, including spatial memory, that become impaired with age are hippocampus-dependent. Therefore, we sought to investigate possible synaptic alterations, particularly in the CA1 - a major output region of the hippocampus, that occur with aging using aged, behaviourally characterized rats. Our previous work has shown that there is distant-dependent synaptic scaling along the CA1 apical dendrites in young adult rats, which is maintained in both aged groups. We have also shown that in young adult rats the basal dendrites exhibit very similar synaptic scaling properties. The exact distribution of synapses along these dendrites in the same aged rats, with and without cognitive impairment, is currently being investigated. The cognitive function of 29 month old male rats was assessed

using trace eyeblink conditioning and the Morris Water Maze; rats that were able to learn both tasks successfully were categorized as aged, memory-unimpaired (AU), whilst those that did not learn were categorized as aged, memory-impaired (AI). These groups were compared with young adult (YA) rats. The total number of perforated and non-perforated axo-spinous synapses in the proximal, middle, and distal portions of the CA1 basal dendrites were then determined using serial section electron microscopy and unbiased systematic random sampling techniques. Through a deeper understanding of the synaptic alterations that occur in these three groups, we may find clues as to those changes that are adaptive, allowing continued cognitive performance with age, and those which are maladaptive, hindering the ability for learning and memory to be maintained with age.

Title: Age-dependent decrease in spontaneous alternation behaviors: potential hippocampal substrates.

Authors: R. M. WILHELM[1], N. R. TANDON[2], *L. T. THOMPSON[1];
[1]Behavioral & Brain Sci., Univ. of Texas At Dallas, Richardson, TX; [2]Biol. Sci., Univ. of Texas at Dallas, Richardson, TX

Abstract: Rats readily repeatedly explore their spatial environments even in the absence of aversive consequences or explicit appetitive rewards. In young rats, this exploratory behavior is not random, but governed by prior behavioral choices. In simple spatial environments, such as Y- or plus-mazes, young rats perform “spontaneous alternation”, i.e. distributing exploratory behavior around all regions of the environment. On subsequent trials, arm entries avoid immediately repeating entries to arms recently visited (extending two, three, or four arms back), supporting a hypothesis that cognitive mapping guides exploration. Memory for space highly depends on hippocampal function, with both spontaneous alternation and direct measures of

hippocampal plasticity degrading under adverse conditions, including high-fat diet ingestion from weaning (Underwood and Thompson, 2016). The current study assessed whether spontaneous alternation declines with age, and whether decrements correlate with age-dependent changes in hippocampal biomarkers.
Cohorts of Fisher 344-Brown Norway (FBN) hybrid rats were socially housed from weaning until behavioral assessment. Rats were handled daily for a minimum of 5 min for 7 d while while being acclimated to the testing room prior to introduction to the maze. Testing was carried out on a 4-arm radial maze (plus-maze), with 58 cm long x 13 cm wide x 24 cm walls high arms joined to a central 20 x 20 cm platform. Each rat was placed in the center area of the maze (facing the same direction) and allowed 12 min for free exploration. Arm entries were monitored, and alternations defined as 4 different arm choices out of 5 consecutive arm entries, scored serially. Alternation scores were calculated, dividing the number of alternations (in overlapping quintuplets of trials) by the number of possible alternations. Afterwards, rats were deeply anesthetized and brain tissue rapidly dissected for assessment of age-dependent changes in protein expression via western blotting.
Through 12 mo, no significant age-dependent differences were observed in spontaneous alternation. Comparisons of young rat behavior to that of aged (24 mo old) rats, however, revealed significant age-dependent decrements in spontaneous alternation. A remaining question is whether these deficits are sex-dependent or shown by both males and females. Behavioral changes across ages are discussed in comparison to altered hippocampal protein expression, including the immediate-early gene Arc, the phosphatase calcineurin, the calcium-sensor hippocalcin, and other biomarkers of signaling pathways critical for regulation of synaptic plasticity and intrinsic excitability.

Title: Estradiol normalizes CA1 GluN receptors surface distribution and declarative memory in aged mice

Authors: *S. AL ABED[1], A. SELLAMI[1], P. TRIFFILIEF[2], L. BRAYDA-BRUNO[1], V. LAMOTHE[1], M. POTIER[1], C. BENNETAU-PELISSERO[1], A. MARIGHETTO[1];

Abstract: One major feature of cognitive aging is the degradation of our capability to form conscious memories of *what happened where and when*, i.e. declarative memory. We recently showed in young adult male mice that estradiol enhances a key component of this memory, i.e. the retention of temporal associations, through CA1 NMDA receptor surface trafficking. Both the retention of temporal associations and the surface distribution of hippocampal NMDA receptors have been shown to be altered in aging. We hypothesized that a treatment with estradiol may normalize these aging-associated alterations and hence rescue the declarative memory deficit occurring in senescence. First, using a trace fear conditioning task, we found that (i) learning induces a redistribution of surface NMDAR in the CA1 subfield of young but not aged mice. This redistribution varied according to the level of the 24h-retention of the temporal (tone-shock) association. (ii) In aged mice, treatment with 17β-estradiol (1μM) via drinking water normalized the pre-learning distribution of CA1-NMDAR and abolished the retention deficit. Secondly, using a radial-maze task in which flexible spatial memory is assessed as a model of declarative memory, we found that the same estradiol treatment abolished the age-associated memory impairment. This effect was associated with the normalization of (i) thin spine density in CA1, leading to a "youthful" apical dendritic spine profile, and (ii) learning-induced CA1 (Fos) activation and functional connectivity. In conclusion, estradiol rescues aging-related defects in CA1 function in temporal associations and declarative memory, potentially through NMDAR surface trafficking.

Title: Cholinergic induction of hippocampal Arc expression in a rat model of normal cognitive aging

Authors: *C. MYRUM, S. L. ROSSI, E. PEREZ, A. M. MORROW, K. H. SCHULZE, J. M. LONG, P. R. RAPP;
Natl. Inst. on Aging, NIH, Baltimore, MD

Abstract: Expression of the immediate-early gene Arc is essential for the formation of long-term memories, and experience-dependent hippocampal Arc transcription and translation are disrupted specifically in aged rats with spatial memory deficits. Considerable evidence also links cholinergic dysfunction to age-related cognitive decline. Prompted by this background, here we examined whether cholinergic-mediated Arc expression is affected in the hippocampus of aged rats. We utilized a well-established rat model of cognitive aging in which aged animals are categorized as impaired or unimpaired relative to young based on performance in a hippocampus-dependent 'place' version of the Morris water maze. The muscarinic cholinergic receptor agonist pilocarpine (25 mg/kg) or vehicle was injected (i.p.) 90 min prior to euthanasia. Brains were fixed, frozen sectioned, immunolabeled for Arc protein and c-Fos, and stained with phalloidin to detect F-actin. Labeling in hippocampal CA1 and CA3 cell fields was digitized using a Typhoon Trio Plus Scanner, and immunofluorescence intensity was quantified using ImageJ. Cholinergic stimulation in young and aged-unimpaired rats lead to similar effects on Arc and c-Fos expression, yielding significant increases in both markers relative to age-matched vehicle control values. In contrast, aged-impaired rats displayed increased basal levels of c-Fos expression relative to young and aged-unimpaired animals, and a failure of both Arc and c-Fos induction following pilocarpine injection. Together these findings suggest that disrupted cholinergic signaling may contribute to uncoupling neuronal activity from hippocampal Arc expression in cognitive aging.

Title: The role of adult neurogenesis in the structure and function of the septohippocampal circuit

Authors: *G. KIRSHENBAUM[1], V. K. ROBSON[2], R. M. SHANSKY[3], L. M. SAVAGE[4], E. D. LEONARDO[2], A. DRANOVSKY[2];
[1]Div. of Integrative Neurosci., Columbia Univ. Press, New York, NY; [2]Columbia Univ., New York, NY; [3]Northeastern Univ., Boston, MA; [4]Binghamton Univ., Binghamton, NY

Abstract: Adult neurogenesis is impaired in disorders of stress, memory, and cognition though its normal function remains unclear. Moreover, a systems level understanding of how a small number of young hippocampal neurons could dramatically influence brain function is lacking. We examined whether adult neurogenesis sustains hippocampal connections across the life span. Long-term suppression of neurogenesis as occurs during stress and aging resulted in a progressing alteration in hippocampal acetylcholine and the slow emergence of profound working memory deficits. These deficits were accompanied by compensatory rewiring of cholinergic dentate gyrus inputs. Our study demonstrates that hippocampal neurogenesis supports memory by maintaining the septohippocampal circuit across the lifespan. It also provides a systems level explanation for the progressive nature of memory deterioration during normal and pathological aging and indicates that the brain connectome is malleable by experience.

Title: Can observational learning stabilize a hippocampal representation of a space that is not directly experienced?

Authors: *T. DOUBLET[1,2], M. NOSRATI[2], C. KENTROS[2];
[1]Kavli Inst. for Systems Neurosci. and Ctr. for Neural Computation, NTNU, Trondheim, Norway; [2]Kavli Inst. for Systems Neurosci. and Ctr. for Neural Computation, Trondheim, Norway

Abstract: Hippocampal place cells are selectively activated when the animal physically occupies a particular location in space, leading to the idea that they comprise a cognitive map of the external world that animals use to solve spatial problems. Our prior work has shown that even extensive visual observation of a region of a rat's environment is insufficient to create a stable hippocampal place cell map without its direct experience (Rowland et al, 2011). However, many studies have shown that sequences of place cells can traverse unoccupied space, in some cases even into unexplored portions of the animal's environment. Moreover, many studies over the years suggest that animals are capable of learning by observation, and that the stabilization of a place cell map depends upon the level of an animals' attention to space. This raises the question of whether rats create stable maps of observed space during observational learning. We have therefore developed an observational spatial learning task that allows us to unambiguously address this question. It relies upon the same arena used in our prior work consisting of two concentric squares: an outer square with asymmetric spatial cues on the walls, and an inner square made out of clear plastic. The only difference is the presence of 12 identical food wells in the outer square. One rat (the Demonstrator) learns the location of a hidden food reward placed in one of the wells, with odor and visual cues rendered uninformative. The other rat (the Observer) is familiarized only to the clear inner square, but is then allowed to watch the behavior of a trained Demonstrator rat. On the test day, the Observer rat is allowed into the outer square for the first time and is scored on which well it chooses to dig in first. Remarkably, the behavior of Observer rats on the test day is indistinguishable from that of the trained Demonstrators, which are both easily distinguishable from naïve animals. The Observer animal thereby shows purely observational learning of spatial knowledge. We present the results of recordings from Observer rats implanted with tetrode arrays in hippocampal CA1 to see whether their demonstrable spatial knowledge of a purely observed space resulted in a stabilization of the animal's hippocampal representation of unexplored space, in whole or in part, purely by virtue of the animal paying attention to an observed space. Title: Enhanced transgenics: a novel means to generate neuroanatomically-specific genetic tools.

Authors: *S. BLANKVOORT[1], M. P. WITTER[1], J. NOONAN[2], J. COTNEY[3], C. KENTROS[1,4];
[1]Kavli Inst. For Systems Neurosci., Norwegian Univ. of Sci. and Technol., Trondheim, Norway; [2]Dept. of Genetics, Yale Univ. Sch. of Med., New Haven, CT; [3]Dept. of Genet. and Genome Sciences, Univ. of Connecticut Hlth. Ctr., Farmington, CT; [4]Inst. of neuroscience, Univ. of Oregon, Eugene, OR

Abstract: Recent years have seen the development of extraordinary molecular tools for neuroscience, from transgenes that allow the control or visualization of neuronal activity to precise and unambiguous neuroanatomical tracing systems. However, the full potential of such tools can only be realized if they are deployed with anatomical specificity that approaches the granularity at which neural circuits operate. This cell-type specificity can only be obtained by molecular genetic methods. To date this has involved using the specificity of native promoters to direct transgene expression, either by using minimal promoter constructs with viral vectors or pronuclear injections into oocytes, or by knocking the transgene directly into the native RNA transcript via homologous recombination. However, despite several initial successes, these techniques have serious limitations. Viruses and transgenic lines made with minimal promoters typically do not faithfully phenocopy native gene expression. Even knock-ins, which can do so, are limited by the fact that very few genes actually express exclusively in a single cell type. Therefore, all these approaches have fatal flaws. Leveraging precise tissue dissection techniques with ChIP-Seq of histone modifications associated with active enhancers, we have identified enhancers active specifically in particular brain regions. Combining these tissue specific enhancers with a mutated minimal promoter incapable of driving gene expression alone has allowed us to generate lines of transgenic mice, which target distinct cell types of particular brain regions. While our first proof-of-principle case targets distinct neurons of the Medial Entorhinal Cortex, this method can be used to target cells of any brain region. Ultimately, this enhancer-based approach should provide a means to deliver any transgene to any cell type in the brain, greatly enhancing our ability to understand the native circuitry of the brain at the level of granularity at which it operates.

Title: Spatial and task-related activity in the subiculum

Authors: *D. LEDERGERBER[1], R. GARDNER[2], V. NORMAND[2], H. T. ITO[3,4], M. P. WITTER[2], E. I. MOSER[2], M.-B. MOSER[2];

Abstract: The subiculum is one of the main output regions of the hippocampal formation. Together with CA1 it provides input to a number of cortical and subcortical regions which rely on spatial and mnemonic information previously processed in the hippocampus proper. While the firing properties of CA1 place cells have been investigated quite extensively, our current knowledge of neuronal computation and representation in the subiculum remains very limited. In previous studies of subicular neurons, Lever et al. (2009) have identified boundary vector cells and Deadwyler and Hampson (2004) have reported the presence of cells with task phase specific firing in a delayed non-match to place task. However, it is unclear how abundant these cells are and little is known about how they are distributed along the subiculum's proximodistal axis and across its layers. Furthermore, it is unknown whether they form distinct functional populations or a single population with mixed selectivity. To address these questions, we performed extracellular recordings of single units in the subiculum while rats were alternating between random foraging for chocolate milk rewards and goal directed running in an adapted version of the Pfeiffer & Foster task (2013), a task where animals search for food rewards in an array of 6 x 6 food wells on an open arena. We found cells that changed their firing rate according to which phase of the task the animal was in. Other cells responded for features of the environment like the food wells or the walls. The response to food wells or walls appeared to be unaffected of, or in some cells even diminished by, the presence reward. These various functional cell types where unequally distributed along the proximodistal axis; while cells that responded to the food wells could only be found in the very proximal part of subiculum (and the distal CA1), the others were more dispersed. It thus appears that the subicular output varies quite substantially along its

proximodistal axis and that the information provided is not amplifying but complementing hippocampal CA1 output.

Title: Supramammillary nucleus modulates spike-time coordination in the prefrontal-thalamo-hippocampal circuit

Authors: *H. T. ITO[1,2], E. I. MOSER[2], M.-B. MOSER[2];
[1]Max Planck Inst. for Brain Res., Frankfurt, Germany; [2]Kavli Inst. for Systems Neurosci. and Ctr. for Neural Computation, Trondheim, Norway

Abstract: Temporal spike coordination enables transient functional coupling between brain regions in accordance with behavioral demands (Singer, 1993, 1999). During navigation, spatial maps in the hippocampus are thought to interact with action-planning systems in other regions of cortex, such that the animal will eventually reach the goal location. In agreement with this idea, previous studies have reported enhanced spike coordination between the medial prefrontal cortex (mPFC) and hippocampal area CA1 on the central stem of a T-maze, before the animal makes a decision about the next lap (Jones and Wilson, 2005). The enhancement is specific for the theta-frequency band. While this spike coordination was thought to reflect enhanced signal flow from CA1 to mPFC, the circuit mechanisms and the functional significance of the coordination are still largely unknown. We now show that spike coordination in mPFC and CA1 can also enhance signal flow in the reverse direction, from mPFC to CA1, by using the midline thalamic nucleus reuniens (NR) as a relay. Rats were trained to perform a continuous alternation task on a T-maze with return paths. Spikes of NR neurons, which receive mPFC inputs and project to CA1, exhibited enhanced phase-locking to theta oscillations in CA1 LFPs on the central stem of the maze. There was not a corresponding increase in phase locking in other parts of the maze.

Consistent with the spike data, there was enhanced theta phase coherence between CA1 and NR LFPs on the stem. Thus, mPFC and CA1 cells are reciprocally coupled at times when animals make decisions about subsequent trajectories. What is the mechanism of coupling between mPFC, NR, and CA1 during decision making on the stem of the maze? We found that the supramammillary nucleus (SUM) in the hypothalamus plays a key role in coordinating the three regions. SUM gives rise to inputs to mPFC, NR and hippocampal area CA2, which in turn projects to CA1. Neurons in SUM exhibited enhanced phase-locking to theta oscillations in CA1 LFPs on the central stem, in the same way as mPFC and NR neurons. When SUM activity was silenced optogenetically, theta-frequency spike coordination in the mPFC-NR-CA1 circuit was significantly reduced. Representations of future trajectories in CA1 place cells, which depend on mPFC-NR inputs (Ito et al., 2015), were reduced after silencing of SUM. Taken together, the findings point to SUM-mediated temporal spike coordination as a key mechanism for controlling signal flow from mPFC through NR to the CA1 during spatial decision making.

Title: Phase relationships between grid cells are preserved during sleep

Authors: *R. GARDNER, M.-B. MOSER, E. I. MOSER;
Kavli Inst. For Systems Neurosci., Trondheim, Norway

Abstract: Grid cells of the medial entorhinal cortex (MEC) are defined by their periodic spatial receptive fields that tile two-dimensional environments. Since the discovery of grid cells, much discussion has focussed on the mechanism responsible for their firing patterns, and computational network models have demonstrated proof of concept for several distinct mechanisms. Although empirical studies of grid cells have yet to provide compelling evidence for any particular mechanism, the observation of fixed spatial relationships between comodular grid cells has been interpreted in terms of low-dimensional attractor-like behaviour, which could

result from selective connectivity of individual grid cells within a module.
We hypothesized that, if specific connectivity is a primary determinant of grid cells' spatial tuning, low-dimensional attractor dynamics might persist during sleep, when grid cells are not engaged in navigational computations. To address this prediction, we performed extracellular electrophysiological recordings of grid cell ensembles in rats *in vivo* using chronically implanted tetrodes, during open field running (OF) and sleep.
We examined pairs of simultaneously recorded comodular grid cells and found that grid cells' spatial phase differences predicted temporal spiking relationships during slow-wave sleep (SWS). Pairs of grid cells with similar spatial phases (indicated by positive rate map correlation values) in OF fired coincidently within latencies of 20 ms during SWS. Conversely, cell pairs with distant spatial phases (indicated by negative rate map correlation values) avoided spiking together within this period. Conjunctive grid/head-direction cells were predisposed to fire simultaneously with grid cells of similar spatial phase, while they also fired synchronously with head direction cells of similar directional tuning, suggesting that the structure of the entire spatio-directional map was retained. During rapid-eye-movement sleep (REM), the same trends were apparent as in SWS, suggesting that the phenomenon is not confined to hippocampal sharp-wave-ripple replay epochs. The time scale of cross-correlations appeared compressed in SWS relative to both REM and OF, consistent with the acceleration of temporal dynamics seen in various brain regions during SWS.
In summary, we found that the spatial tuning relationships of individual grid cells, conjunctive grid/head-direction cells, and pure head-direction cells, predicted their temporal spiking correlations during sleep, supporting the hypothesis that selective connectivity forms an important contribution to the spatial firing properties of grid cells.

Title: Spatial dynamics of grid cells during novelty

Authors: ***M. HAGGLUND**, E. I. MOSER, M.-B. MOSER;
Kavli Inst. for Systems Neuroscience,CNC,NTNU, Trondheim, Norway

Abstract: Grid cells in the enthorinal cortex fire in a triangular pattern that tessellates the surface of the surroundings. Detailed analysis has shown that the grid pattern displays local distortions in the shape and the orientations of the grid vertices, distortions that often are related to the walls and corners of the recording enclosure. Consistencies in the pattern of distortions over animals suggest that they arise from a common mechanism, possibly reflecting anchoring of the grid to the local geometry of the environment.
The aim of the present study was to determine how grid patterns develop and how they anchor to the environment during the first minutes of experience in a new enclosure in an unfamiliar room. Cells were recorded for several sessions subsequent to the initial exposure to monitor the long term development of the grid pattern. To visualize local changes in the grid we used a sliding window crosscorrelation on rate maps within or between sessions during familiarization to the novel environment.
The stability of the grid in a new environment varied between different experiments and ranged from being stable after the first session to needing several sessions to stabilize. There was variation in the stability of different fields of the same grid cell, both during the first and during subsequent sessions. Whereas some fields were stable from the first visit to a location, others shifted across visits. New fields sometimes arose in locations already visited by budding off from neighboring fields. In some experiments, a large part of the grid, consisting of several vertices, shifted coherently while the rest was stationary or moved in a different direction. This partial shift, which was consistent over simultaneously recorded cells, could be an indication that the grid over time reduces mismatches in grid fragments with different initial anchoring locations.
To conclude, grid cells display rich dynamics when animals learn a new environment, possibly reflecting how the entorhinal cortex uses sensory cues such as corners and walls of the environment for anchoring.

Title: Spatial periodicity of grid cells depends on inhibition from parvalbumin- but not somatostatin-expressing interneurons

Authors: *Q. CAO[1,2], C. MIAO[1,2], M.-B. MOSER[1,2], E. I. MOSER[1,2];

Abstract: The medial entorhinal cortex is one of the central hubs of the mammalian spatial representation system. A key component of this system is the grid cell, whose firing fields tile the available space in a remarkably periodic hexagonal pattern. Grid cells are unique in the sense that no similar pattern exists in the animal's sensory inputs, pointing to intrinsic circuits of the spatial representation system as the source of the pattern. Recent theoretical models have identified the inhibitory network of the MEC circuit as a potential critical element in the formation of grid patterns (Burak and Fiete, 2009; Couey et al., 2013). In the present study, we designed experiments to test whether grid cells depend on local inhibitory interneurons and if they do, whether specific classes of interneurons are required. A pharmacogenetic approach was employed to silence specifically either parvalbumin (PV)-, somatostatin (SST)- or vasoactive intestinal polypeptide locus (VIP)-expressing interneurons during recording from spatially modulated MEC cells in freely moving mice. Three different Cre lines of transgenic mice were used - PV-Cre, SST-Cre and VIP-Cre. During surgery, each mouse was injected in MEC with Cre-dependent adenoassociated virus (AAV) expressing the pharmacologically selective designer Gi-protein-coupled muscarinic receptor hM4D (Armbruster et al., 2007). This led to selective expression of hM4D receptors in PV, SST or VIP interneurons. Subsequent i.p. injection of clozapine-N-oxide (CNO), a specific ligand of hM4D, caused selective inactivation of the respective interneuron subtypes. CNO caused a clear disruption of the hexagonal firing pattern in grid cells when the hM4D receptor was expressed specifically in PV-positive interneurons in the PV-Cre line. Spatial periodicity was reduced, and firing was dispersed across most of the recording environment. In sharp contrast to the PV-Cre line, there was no change in the grid pattern in SST-Cre mice. Firing rates increased after CNO in both mouse lines. VIP-Cre animals are currently being tested. The effect in the PV-Cre group was selective for grid cells; no changes in the spatial firing properties of border cells or the directional tuning of head direction cells could be detected. Taken together, these findings point to a unique role for PV-expressing interneurons in the local functional connectivity that enables formation of grid patterns in principal cells of the MEC.

Title: Disrupted spatial representation following knock-out of NMDA receptors in the medial entorhinal cortex

Authors: *N. DAGSLOTT, F. DONATO, Ø. A. HØYDAL, T. WAAGA, M.-B. MOSER, E. I. MOSER;
Kavli Inst. for Systems Neurosci. and Ctr. for Neural Computation, Norwegian Univ. of Sci. and Technol., Trondheim, Norway

Abstract: The medial entorhinal cortex (MEC) is a key element of the brain circuit responsible for spatial mapping of the local environment. An important component of this circuit is the network of grid cells, cells with hexagonally patterned firing fields that, together with head-direction and border cells in the same region, provide a dynamic representation of the animal's changing position in space. The characteristic hexagonal firing pattern of grid cells appears at a late stage of postnatal development (around postnatal day P28 in rats, Langston et al., 2010), suggesting that the grid-cell system is not hardwired at birth but matures in conjunction with the animal's first spatial experiences. However, the mechanisms underlying the development of grid cells and the possible contribution of synaptic plasticity have not been determined. To address these questions, we applied Cre-lox technology to specifically knock out (KO) the NR1 subunit of the N-methyl-D-aspartate (NMDA) receptor in MEC. Floxed NR1 mice were bilaterally injected with an adeno-associated viral (AAV) vector encoding for Cre recombinase, either at P1 or in adulthood, and then surgically implanted with electrodes for subsequent recording of neuronal activity in MEC during exploration of a familiar 1 x 1 meter open arena. Recording electrodes targeted layer II of dorsal MEC in all animals. A subset of the injected animals was used to verify KO of NMDA -receptors using *in vitro* patch clamp recordings. These recordings showed that the Cre-lox system reliably disrupted NMDA-currents in MEC cells. Grid-like firing in the open arena was consistently disrupted in KO mice injected with AAV-Cre at P1, while the control group (consisting of floxed NR1 animals injected with an AAV-vector encoding for a

control fluorophore) displayed normal hexagonally patterned fields. The effect of injections at adult age is currently under investigation. Taken together, these findings point to a critical role for NMDA receptor-dependent synaptic plasticity in the formation or maintenance of grid-like firing patterns in MEC cells.

Title: Stellate cells drive layer II microcircuit development in the medial entorhinal cortex

Authors: *F. DONATO, R. I. JACOBSEN, M.-B. MOSER, E. I. MOSER;
Kavli Inst. For Systems Neurosci., Trondheim, Norway

Abstract: The medial entorhinal cortex (MEC) contains the basic elements of the brain's representation of space. The most abundant cell type in this representation is the grid cell, which fires at the vertices of a periodic hexagonal array that covers the entire available environment. Since no external stimulus occurs with a grid-like pattern, it is thought that the periodic firing pattern of the grid cells is formed by network computations and, as such, should be influenced by local microcircuit connectivity. In support of this hypothesis, and unlike other spatially modulated cells, the regular firing of grid cells emerges at the end of a protracted period during postnatal development, which coincides with the structural and functional maturation of the layer II (LII) microcircuit. However, the mechanisms regulating LII network development and its possible influence on computation in grid cells are poorly understood. Here we investigate the structural maturation of the MEC network, looking at the interplay between excitatory neurons

(stellate and pyramidal cells) and fast-spiking interneurons. By systematic labeling of neuroblasts targeted by in-utero infection during neurogenesis, and quantitative analysis of maturation markers, we primed cohorts of neurons born in specific time windows ("isochronic cells") for further characterization and manipulation. MEC cells developed in a cell type-dependent manner. In stellate cells neurogenesis progressed topographically, with the earliest born cells located in the dorsal MEC and later born at progressively more ventral locations. A similar dorso-ventral gradient was not observed in pyramidal cells or interneurons. In contrast, all cells showed dorsal-to-ventral topography in maturation, but in pyramidal cells and fast-spiking interneurons, this topography was completely disrupted by chronic pharmacogenetic silencing of isochronic stellate cells during postnatal days P14-P20. Maturation of stellate cells was unaffected by such silencing, independently of birth date and dorso-ventral position of the inactivated cohort. The findings suggest that maturation of the MEC LII microcircuit is driven by excitatory activity in developing stellate cells. Local excitation is necessary for maturation of pyramidal cells and fast-spiking interneurons but not stellate cells. The topographical distribution of isochronic cohorts of stellate cells may set the pace for the dorsal-to-ventral topography of MEC maturation.

Abstract: In the medial entorhinal cortex (MEC), speed cells form a functionally distinct neuronal population, consisting of cells whose firing rates increase linearly as a function of locomotion speed. This speed signal is believed to be a key component for the dynamic update of grid cell activity. However, the origin of this speed signal has not been determined. Recently, several studies have reported speed-coding neurons in the mesencephalic locomotor region (MLR), an area where electrical stimulation has long been known to induce locomotion, but it remains unclear whether and how signals from these neurons reach the MEC. Here we combined classical anatomical tracing studies with chronic unit recording and optogenetics in freely moving rats to search for a putative speed circuit between the pedunculopontine tegmental nucleus (PPN), a functional component of the MLR, and the MEC. Simultaneous injections of a retrograde tracer in the MEC and an anterograde tracer in the PPN revealed strong overlap between labelled PPN axons and MEC-projecting cell bodies in the ventral medial septum and diagonal band of Broca (MS/DB). Chronic *in vivo* tetrode recordings during free foraging in an open field confirmed the presence of speed cells with linear speed-rate relationships at all three levels of the putative circuit - PPN, MS/DB, and MEC. Optogenetic stimulation of channelrhodopsin-2-expressing neurons in PPN was followed, at regular latencies, by activation of subsets of cells in MS/DB, and we are currently searching for similar responses in MEC to assess the possibility that speed cells in the three areas are synaptically connected. We are also currently investigating whether speed coding in PPN and MS/DB is prospective, as it is known to be in MEC, and as would be expected if the code is derived from ascending motor-efference signals. Taken together, the results raise the possibility that the PPN-MS/DB-MEC circuit mediates the coding of a speed signal with relevance for dynamic spatial mapping and navigation.

Abstract: The medial entorhinal cortex is the hub of a spatial representation system consisting of a variety of functional cell types - including grid cells, border cells and head direction cells - which each represent a specific element of the animal's current location. For activity to be translated from one group of active cells to another in a way that reflects the animal's movement in the environment, these cells must have access to information about the current speed of the animal. Speed-responsive cells have recently been shown to exist in the MEC circuit (Kropff et al., 2015). Here we show that almost half of the entorhinal speed-cell population has interneuron-like firing properties, such as narrow waveforms and high firing rates. More than 70% of all fast-spiking cells were speed cells, as was more than one-third of the hippocampus-projecting fast-spiking cells. Using GAD65-Cre, PV-Cre, SST-Cre, VIP-Cre, and CCK-Cre transgenic mice, in combination with local entorhinal injections of channelrhodopsin (ChR2)-expressing Cre-dependent adeno-associated virus (AAV), we are currently testing with an optogenetic tagging approach whether speed cells in MEC express markers for specific classes of interneurons.

Title: Development of grid cells requires only minimal experience with geometric boundaries

Authors: *I. U. KRUGE, T. WAAGA, T. WERNLE, E. I. MOSER, M.-B. MOSER; NTNU, Kavli Inst. For Systems Neurosci., Trondheim, Norway

Abstract: The medial entorhinal cortex (MEC) is a hub of a brain network for dynamic representation of location. MEC neurons are functionally specialized in the sense that different neurons encode different features of the animal's position within an environment. The most abundant cell type is the grid cell, which on open surfaces is characterized by periodic firing fields that form a triangular lattice across the entire environment visited by the animal. While most cell types of the MEC network express adult-like firing when rats are exposed to an open spatial environment for the first time a few days after eye opening, grid cells mature more slowly, over a two-week period after the animals leave the nest. Whether the slow emergence of grid patterns reflects a need for experience with salient spatial cues has not been determined, however. Here we show that grid cells can still be formed in rats that are raised for the first months of their life in opaque spherical environments, in the absence of stable reference boundaries that can be used for spatial orientation. In such animals, grid-like firing patterns are almost absent during the first trial in an environment outside the sphere, but grids emerge upon repeated exposure. In rats that are raised in a similarly opaque cube, with sharp vertical boundaries, cells express grid-like firing from the beginning. A mild disruption of grid formation was observed in rats with similarly prolonged exposure to spherical environments at adult age. Taken together, the results suggest that the periodic firing of a grid cell is determined primarily by intrinsic network dynamics, although a minimum of experience with geometric references, at young or adult age, is required for stable expression of grid patterns.

Title: Grid spacing is related to total distance traveled on non-planar surfaces

Authors: *A. H. BAHLE, E. I. MOSER, M.-B. MOSER;
Kavli institute for Systems Neurosci., Trondheim, Norway

Abstract: In the medial entorhinal cortex (MEC), grid cells represent environmental distances in the form of repeating firing fields and are thought to serve as a metric for navigation. On planar surfaces grid fields form an approximately evenly spaced, tessellating pattern, however it is not known how grid fields are organized on more complex, undulating terrain that is common in natural environments. Here we recorded from grid cells in freely moving rats as they foraged in a rectangular arena (2 x 1m), with either a flat floor or a floor with three evenly spaced hills. To accomplish this in the same recording arena, we covered the hills for a portion of the trials with a removable floor (see right part of figure). We found that the pattern of grid cells tended to contain more fields on the bumpy floor than the flat floor, consistent with its greater total surface area. Furthermore, the horizontal projections of the grid pattern on the hilly floor had decreased average grid spacing compared to the flat surface, which was partially recovered by using the total 3 dimensional distance between field centers. Preliminary analysis suggests that the decrease in spacing depends on the size of the grid. In animals in which we recorded grids from larger modules, the change in spacing was substantial and primarily due to a decrease in field distances along the length of the box. In animals with smaller grids (< 30cm), this effect was diminished or absent. Experiments are underway to distinguish whether these differences are consistent across animals. Together these observations raise the possibility that grids with different spacing encode distances in different ways, with at least some modules taking into account the total distance traveled on non-planar surfaces to estimate position in three dimensions.

Title: Grid phase and grid-field firing rates are not uniformly distributed across the environment

Authors: *Y. ROUDI[1], D. WENNBERG[2], Z. HUANG[2], B. DUNN[2], Ø. A. HOYDAL[2], M.-B. MOSER[2], E. MOSER[2];
[1]Kavli Inst. For Systems Neurosci., Trondheim, Norway; [2]Kavli Inst. for Systems Neurosci. and CNC, Norwegian Univ. of Sci. and Technol., Trondheim, Norway

Abstract: Grid cells in the medial entorhinal cortex of mammals form a hexagonal pattern that tessellates the space in which the animal navigates. There are however two key issues that are still unclear about the properties of grid cells with major impact on understanding how they can be used in navigation. First, it is unknown whether the different fields of a single grid cell are simple replicas of each other. If each field is simply a translation of another field, the code provided by a single grid cell about where the animal is in the space is ambiguous. This ambiguity will certainly decrease if there are stable field-to-field variations in, for instance, the firing rate of a grid cell. The second issue is if grid cells cover the space uniformly, namely, if at any position in space, the number of cells coding for that position is the same as at any other position. A uniform coverage, for which some evidence exists in the literature, is consistent with one of the major models of grid cells, the continuous attractor models. In fact, the uniformity of coverage is required for attractor networks as currently implemented to function at all. However, from a coding perspective it makes little sense to cover the space uniformly, allocating similar number of cells (that will lead to similar accuracy in representing the space) to behaviorally relevant positions versus others.
We assessed the differences in the firing rate of the various fields of grid cells, as well as the uniformity of the coverage, by analyzing a total of 562 grid cells from multisite tetrode recordings in five rats, and 48 grid cells recorded in a mouse using a microdrive of tetrodes All the data was recorded in familiar, square, open-field environments.
For each cell, we observed stable and reproducible variations in the firing rate of the cell across its fields, proving that each field is not simply a translation of another one. Regarding the uniformity of the spatial coverage, we found that the result depended on the modular structure of the grid cells. Of the ten modules with sufficiently many cells to perform a meaningful statistical test, there were six with small spacing and four with large. Evidence of lack of uniformity (clustering) was found in half of the modules.

Title: Integration of independently anchored grid maps in merged environments

Authors: *T. WERNLE[1,2], M. MORREAUNET[1], A. TREVES[3], E. I. MOSER[1], M.-B. MOSER[1];
[1]Kavli Inst. For Systems Neuroscience/Cnc, Trondheim, Norway; [2]Janelia Res. Campus, Ashburn, VA; [3]SISSA-Cognitive Neurosci., Triest, Italy

Abstract: In natural environments, local maps of grid cells and place cells are thought to be stitched together at salient landmarks. Each map may be anchored to different features of the environment but the mechanisms for generating transitions between differentially anchored spatial maps have not yet been established. To search for these mechanisms, we trained rats in two rectangular compartments A and B (each 1x2m) separated by a wall. Once two distinct grid maps were established, one for each environment, we removed the partition wall and allowed the rat to explore the merged open square box (2x2m). Exploration in the large environment was not accompanied by de novo grid formation. Instead, the original grid patterns of the rectangular boxes were largely retained, but with decreasing similarity along an axis from the outer walls towards the centre. Centrally in the box, where A and B environments merged, individual grid fields changed location, resulting in increased local spatial periodicity and the creation of local continuity between the two original maps. The grid pattern was rarely a simple extension of the A map or the B map. The reorganization of the grid maps was expressed already during the first exposure to the merged environment, suggesting that it takes place on a fast time scale. Grid cells of the same module responded coherently to the intervention, more than grid cells from different modules, suggesting that the reorganization was modular. Taken together, the data suggest that when environments are merged, differentially anchored grid maps fuse very rapidly, with reorganization of the grid field locations in the centre, in a direction that causes local periodicity to be established throughout the environment.

Title: Postsynaptic targets of inputs to the lateral entorhinal cortex.

Authors: *T. P. DOAN, E. S. NILSEN, M. P. WITTER;
Kavli institute for Systems Neuroscience, Ctr. for Neural Computation, Norwegian Univ. of Sci. and Technol., Trondheim, Norway

Abstract: The entorhinal cortex (EC) constitutes the main cortical gateway to the hippocampal formation. EC comprises two divisions, the lateral (LEC) and medial entorhinal cortex (MEC), which are functionally different. While neurons in MEC code information relevant for spatial navigation, neurons in LEC code for objects and their position in the environment. In the present study, we aimed to characterize the postsynaptic targets of inputs in LEC from perirhinal cortex (PER), piriform cortex (PIR) and MEC. We first injected anterograde tracers in mice to study the distribution of projections from these areas, showing that axons from all three regions distribute in superficial layers of LEC. Second, we injected adeno-associated virus (AAV) carrying channelrhodopsin (ChR2) either in MEC or in PIR. We subsequently performed patch clamp recordings from superficial LEC neurons in acute semi-coronal brain slices, optimized to maintain PER to LEC connectivity, while optogenetically stimulating the AAV labeled fibers and activating PER with a bipolar electrode. We recorded from 43 superficial principal neurons, identified by their biophysical features. Neurons responded to laser stimulation of AAV labeled PIR axons (N=10), to electrical stimulation of PER (N=21), or to both electrical stimulation of PER and laser stimulation of axons from MEC (N=4) or PIR (N=8). We are currently identifying the recorded principal neurons morphologically and immunochemically. Our results indicate that superficial principal neurons in LEC likely receive convergent information. * *T.P.D. and E.S.N. contributed equally to this study*

Title: Medial entorhinal cortex layer III pyramidal cells form dendritic bundles in a grid-like hexagonal pattern and receive specific inputs from the presubiculum

Authors: N. HENN-MIKE[1], M. KECSKÉS[1], Z. KRABÓTH[1], H. SEBESTYÉN[1], *C. VARGA[2,1];
[1]Szentagothai Res. Ctr., Pecs, Hungary; [2]Physiol., Univ. of Pecs, Pecs, Hungary

Abstract: The direct, monosynaptic input from the entorhinal cortex to the CA1-CA3 place cells arrives mostly from layerIII entorhinal cortical pyramidal cells, which are conveying spatial and non-spatial information as well. A particularly interesting spatial information generated in the medial entorhinal cortex is the so called grid-cell firing. How this geometrically aligned firing pattern arises is still a continuous debate. One entorhinal cortex specific cytoarchitectonic feature is the patch-like islands in layerII, which has been recently theorized to play a major role in forming grid-cell firing. This patchy structure of layerII, however, do not appear in deeper cortical layers where grid cells are also present. Therefore, we investigated the layerII-III cells dendritic and somatic alignment. Recent studies suggested that only the layerII calbindin positive cells form patchy structures in the MEC and the apical dendrites of deeper cortical layer located pyramidal cells fill up the space around these patches as a "matrix". We found that the cell bodies of both layerII and III principal cells are relatively homogeneously aligned, however, the dendrites of both the layerII calbindin positive pyramidal cells and the layerIII pyramidal cells form well defined dendritic clusters which are aligned in a patch-like structure. With the help of light, electronmicroscopical and super-resolution microscopy we also revealed that these patches of layerIII apical dendrites receive excitatory inputs from the presubiculum. The presubical axons largely prefer the spines of layerIII pyramidal cells over the layerII calbindin positive pyramidal cells. Importantly, presubiculum conveys both head-directional and grid-cell firing information, therefore we suggest that the grid-cell firing in layerIII might be formed in a parallel manner with the layerII grid-cells.

Title: Structural development and dorsoventral maturation of the medial entorhinal cortex

Authors: *S. RAY, M. BRECHT;
Bernstein Ctr. For Computat. Neurosci., Berlin, Germany

Abstract: We investigated the structural development of superficial-layers of medial entorhinal cortex and parasubiculum in rats. The grid-layout and cholinergic innervation of calbindin-positive pyramidal cells in layer 2 emerged around birth while reelin-positive stellate cells were scattered throughout development. Layer 3 and parasubiculum neurons had a transient calbindin-expression, which declined with age. Early postnatally, layer 2 pyramidal but not stellate cells co-localized with doublecortin - a marker of immature neurons. This suggested delayed functional maturation of pyramidal cells compared to stellate cells and mirrored the dichotomy of functional maturation of grid and border cells respectively. Three observations indicated a dorsal to ventral maturation of entorhinal cortex and parasubiculum: (i) calbindin-expression in layer-3 neurons decreased progressively from dorsal to ventral, (ii) doublecortin in layer-2 calbindin-positive patches disappeared dorsally before ventrally, and (iii) wolframin expression emerged earlier in dorsal than ventral parasubiculum. The early appearance of calbindin pyramidal grid organization in layer 2 indicates that this pattern is instructed by genetic information rather than experience. Superficial layer microcircuits mature earlier in dorsal entorhinal cortex, where smaller spatial scales are represented while microcircuits in the ventral entorhinal cortex - representing larger spatial-scales - mature later around the onset of spatial exploratory behavior.

Title: Interaction of self-motion and vision in the entorhinal cortex

Authors: *M. G. CAMPBELL, C. S. MALLORY, L. M. GIOCOMO;
Stanford Univ., Stanford, CA

Abstract: To form stable estimates of location, the brain must combine input regarding sensory landmarks with input regarding the animal's motion relative to these landmarks. The velocity estimate could derive from many sources, including locomotor, vestibular, and optic flow cues. To probe the relative contributions of different classes of inputs to spatial coding in the medial entorhinal cortex (MEC), we compared entorhinal activity in mice between open arenas and head-fixed virtual reality. Grid, as well as other entorhinal, cells were tuned to multiple positions on the virtual linear track. Gain manipulations, which put self-motion and visual cues in conflict, revealed that grid cells were influenced by self-motion cues more strongly than any other cell type. Speed cells maintained their tuning on the virtual track, though with an average decrease in slope that quantitatively matched the expansion of grid cell spacing in VR, and responded to gain manipulations in a manner consistent with grid cell responses. During gain manipulations, grid cells, speed cells, and theta were driven more strongly by self-motion during decreases in gain than increases in gain, suggesting that the relative strength of self-motion and visual inputs to speed estimates may be contextually dependent. Despite the importance of self-motion cues to grid cells and subsets of other MEC neurons, all cell types were sensitive to the presence of visual landmarks on the track, showing pronounced reductions in stability when landmarks were removed, even when optic flow cues were still available. These data indicate that a subset of the MEC population, including most grid cells, estimates position by integrating self-motion signals over time, but that this estimate rapidly degrades in the complete absence of environmental landmarks.

Title: Understanding principles of encoding navigationally-relevant variables in medial entorhinal cortex

Authors: *K. HARDCASTLE[1], N. MAHESWARANATHAN[1], S. GANGULI[2], L. M. GIOCOMO[1];
[1]Neurobio., [2]Applied Physics, Stanford Univ., Palo Alto, CA

Abstract: In order to survive, animals must maintain an internal representation of their current location and movement. Superficial medial entorhinal cortex (sMEC) likely supports this representation, as sMEC neurons have been shown to modulate their activity with the animal's position, head direction, or running speed. However, the conventional tuning curve-based methods that are typically used to characterize a cell's coding properties fail to describe >50% of recorded cells, indicating that these heuristics may only reveal the tip of the iceberg of sMEC coding properties. To gain an unbiased understanding of sMEC encoding properties, we employed a statistical model-based approach in which we fit a series of nested generalized linear models (GLMs) containing various combinations of position, head direction, and speed information. We then used principled hierarchical probabilistic model selection methods to detect which variables each cell encodes.
Our method reveals that classical metrics miss several important features of entorhinal coding. First, we detect more navigationally-relevant neurons: of 794 neurons recorded from mice during open field navigation, we find that 72% encode at least one variable, while classical metrics detect only 45%. Second, we observe increased conjunctive encoding: the model-based method reports that 37% of cells encode multiple variables, while classical methods report 6%. Third, we observe a striking degree of heterogeneity across the population: we see a wide range of tuning

curves, no evidence of a relationship between the variables a cell encodes and the tuning curve it exhibits, and little structure in the degree to which a cell differentially encodes these variables. Why might sMEC exhibit high levels of conjunctive coding and heterogeneity? First, previous information theoretic analyses suggest that conjunctive cells are advantageous when sensory inputs vary rapidly (Finkelstein et al., COSYNE, 2015). Consistent with this, we find that the fraction of conjunctive cells increases with running speed, with some cells adaptively gaining features under faster speeds. Second, through simulated population-level recordings, we find that the number of linearly independent neural activity patterns increases with the degree of conjunctive coding and heterogeneity. Importantly, this is advantageous for operations like robust pattern separation in dentate gyrus.
Combined, our methods successfully confront MEC heterogeneity, uncover adaptive behavioral-state dependent changes in its coding properties, and show that MEC exhibits characteristics that are specifically advantageous for downstream decoding.

Title: Entorhinal HCN1 sets the scale of spatial maps and enables rapid place learning

Authors: *C. S. MALLORY, J. BANT, K. HARDCASTLE, L. GIOCOMO;
Neurobio., Stanford Univ., Stanford, CA

Abstract: Medial entorhinal cortex (MEC) grid cells fire at regular spatial intervals and project to the hippocampus, where place cells are active in restricted locations. Germline deletion of forebrain HCN1 channels increases both grid and place cell spatial scales, pointing to HCN1-dependent ion channel kinetics as crucial for setting the scale of spatial representations. However, the mechanism of these effects, and the precise role of HCN1 in spatial memory remain unknown. We addressed these questions by specifically reducing HCN1 in the MEC of adult mice. First, we find that grid scale expands, demonstrating that the influence of HCN1 on

grid scale is not confined to developmental window. Strikingly, CA1 place field size also increases, despite the preservation of speed, head direction, and border cells, suggesting that changes in grid scale may directly influence the scale of place representations. This expansion is strongest in place fields located within the center of the environment, where grid cell, rather than border cell, input may have a stronger influence on place cell properties. Finally, we probed the impact of increased spatial scale on learning and memory. In HCN1 knockdown mice we observed normal reference memory on the Barnes and Morris Water Maze tasks, but impaired rapid place learning on a delayed match to place task. Ongoing experiments will help reveal whether this selective impairment results from an inability to encode orthogonal spatial locations within a single spatial context. Together, our data point to HCN1-dependent membrane biophysics as major contributors to grid scale, and suggest that HCN1-driven grid scale expansion results in expanded CA1 place fields and impaired spatial memory.

Title: Entorhinal border cells can convey environmental deformations to grid and place fields

Authors: *A. T. KEINATH[1], R. A. EPSTEIN[1], V. BALASUBRAMANIAN[2];
[1]Psychology, [2]Physics, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Spatial representations in the hippocampus and entorhinal cortex are systematically affected by deformations of environmental geometry. When a familiar environment is deformed, the firing fields of large-scale entorhinal grid cells stretch to match the deformation, while the fields of small-scale grid cells remain unchanged. Similarly, the firing fields of hippocampal place cells stretch, bifurcate, or disappear as the environment is progressively deformed. The origin of these stereotyped responses is not yet known. We propose a mechanism that involves input from entorhinal border cells which are active only near particular environmental boundaries, and stretch to continue covering that boundary when it is elongated. To test our proposal we constructed a model of the interaction between grid cells, place cells and border

cells and asked whether input from entorhinal border cells alone might be sufficient to account for the diverse influences of environmental deformations on grid and place cells. Specifically, we modeled multiple grid cell modules, each corresponding to a different spatial scale, as separate attractor networks (Burak & Fiete, 2009), elaborated to include additional input from border cells. Although initially random, connections from border to grid cells were tuned via competitive Hebbian learning during simulated exploration of the environment. Similarly and simultaneously, place cells were developed from initially random grid and border cell inputs tuned via competitive Hebbian learning during simulated exploration (Pilly & Grossberg, 2012). To test the model, we first simulated grid and place cell responses to parametric deformations of a familiar open field environment. We observed changes in the firing properties of simulated grid and place cells matching the responses of recorded grid (Stensola, et al., 2012) and place cells (O'Keefe & Burgess, 1996). Exploring further, we found that parametric compressions of a familiar linear track resulted in simulated place cell responses which closely mirrored the responses of recorded place cells (Gothard, et al., 1996). Lastly, we develop novel predictions of the model by characterizing the response of the network to simulated lesions. Together, these results demonstrate that input from border cells can account for the influence of environmental deformations on grid and place fields.

Title: Local transformations of entorhinal grid maps

Authors: *J. KRUPIC, M. BAUZA, S. BURTON, J. O'KEEFE;
CDB, Univ. Col. London, London, United Kingdom

Abstract: Entorhinal grid cells have multiple fields distributed across the entire environment arranged in hexagonal symmetry in the circular and square enclosures commonly used in most laboratories. The hexagonal symmetry and seeming invariance of the grid cell firing pattern has

suggested that they represent the internal universal metric of space. Previously we have shown that grid cells become more elliptical and non-homogeneous in more polarized environments such as trapezoids. Here we further demonstrate how local changes of the geometry of the environment induce local transformations of the grid patterns. Local transformations were also observed in co-recorded place cells supporting the idea of a major role for place cells in determining grid cell properties or a substantial interaction between the two.

Title: Visual landmarks sharpen grid cell metric and confer context specificity to neurons of the medial entorhinal cortex

Authors: *J. A. PÉREZ-ESCOBAR, O. KORNIENKO, P. LATUSKE, L. KOHLER, K. ALLEN;
Dept. of Clin. Neurobio., Med. Fac. of Heidelberg Univ. and DKFZ, Heidelberg, Germany

Abstract: Spatial representations provided by neurons of the medial entorhinal cortex (MEC) are essential for navigation. Within this network, the firing fields of grid cells act as a metric element for position. The location of the grid firing fields is controlled by interactions between self-motion cues, geometrical properties of the environment and nonmetric contextual information. Here, we test whether and how visual information, including nonmetric contextual cues, regulates the firing rate of MEC neurons. Removal of visual landmarks caused an impairment in grid cell periodicity. In addition, speed cells changed their firing rate in darkness and the activity of border cells was less confined to environmental boundaries. The firing rate of approximately half of MEC neurons was changed in darkness. Finally, manipulations of nonmetric visual cues in a 1D environment caused rate changes in grid cells. These findings reveal context specificity in the rate code of MEC neurons.

Title: Mixed mode oscillations determine the periodicity of networks in the medial entorhinal cortex

Authors: A. NERU, *C. G. ASSISI;
Indian Inst. of Sci. Educ. and Res. Pune, Pune, India

Abstract: Stellate cells are the most populous principal cell type in the medial entorhinal cortex (MEC). These neurons possess conductances that endow them with mixed mode oscillations, that is, sub-threshold oscillations coexist with periodic spiking. In this study we examine the role of mixed mode oscillations on the collective dynamics of the network. In MEC networks, stellate cells interact with each other, primarily, via an inhibitory intermediary. In a model network of stellate cells coupled via inhibitory interneurons, we demonstrate a novel mechanism of switching where individual stellate cells either exhibit mixed mode oscillations or bursts of spikes. Stellate cells switch from one mode to the other due to a rebound from inhibition induced by the inhibitory interneurons. The timing of the switch is effectively regulated by sub-threshold oscillations generated by stellate cells that are in turn determined by the intrinsic properties of stellate neurons. These properties, in particular, the h-conductance and the inhibitory drive to the network, vary systematically along the dorso-ventral axis of the MEC and have been shown to play a role in determining the spatial periodicity of grid cell firing fields. We vary these parameters in our model network and show that the periodicity of spike bursts generated by stellate cells and the sequential ordering of bursts between cells change in a manner consistent with that seen along the dorso-ventral axis of the MEC.

Title: A hybrid code from grid and place cells

Authors: *D. SCHWARTZ, O. O. KOYLUOGLU;
Electrical and Computer Engin., Univ. of Arizona, Tucson, AZ

Abstract: Place cells in the hippocampus are active when an animal visits a certain location (referred to as the place field) within an environment, and remain silent otherwise. Grid cells in the medial entorhinal cortex (mEC) respond at multiple locations, where the firing fields exhibit a hexagonally symmetric periodic pattern. Both cell types have a dorso-ventral organization with larger firing fields distributed towards the ventral end. In addition, grid cells are clustered within discrete modules, wherein cells share scale and rotational phase, but differ in spatial phase offset. The joint activity of grid and place cell populations, as a function of location, forms a neural code for space.

Different neural networks are constructed by varying the numbers of cells, grid modules, and grid scaling ratios. An ensemble of codes, for a given set of parameters, is generated by randomly selecting grid cell phases and place cell tuning curves. For each code in the ensemble, codewords are generated by stimulating a network with a discrete set of locations. The resulting code's resilience to neural noise is measured by the minimum pairwise distance between codewords, d. A larger d implies a more noise tolerant representation of space. Normalized code rank, on the other hand, measures dimensionality of the code space. Code rate, the number of locations represented per neuron, measures resolution of location.

This hybrid code has the following properties: For a fixed number of place cells, grid cell parameters may be chosen to produce a code with nearly any desired rank. For a fixed set of grid cell population parameters, increasing the number of place cells increases rank to a maximum, after which, inclusion of additional place cells lowers rank. For a fixed code rate, there is a sharp tradeoff between rank and d, i.e. maximizing either minimizes the other, and lower rates yield more desirable tradeoffs. There is a similar tradeoff between d and code rate. These findings hold for any scaling ratio between consecutive grid modules, L. An intermediate value of L yields a better tradeoff between d and rate. Increasing the number of grid modules increases d, but does not impact rank.

Finally, these coding theoretic observations are revisited by measuring the performances of biologically realizable algorithms (e.g., winner take all) implemented by a network of place and

grid cell populations, as well as interneurons, which implement de-noising operations. Simulations demonstrate that de-noising mechanisms analyzed here can significantly reduce mean squared error (MSE) of location decoding. Furthermore, the modular organization of grid cells can be exploited to improve MSE.

Title: Investigating roles of medial entorhinal cortex stellate cells in path integration

Authors: *S. TENNANT, L. FISCHER, D. L. F. GARDEN, C. J. MCCLURE, G. SURMELI, I. DUGUID, M. NOLAN, E. R. WOOD;
Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: Storage and recall of spatial memories relies on accurate estimation of location. This can be achieved through use of landmarks or by path integration, which involves inference about location from direction and distance moved relative to a known start point. The extent to which animals can use path integration to solve spatial memory tasks is unclear and implementation of tasks that dissociate path integration from other strategies is challenging. The roles of specific cell types are also unknown. Within the hippocampal-entorhinal circuit, place, grid, head direction and border cells encode information that can be used to estimate location. The extent to which these cell types contribute to path integration or other strategies for solving spatial tasks is still unclear. To investigate these issues, we developed a spatial memory task for mice, which uses virtual reality to generate sensitive measures of an animal's ability to path integrate. In this task mice are trained to locate a reward zone marked with a visual cue within a 2-meter long virtual linear track. Use of path integration strategies can be tested in trials in which the reward zone is unmarked. We show that in this task male and female wild-type mice can locate the reward zone using either proximal cues or a path integration strategy. To assess whether self-motion derived motor information or visual feedback is used for path integration we manipulated the translation between physical and virtual movement. These manipulations revealed mice use self-motion information to locate the reward zone on path integration trials. To test roles of identified cell types in the task we injected adeno-associated virus expressing the light chain of

tetanus toxin, conditionally in the presence of Cre, into the medial entorhinal cortex of mice expressing Cre specifically in stellate cells in layer 2. We show that this manipulation abolishes synaptic output from stellate cells and interferes with performance of the spatial task. Our data establish a novel behavioural test for spatial learning in which roles of landmark cues and path integration can be dissociated. We provide evidence that stellate cells in the medial entorhinal cortex are required for successful performance of this task.

Title: On the role of input-specific perturbations of medial septal projections to the grid cell network

Authors: M. E. LEPPERØD[1], M. B. WIGESTRAND[2], M. M. FREY[2], K. K. LENSJØ[2], *G. T. EINEVOLL[3], T. SOLSTAD[4], M. FYHN[2], T. HAFTING[1];
[1]Inst. of Basic Med. Sci., Oslo, Norway; [2]Ctr. for Integrative Neuroplasticity, Oslo, Norway; [3]Norwegian Univ. Life Sci., Aas, Norway; [4]Fac. of Teacher and Interpreter Educ., Trondheim, Norway

Abstract: The mechanisms underlying the spatial firing pattern of grid cells in medial entorhinal cortex (MEC) are still not fully understood. Pharmacological inactivation of medial septum (MS) disrupts both the spatial firing pattern of grid cells and theta oscillations in local field potential (LFP) in the MEC (Koenig et al., 2011; Brandon et al., 2011). The disruption of the grid cell pattern could potentially be caused by indirect effects from MS inactivation associated with the hippocampus, as hippocampal inactivation also disrupt grid cell firing (Bonnevie et al. 2013). In the majority of grid cells, spiking activity shows a striking relation to LFP theta oscillations, suggesting that theta oscillations are closely related to the grid pattern. In contrast, grid cells in bats lack this relationship in grid cell activity, indicating the grid cell spatial representation to be dissociated from theta oscillations. To better understand these opposing views it is imperative to understand the effects of a selective manipulation of MS projections to the MEC. The aim of the present work was to assess the function of MS projections to the MEC in a combined

computational and experimental study.
Septal input projections to the MEC in adult Long Evans rats were optogenetically manipulated. Manipulations in behaving animals were directly assessed with chronically implanted tetrodes mounted on a microdrive. Grid cells displayed increased activity due to activation of MS projections to the MEC. During stimulation, theta modulation of grid cell firing was disturbed while the spatial firing pattern in a familiar environment remained stable. These preliminary results indicate that the spatial activity of grid cells is resilient to temporal alterations of the MS input and is not dependent on theta oscillations.
In order to further understand mechanisms of the grid cell network, we developed a model consisting of adaptive exponential integrate and fire (AdEx) neurons. We found a parameter regime where the AdEx model reproduces temporal dynamics of stellate cells consistent with experimental data e.g. resonance, sag, rebound spiking. Using these parameters, we constructed a sparsely connected network of 80 % excitatory neurons with recurrent interactions in inhibitory neurons. Preliminary results show that this network acts as an oscillator with its natural frequency in the theta band, indicating that large amplitude theta oscillations in MEC can be due to network resonance from oscillations in MS input.

Title: The role of extracellular matrix molecules for spatial representations in medial entorhinal cortex

Authors: *T. HAFTING-FYHN[1], C. CHRISTENSEN[1], M. E. LEPPERØD[1], K. K. LENSJØ[2], M. FYHN[2];
[1]Inst. of Basic Med. Sci., Univ. of Oslo, Oslo, Norway; [2]Univ. of Oslo, Centre for Integrative Neuroplasticity, Norway

Abstract: The medial entorhinal cortex (MEC) is central in a distributed network of the brain's navigational system. Grid cells in MEC show a remarkable repetitive firing pattern providing stable spatial representations. Grid cells are connected through a network of fast-spiking

parvalbumin (PV+) expressing inhibitory neurons suggesting that this network of inhibition may contribute to the firing pattern of grid cells. The PV+ cells in the adult brain are enwrapped by specialized extracellular matrix molecules called perineuronal nets (PNNs). Emerging evidence suggests that perineuronal nets stabilize synaptic connections and restrict plasticity in the adult brain. Indeed, experimental disruption of PNNs has been shown to induce high degrees of plasticity in several brain regions of adult animals. The MEC shows dense expression of PNNs but their role for the grid cell network or spatial processing remains elusive.In the present study, we investigated how enzymatic degradation of PNNs affects spatial representations in the MEC of adult Long Evans rats. In contrast to neocortex where PNNs mainly surround PV+ neurons, PNNs enwrap a more diverse population of neurons in MEC accounting for 70% of PV+ neurons and a fraction of reelin positive and and some calbindin positive neurons. Histological examinations revealed that PNNs mature at a postnatal age similar to when grid cell activity has been reported. To investigate the role of PNNs for spatial representations in MEC, bilateral injections of the enzyme chondroitinase ABC in the dorsolateral band of MEC were used to disintegrate the PNNs. The animals were implanted with tetrodes in MEC and single unit activity and local field potentials were recorded from rats exploring open fields (1x1m). To compare stored representations and the encoding of novel maps where plasticity is required, the same units were recorded on repeated trials in a familiar environment and in a similar box in a novel room. There were clear effects of PNN removal on spatial representations and unit activity. In the familiar room, grid cells from treated animals had increased average firing rates but reduced spatial information while putative inhibitory units showed decreased activity. When placed in a novel environment, grid cells from treated animals showed a dramatic reduction in gridness scores a lower spatial correlation throughout the recording session compared to grid cells from control animals. Together, these results indicate a role for the PNNs for stable spatial representations of MEC in adult animals.

Title: Sequential synaptic innervation of interneurons and principal cells along axons in medial entorhinal cortex

Authors: *H. SCHMIDT[1,2], K. BOERGENS[2], Y. HUA[2], J. STRAEHLE[2], M. BRECHT[1], M. HELMSTAEDTER[2];
[1]BCCN, Humboldt Univ. Berlin, Berlin, Germany; [2]Max Planck Inst. for Brain Res., Frankfurt am Main, Germany

Abstract: The precise delineation of synaptic contact patterns is typically done by ultrastructural methods in very small tissue samples; larger scale connectivity patterns are then extrapolated from such data. As a consequence we have good understanding about the overall statistics of neural connectivity, but we know little about synaptic connectivity of individual axons, which extend through large tissue samples. Here, we use large-scale EM-based circuit reconstruction in the rat medial entorhinal cortex, the site of grid-like spatial representations, to delineate the connectivity of individual axons. We find that medial entorhinal cortex axons sequentially innervate inhibitory neurons, followed by excitatory targets. This axonal synapse sorting is substantial, allows for significant temporal delay generation, reflects high synaptic target specificity, and its magnitude is unique when compared to circuits from mouse primary somatosensory cortex. This data suggests that highly ordered synaptic wiring may be a neural mechanism for both sequence generation and analysis in a part of the cortex widely known for its precise temporal discharge patterns.

Title: What modulates memory for emotional stimuli? Considering the effects of the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic nervous system

Authors: *K. R. MICKLEY STEINMETZ, K. S. ARJUNE;
Psychology, Wofford Col., Spartanburg, SC

Abstract: High arousal states first engage the fast-acting sympathetic nervous system, and subsequently engage the hypothalamic-pituitary-adrenal (HPA) axis, stimulating cortisol release. These two arousal-modulated systems may influence cognition in a complex manner. To investigate this, participants encoded scenes that included either a high-arousal, neutral, or moderate-arousal object placed on a neutral background. Forty-eight hours later participants underwent either a stressor or a control condition and recognition memory was assessed for objects separately from the backgrounds. Heart rate was measured during the stressor as a metric of sympathetic response and cortisol samples were taken throughout the experiment as a measure of HPA response. Elevations in cortisol at retrieval were associated with impaired memory for objects, but not backgrounds. Increased heart rate was associated with impaired memory for both items and backgrounds. These findings suggest that sympathetic and HPA response in reaction to stress differentially impact memory for items and backgrounds.

Title: Endogenous Brain Stimulation through EMG: investigation using intracranial EEG and volume conductor modeling

Authors: *L. D. J. FIEDERER[1], J. LAHR[1], J. VORWERK[2], F. LUCKA[3], C. H. WOLTERS[2], A. SCHULZE-BONHAGE[1], T. BALL[1];

Abstract: Chewing has been shown to have effects on various aspects of cognition, on time scales from minutes [1] to years [2]. These effects have previously been attributed to increased arousal, metabolism, blood flow, somatosensory processing, as well as to shared resources and to reduced stress. We hypothesize that the effects of chewing on cognition, at least partly, arise from the modulation of brain activity by the electric fields (EF) generated by the chewing muscles. Previously, EF induced by exogenous brain stimulation or neuronal activity have been shown to have measurable effects above a critical amplitude threshold of approx. 0.2 V/m [3,4].
To verify our hypothesis we quantified the EF amplitudes reaching the brain during chewing. We present results obtained intracranially in epilepsy patients undergoing pre-neurosurgical evaluation and extrapolate these to healthy subjects using finite element method (FEM) head modeling and non-invasive electroencephalography measurements. Five epilepsy patients and 3 healthy subjects were analyzed. The amplitudes of the muscle activity reaching cortex during the single chew events (CE) was used to calibrate our FEM model. Skull defects and silicone sheets of the implantation were modeled to ensure an accurate calibration. Single CE EF gradients were then simulated for the whole brain, removing skull defects and silicone sheets from the model to approximate a healthy subject. Finally, the single CE EF were scaled by the ratio of the non-invasive amplitudes of the chewing activity of healthy subjects and patients. As several analysis parameters strongly influenced the results, a comprehensive range of parameters was tested to find a conservative set.
Using these conservative parameters, our results show that during chewing gum and licorice 25% and 80% of CE produced cortical fields exceeding the critical threshold of 0.2 V/m, respectively. Peak EF amplitudes occurred at the temporal pole and extended along the anterior temporal lobe. Furthermore, we observed that chewing repetition rate and the frequency profile of the muscle activity both matched brain stimulation parameters described in the literature.
We conclude that the cortical EF caused by gum chewing could be strong enough to modulate ongoing neural activity in the cerebral cortex and might thus influence cognitive performance. Further investigations using direct measurements of intracranial EF gradients with hippocampal and skull base electrodes are in progress.

Title: Objective assessment of mental demand in expert pilots during varying degrees of task difficulty

Authors: *K. JAQUESS[1], L.-C. LO[1], H. OH[1], Y. TAN[1], J. C. RIETSCHEL[2], M. W. MILLER[3], R. J. GENTILI[1], B. D. HATFIELD[1];
[1]Kinesiology, Univ. of Maryland, Col. Park, College Park, MD; [2]Veteran's Admin., Baltimore, MD; [3]Auburn Univ., Auburn, AL

Abstract: The overarching purpose of the study was to extract and quantify multiple biomarkers that are sensitive to mental demands imposed on a highly skilled individual performing an ecologically-valid cognitive-motor task. Nineteen experienced pilots from the US Navy and US Air Force performed a series of tasks of varying nominal difficulty (easy, medium, & hard) using a computer-based flight simulator while EEG, eye-tracking, ECG, self-report, and performance data was collected. Self-reports of task demand revealed a positive relationship with task difficulty while objective performance displayed a negative relationship with difficulty. Overall, psychophysiological measures also revealed expected results. Theta band power had a positive relationship with difficulty, while both alpha band power and P3a amplitudes decreased with increasing difficulty. Blink rate decreased with increasing task difficulty while gaze patterns also indicated an increase in difficulty. Steps are currently underway to combine these various sources of information in order to identify robust a network of biomarkers via machine learning techniques that could be utilized as a "workload metric". Such a metric may potentially be used to infer the state of a performer in real-time and would be useful is a variety of real-world environments.

Title: Behavioral oscillations during working memory maintenance

Authors: *J. LIU, T. LIU, S. RAVIZZA;
Dept. of Psychology, Michigan State Univ., East Lansing, MI

Abstract: Persistent neural activity in the absence of external stimuli has been argued to reflect working memory (WM) maintenance (D'Esposito & Postle, 2015). However, recent evidence suggests that sustained activity might not be necessary for maintaining representations in WM (LaRocque et al., 2013). Instead, computational modeling based on neuronal firing patterns suggested that multi-item WM is manifested by sporadic and coordinated bursts among cell assemblies (Lundqvist et al., 2016). Furthermore, a human magnetoencephalography study identified a theta-coupled periodic reactivation of maintained information underlying the retention of one item in WM (Fuentemilla et al., 2010). Though converging evidence from neurophysiological recordings has unveiled the role of neuronal oscillations in WM maintenance, direct behavioral evidence is still lacking. To investigate the possibility that selective attention could sample multiple mental representations rhythmically, we measured recall precision performance on two simultaneously presented oriented gratings at varying intervals (0.2-1.8s in steps of 50ms) after a cue that indicated the probability of each grating being probed (retrocue). This manipulation also allowed us to assess the ability to modulate potential oscillations by cue validity (100%/0, 60%/40%, 50%/ 50%). Our preliminary results revealed dynamic oscillatory patterns in all three retrocue conditions. We found peak frequencies for 100% valid and 50% valid/invalid cues in the range of theta frequency band (4-8Hz). However, 60% valid/invalid cue condition induced higher peak frequencies. These findings provided the direct behavioral evidence for the oscillation underlying WM maintenance, and revealed the impact of reliability cue on this dynamic pattern.

Title: Affective content and episodic memory recall: Repetition suppression for aversive stimuli, but repetition enhancement for appetitive stimuli

Authors: Z. YAKER[1], K. RAMASESHAN[1], P. SOLOFF[2], *V. A. DIWADKAR[1];
[1]Psychiatry & Behavioral Neurosci., Wayne State Univ. SOM, Detroit, MI; [2]Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Background: Exposure to a repetitive stimulus results in a change in behavioral response to that stimulus that is associated with a change in the brain's neural response (Horner and Henson, 2008). Re-exposure to a stimulus can result in suppression or enhancement of the brain's neural response, in what are known as repetition suppression and repetition enhancement (Segaert et al., 2013). Re-exposure is a facet of episodic memory when judgments must be made about whether current stimuli were previously seen/experienced or not. Yet the effects of stimulus valence on suppression or enhancement during episodic recall have not been well studied. We used fMRI to study functional responses during re-exposure to aversive or appetitive stimuli in the context of episodic memory.
Methods: Fifteen healthy participants underwent fMRI (3.0 T Siemens Trio) during which subjects performed a stimulus-driven episodic memory task using emotionally contextual images from the International Affective Pictures System (IAPS). Images were presented in a mixed block-event related design, with alternating encoding and retrieval epochs (6 images, 27 s each for old vs. new judgment), with a period of rest between each epoch (9 s) (Soloff et al., 2015). fMRI data were processed using standardized methods (SPM8). Events (aversive or appetitive scenes) were modeled using time and dispersion derivatives for both encoding and retrieval. fMRI responses to Targets (i.e., scenes present in both encoding and retrieval) were estimated. In second level random effects analyses, directional contrasts, Enc [Aversive] vs. Ret [Aversive] or Enc [Appetitive] vs. Ret [Appetitive] were employed to assess patterns of repetition suppression or enhancement ($p<.05$, cluster level).
Results: Suppression of fMRI responses during retrieval was associated primarily with aversive stimuli, in areas including the prefrontal cortex, medial temporal cortex, and primary visual cortex. By comparison, enhancement of fMRI responses during retrieval was associated primarily with appetitive stimuli, in areas including the orbitofrontal cortex, posterior cingulate cortex, and visual cortex.

Discussion: These results provide fMRI evidence of enhanced hemodynamic response to rewarding vs aversive stimuli in the context of episodic memory, implying a correlation between valence and episodic recall. The healthy brain appears able to suppress negative or aversive memories, but primed to enhance positive or rewarding memories. These findings provide a basis for further studies pertaining to disorders of memory and emotion, particularly in the context of stress and trauma.

Title: Activation in mesolimbic reward circuitries facilitates implicit memory consolidation in musical listening

Authors: *K. KATO[1], S. TSUCHIMOTO[2], D. NISHIDA[3,4], H. EBATA[3], J. USHIBA[2]; [1]Dept. of Rehabil. Medicine, Keio Univ. Sch. of Med., Tokyo, Japan

Abstract: In every daily life, we are unconsciously consolidating external events as memory function. Music has also a stimulating effect to be implicitly consolidated to the human memory system dependent on their emotional states. However, the underlying neural substrates for consolidating the musical memory largely remain unclear. To tackle this, we investigated the whole-brain hemodynamic responses associated with memorizing unheard music using the 1.5 Tesla functional magnetic resonance imaging (fMRI). Sixteen healthy participants, who preferably listen to “foreign popular music” around 1-3 hours per day, were selected in this study. In the fMRI scan, they listened to 32 60-s unheard musical clips selected from their preferences based on a musical recommendation software. In this experiments, we did not explain to them that they should memorize each musical clip. After 1 week, however, we graded musical memory by means of 4 rank questionnaire to evaluate whether the participants remembered the previously heard musical clips with their confidence levels (i.e. heard with high confidence, heard with low confidence, unheard with low confidence, or unheard with high confidence). Whole-brain analysis of hemodynamic activities with fMRI during the 60-s listening period of memorized music excerpts with high confidence level showed the increased activity in the nucleus accumbens, caudate, and hippocampus, which are the key regions in

reward-related mesolimbic circuits ($p<0.001$, (uncorrected)). These results suggest that the increased activities among mesolimbic reward circuitries induced by musical listening lead to implicitly consolidate new experiences in musical listening as memories.

Title: Visual working memory benefits from luminance inputs - evidence from psychophysics and EEG.

Authors: *M. KOSILO[1], J. MARTINOVIC[2], C. HAENSCHEL[1];
[1]Dept. of Psychology, City Univ. London, London, United Kingdom; [2]Univ. of Aberdeen, Aberdeen, United Kingdom

Abstract: Working memory (WM) is the ability to encode and temporarily maintain information. There is some evidence that early perceptual processes make an important contribution to successful WM performance. However, perceptual contributions to WM are not yet fully understood. In a series of experiments we investigated whether stimuli specifically designed to engage luminance or the cone-opponent chromatic mechanisms in the visual system would differentially influence WM performance.
In the first psychophysical experiment, 16 participants performed a delayed match-to-sample task, with one, two or three abstract shapes presented one at a time, followed by a delay and finally a memory probe. We created three classes of shapes designed to stimulate luminance mechanism (L+M), or two isoluminant, chromatic mechanisms (L-M and S(L-M)). Using a staircase procedure, we obtained WM thresholds by measuring the level of contrast at which the stimuli were memorized with 75% accuracy for three levels of WM load for each stimulus class.
In a second experiment (N=19), the same delayed match-to-sample task was used, however stimulus intensity was fixed at a suprathreshold level based on a baseline measurement of discrimination thresholds. We recorded event-related potentials (ERPs) to investigate changes in neural signature during WM encoding in response to the different classes of visual stimuli.
We predicted that encoding of luminance-defined shapes would lead to lower WM thresholds and better behavioural performance.
Experiment 1 showed that contrast thresholds increased for all three classes of stimuli with the

increase in WM load. However, threshold increases with increments in load in response to luminance stimuli remained lower than those for chromatic stimuli. Results of the ERP experiment showed that luminance-defined shapes resulted in higher WM accuracy and faster reaction times. This benefit was mostly evident at higher WM loads. ERP responses during encoding for luminance-defined stimuli showed that the early visual component P1 was modulated by working memory load. P1 amplitude also correlated with behavioural performance.
Results from these experiments point to the importance of early encoding processes in working memory. In particular, we demonstrated that luminance signals provide an advantage over chromatic signals in working memory processing. This advantage is reflected in both behavioural and neural responses.

Title: Selective maintenance mechanisms of seen and unseen sensory features in the human brain

Authors: *J. KING;
New York Univ., New York, NY

Abstract: Recent studies of "unconscious working memory" have challenged the notion that only visible stimuli can be actively maintained over time. In the present study, we investigated the neural dynamics of subliminal maintenance using multivariate pattern analyses of magnetoencephalography recordings (MEG). Subjects were presented with a masked Gabor patch whose angle had to be briefly memorized. We show with an unprecedented level of precision, that irrelevant sensory features of contrast, frequency and phase are only encoded transiently. Conversely, the relevant feature of angle is encoded and maintained in a distributed and dynamically changing manner throughout the brief retention period. Furthermore, although the visibility of the stimulus correlates with an amplification of late neural codes, we show that

unseen stimuli can be partially maintained in the corresponding neural assemblies. Together, these results invalidate several predictions of current neuronal theories of visual awareness and suggest that visual perception relies on a long sequence of neural assemblies that repeatedly recode and maintain task-relevant features at multiple levels of processing, even under invisible conditions.

Title: Competition and forgetting during context-based episodic memory retrieval

Authors: M. HOLLENBECK[1], *J. A. LEWIS-PEACOCK[2,3];
[1]Dept. of Computer Sci., [2]Dept. of Psychology, [3]Imaging Res. Ctr., Univ. of Texas at Austin, Austin, TX

Abstract: Does shared encoding context for items in episodic memory increase the likelihood that those items will compete and get weakened when the context is reinstated during memory retrieval? Recent memory models suggest that retrieval uses contextual information as a "spotlight" for probing memories during recall (Polyn et al., 2009). These models predict that greater overlap of features between a memory probe and the memory trace enable easier access and reactivation of the target (Eich, 1985). A consequence of context-based memory retrieval is that related items bound to the same context may also reactivate and compete with the selection of the target memory, leading to retrieval-induced forgetting of the competing memories (Anderson et al., 2000). Neural network modeling has proposed oscillating feedback inhibition as the mechanism underlying the weakening of competing memories (Norman et al., 2007). This model predicts a non-monotonic relationship between the strength of neural activation of a memory and its subsequent accessibility. In particular, memories that activate to a moderate degree are susceptible to weakening and subsequent forgetting. Here, we hypothesize that retrieval-induced forgetting will be more likely for contextually similar competitors. We developed an fMRI experiment in which participants first encoded objects presented in triplets over a background scene image that was unique for each triplet. They were instructed to create mental associations between the consecutive objects and their corresponding scene. Later, the background scenes were presented as retrieval cues, followed by temporal order cues (1^{st}, 2^{nd}, or 3^{rd} object), to bias episodic retrieval toward a particular object and to establish the other objects from that context as competitors. The experiment ended with a surprise recognition memory test for all studied objects. We predict that competitor objects that reactivate to a moderate degree (vs. strongly or not at all) will be more susceptible to weakening and subsequent forgetting. Representational similarity analysis of fMRI data in ventral temporal cortex was used to identify object-specific representations and track their reactivation during the cued retrieval task. Preliminary data suggest there is a non-monotonic relationship between reactivation strength and recognition performance: competitors with the highest reactivation (corresponding to “moderate” activation relative to more strongly reactivated targets) were associated with lower subsequent memory performance. These results suggest that incidental reactivation of contextually related memories during retrieval can trigger forgetting.

Title: Complex waves in the human cortex during memory encoding and retrieval

Authors: *V. SREEKUMAR[1], A. JANG[2], J. WITTIG, Jr[2], S. INATI[3], K. ZAGHLOUL[2]; [1]Functional and Restorative Neurosurg. Unit, [2]Dept. of Functional and Restorative Neurosurg., [3]Office of the Clin. Director, NINDS/NIH, Bethesda, MD

Abstract: Recent studies have quantified the emergent spatiotemporal patterns of population neuronal activity in the primate cortex during rest. Here, we draw upon the physics of wave propagation to characterize the spatiotemporal organization of activity in the human cortex during memory encoding and retrieval. Specifically, we examined local field potential (LFP) signals captured from microelectrode arrays (10x10, 400um spacing) implanted on the cortical surface of the middle temporal gyrus in four patients with medically refractory epilepsy. Patients engaged in a paired associates task, and we examined the instantaneous power and phase of bandpass filtered LFP signals at each electrode during encoding and retrieval trials. We calculated phase velocity fields to capture changes in the spatial organization of activity across time. Using dynamical systems methods to assess stability, we identified and characterized the emergence of different types of propagating complex waves during successful encoding and retrieval. Although we found node, spiral, and saddle point wave activity, the majority of complex waves that were identified using an automatic classifier were unstable saddle points. Plane waves and synchronized activity comprised the remaining classified patterns of activity.

Title: Neural oscillations during conditional associative learning

Authors: *A. CLARKE, B. M. ROBERTS, C. RANGANATH;
Univ. of California Davis, Davis, CA

Abstract: Adaptive behavior relies on the ability to learn arbitrary associations. Such associative learning depends on a distributed network across the medial temporal lobes, frontal and parietal lobes, that show linear changes that scale with how well associations have been learned (Law et al., 2005). Work in animals points to a crucial role of theta and beta oscillations during associative learning (Rutishauser et al., 2010; Hargreaves et al., 2012), but we know little about how human neural oscillations change during the learning and retrieval of associations in memory. Here, we address this issue by relating oscillatory activity to measures of learning arbitrary visuo-motor associations. We recorded EEG while participants performed the task, where they learned 48 associations where each of the 48 images could be associated with one of 4 button presses. On each trial, an abstract image was displayed (cue period) before a blank delay period. Participants were then prompted to select one of 4 buttons, after which feedback was provided to indicate whether the response was correct or incorrect. Learning of the 48 associations occurred across 12 repetitions of each image. Results from a final testing session showed that participants learned the majority of associations (mean accuracy 90%). Trial-wise learning (or "memory strength") was quantified using a state-space model of learning to estimate the probability of a correct response on a given trial (Smith et al., 2004). We performed two complementary analyses that related memory strength to neural oscillations, (1) Linear modelling between power and memory strength, and (2) pattern similarity analysis of oscillatory power across learning. First, using linear models we related memory strength to oscillatory power while controlling for the effects of experiment time, reaction time and reaction time on the previous trial. During the cue period, bilateral parietal electrodes showed a significant positive relationship between alpha/low-beta power and memory strength. During the delay period, frontal midline electrodes showed a significant negative relationship between theta power and memory strength. Second, multivariate analysis of spatial activity patterns revealed that, over the course of learning, the presentation of each association elicited increasingly distinct patterns of theta and alpha/low-beta activity. Our results show that theta and alpha/beta oscillations across

frontal and parietal sites track associative learning, and that the topography of these oscillations could track the differentiation of neural representations over the course of learning.

Title: Posterior parietal cortex contributions to mnemonic decisions are independent of action intention

Authors: *S. A. GAGNON[1], A. M. GORDON[1], A. D. WAGNER[1,2];
[1]Dept. of Psychology, [2]Neurosci. Program, Stanford Univ., Stanford, CA

Abstract: Episodic memory experiments typically observe an "old/new" effect in the medial temporal lobe and fronto-parietal regions, including left intraparietal sulcus (IPS). Over the past decade researchers have proposed several hypotheses to account for IPS activity during retrieval, including top-down attentional processes, accumulation of mnemonic evidence, or the conversion of mnemonic evidence to action outcomes. However, in the majority of previous studies responses were indicated with manual button presses; this raises the possibility that left IPS effects are specific to the transformation of mnemonic signals into manual motor responses. To examine the nature of IPS activity during mnemonic decision-making, the present experiment required participants to make recognition decisions while varying the effector system used to implement responses. First, participants studied a series of words while making abstract/concrete judgments. Then, they entered the MR scanner and performed a recognition memory task. Critically, each run was split into miniblocks in which participants were prompted to respond with either their eyes (saccading to left/right targets; oculomotor) or hands (making button presses with left/right pointer fingers; manual). Prior to each run of this task, participants were instructed that old and new choices should be indicated with left and right (or right and left) responses respectively. After the recognition memory task, participants performed an effector (manual/oculomotor) response localizer task. ROI analyses revealed that effector-specific fronto-parietal regions (a) tracked the effector used to make mnemonic judgments, and (b) were

generally sensitive to decision processes (indexed by response time), although independent of the effector system used to implement the response. In addition, IPS regions tracked old/new status regardless of whether the effector system was manual or oculomotor, suggesting that IPS activity during retrieval is not selectively involved in the transformation of mnemonic evidence to actions. Finally, the IPS region sensitive to old/new status also tracked decision response time for both effectors, suggesting that resources engaged during retrieval may also be drawn upon in situations of decision uncertainty.

Title: Emergence of item-based contextual significance representations revealed by Bayesian model-based fMRI

Authors: *M. C. INHOFF[1], L. A. LIBBY[2], T. NOGUCHI[3], B. C. LOVE[3], C. RANGANATH[1]; [1]Psychology, [2]Ctr. for Neurosci., UC Davis, Davis, CA; [3]Univ. Col. London, London, United Kingdom

Abstract: Recent models of memory differentiate between neural representations of context and object information, positing that these aspects of memory are represented by separable brain regions. In practice, however, contextual information can be used to disambiguate the meaning and significance of objects (i.e. “contextual significance”). Despite this, little is known about how context-dependent information is incorporated into object representations. Given that the hippocampus and perirhinal cortex (PRc) are known to contribute to the learning of object-context associations, analyses targeted these regions of interest. Additionally, we identified a region of interest in orbitofrontal cortex (OFC), as this area is critical for making decisions about the significance of objects. Functional magnetic resonance imaging (fMRI) was used to measure activity in these areas as participants learned context-dependent information about the significance of 16 fully crossed pairs of 8 novel objects. During each learning trial, participants

saw a pair of sequentially presented objects, followed by one of two categorical outcomes (hat/glove). Half of the objects were always presented first in a pair (Cue 1), whereas the remaining objects were always presented second (Cue 2). During Cue 2 presentation, participants predicted the upcoming category outcome, and were subsequently given feedback on their choice. The experiment was designed such that no individual object, in and of itself, was predictive of any outcome, however each Cue 1-Cue 2 object sequence was 100% predictive of categorical outcome. Critically, this design also created subsets of objects that had equivalent information about possible cue pair-outcome associations ("contextual significance"). In order to model individual learning curves and fMRI data, a Bayesian computational model was employed. Preliminary fMRI analyses, guided by parameters derived from the Bayesian computational model, indicate that the hippocampus, PRc and OFC are involved in the building of object pair-outcome predictions as learning progresses, and that parameter estimates in these regions track behavioral generalization across objects with similar contextual significance.

Title: Effects of emotional anticipation on neural oscillations involved in context-guided prediction

Authors: *M. RITCHEY[1,2], M. J. GRUBER[1], A. S. DHILLON[1], G. M. O'DAY[1], C. RANGANATH[1];
[1]Ctr. for Neurosci., UC Davis, Davis, CA; [2]Boston Col., Chestnut Hill, MA

Abstract: In uncertain situations, a representation of ongoing context can be useful for predicting the likelihood of an emotionally salient event. Studies have suggested that neural oscillations might play a role in anticipatory states, but it is not clear whether or how these states may differ between emotional and neutral contexts. Accordingly, we used scalp EEG to investigate the neural dynamics of emotional anticipation during a context-guided prediction

task. We predicted that anticipation of emotionally salient events would affect neural oscillations previously linked to context maintenance and anticipation (e.g., in the theta and beta frequency bands). We also investigated whether these effects would be related to changes in learning of neutral information encountered in emotional contexts. To accomplish these goals, scalp EEG data were collected from healthy young adults while they completed a context-guided prediction task. Neutral objects were presented in one of three contexts and were preceded by a context-specific cue and 2.5 s delay period. In the emotional context, there was a 12.5% chance that the cue would be followed by an emotionally negative scene, rather than a neutral object. In the other "safe" contexts, the cue was followed by a neutral object or neutral scene, but never an emotional scene. Subsequent recognition memory for the objects was also tested. Time-frequency analyses focused on the delay period between the cue and item onset, during which time participants were expected to generate predictions about upcoming stimuli. Estimates of theta (4-7 Hz), alpha (8-12 Hz), and beta (13-30 Hz) power were obtained for each condition, and permutation tests were used to correct for multiple comparisons across channels and time-points. Relative to the safe contexts, the emotional context was associated with a significant decrease in widespread alpha and beta power during the anticipation/delay period. Beta power decreases during the delay also predicted subsequent forgetting of neutral objects on the recognition memory test. The present results support the idea that anticipation of emotional events is associated with changes in neural oscillations involved in context-guided prediction. Future analyses will use multivariate pattern analyses to determine whether oscillatory activity patterns carry information about emotional scenes during the delay period.

Title: Dissociating the content of a stimulus from the rule that allow us to remember this content

Authors: *R. QUENTIN[1], J.-R. KING[2], E. SALLARD[1], E. BUCH[1], N. FISHMAN[1], R. THOMPSON[1], L. G. COHEN[1];

Abstract: Working memory enables transient holding of information. It is required for learning, reasoning, updating information, and performing everyday visuomotor tasks. Intra-cortical recordings in nonhuman primates and fMRI studies in humans demonstrated the involvement of the frontal cortex during working memory. However, it is not known whether such frontal involvement reflects the encoding of information content itself or the rule allowing one to recall this content. Using a machine-learning algorithm (multivariate pattern analysis), it was recently reported that occipito-parietal BOLD fMRI signal and MEG signal successfully decodes visual input [1,2]. Disentangling the spatio-temporal encoding of memory content and memory processing would go a long way to address this question. We developed an original working memory task in which two visual stimuli with different orientation and spatial frequency were presented to the participant. After a short delay, a post-cue instruction indicated which visual feature (spatial frequency or orientation) of which stimulus (left or right) the participant had to remember. A group of 10 healthy adults performed with a high accuracy (83% correct response) this task inside a CTF-MEG system with 275 channels and the signal was recorded at 1200-Hz sampling. Three head position indicator coils were placed on the scalp of the participant and head position was measured at the beginning and at the end of each block. Eye movements were monitored during each trial to ensure correct central fixation. When participants broke the central fixation, they received an alert message on the screen and the trial was repeated in random position in the remaining trials. Multivariate pattern analysis showed first that both spatial frequency and orientation could be decoded from MEG early visual responses. In addition, we observed how trained classifiers generalized across time to get information on the dynamic representations of working memory states. Our results demonstrate that while visual spatial frequency and orientation (content) are simultaneously encoded, each one in a serial manner, information about the cue (rule) is encoded in a durable manner with a sustained representation over time.

Title: Oscillatory patterns associated with sequence learning

Authors: *J. CRIVELLI-DECKER, L.-T. HSIEH, A. CLARKE, C. RANGANATH;
Ctr. for Neurosci., UC Davis, Davis, CA

Abstract: Episodic memories are organized as sequences of events. Computational models suggest that neural oscillations play a role in the coding of temporal sequences, but the extent to which oscillations support sequence representation remains unclear. To address this question, we used scalp electroencephalography (EEG) to examine oscillatory activity over during learning of different object sequences. Participants made semantic decisions on each object as they were presented in a continuous stream. For three of the sequences, the order of the objects was always fixed. Activity during learned sequences was compared to a “Random” and a “Novel” sequence. Random sequences consisted of the same objects presented in a different order on each repetition, whereas Novel sequences consisted of trial-unique objects. Behavioral results showed that, over the course of learning, semantic judgments were faster for objects in learned sequences, as compared to objects in Random and Novel sequences. These findings indicate that, although participants were not required to recall sequence information during the semantic decision task, they used knowledge of learned sequences to optimize their decisions. EEG analyses revealed increased oscillatory power in the beta (13-27Hz) band and decreased power in the theta (4-8Hz) band for objects in learned sequences compared to objects in random sequences. These effects were most evident in late learning blocks, suggesting a role of beta and theta oscillations in representing structured order information over the course of sequence learning. Preliminary spatial pattern similarity analyses revealed increased pattern similarity in the theta band for objects in learned sequences compared to objects in random sequences. Further analyses will evaluate the contributions of spectral patterns in other frequency bands to sequence learning.

Title: Functional connectivity in human intracranial eeg during cued recall

Authors: *R. YAFFE, J. CHAPETON, S. INATI, K. ZAGHLOUL;
NINDS, Bethesda, MD

Abstract: We investigated functional connections in human intracranial EEG data during cued recall. Our approach capitalizes on an important feature of functional connections that mediate communication in the human brain. Whether through direct or indirect synaptic connections, changes in local field potential signals coordinated across regions, or even the propagation of electric fields, communication between brain regions must occur through a physical connection of some kind. Importantly, the constraints associated with any physical connection imply that the time required for communication should be well defined and preserved. Every time information is conveyed from one point to another, it should take approximately the same amount of time to do so. Hence, one plausible requirement for identifying a functional connection between brain regions is that the communication between them occurs with a consistent time delay.
Here, we investigate functional connections in iEEG recordings as patients with medically refractory epilepsy participate in a paired-associates verbal memory task. Using the temporal precision afforded by iEEG, we used time-lagged mutual information (MI) to identify functional connections in the human brain that exhibit a consistent and significant increase in MI with a specific time delay. Mutual information (MI) is attractive in that it captures all temporal relations between two brain regions, and is agnostic to the particular neural mechanism underlying how those regions are communicating. Each significant connection identified in this manner is therefore defined by its latency, its direction, and the consistency of its communication at that latency. We examine these identified functional connections, how these connections mediate communication during memory encoding, and how such communication is reinstated during retrieval. Our data provide novel insights into the network mechanisms that bind distributed patterns of neural activity during memory formation and retrieval.

Title: Forgetting emotional material in working memory

Authors: *E. MIZRAK, I. OZTEKIN;
Psychology, Koc Univ., Istanbul, Turkey

Abstract: Proactive interference (PI) - the tendency for previously acquired information to negatively impact memory performance for more recently learned information - is a major cause of forgetting. Although a large body of research has investigated the detrimental effects of PI on memory, most studies have focused on the experimental induction of non-affective PI. Recently, however, it has been shown that emotion slowed down the build up of PI while hindering the controlled processes that resolves it (Mızrak & Öztekin, 2015). Here, we tested the neural mechanisms that modulate the interaction between emotion and interference resolution in memory. We manipulated PI using the release from PI paradigm, in which study material from the same semantic category is presented for several consecutive trials, resulting in accumulation of PI in the retrieval context. We introduced emotional (i.e., disgust and fear) and neutral (i.e., kitchen utensils and furniture) categories and evaluated the build up and resolution of PI across emotional and neutral categories. Participants were scanned using functional Magnetic Resonance Imaging (fMRI) while performing a 5-item short term recognition task. Behavioral measurements showed that accumulation of PI reduced the recognition accuracy for neutral trials but not for emotion trials. In contrast, response times to emotion trials linearly increased as a function of PI. Neuroimaging results implicated the ventrolateral prefrontal cortex (VLPFC) to mediate successful resolution of PI. In addition, neural activation in amygdala and the hippocampus was associated with higher recognition accuracy to high PI emotion trials compared to high PI neutral trials. The data further implicated higher anterior VLPFC activation for high PI emotion compared to neutral trials, suggesting that resolving PI for emotional material was more effortful than neutral study material.

Title: Single-unit activity from the human middle temporal gyrus reflects successful associative memory encoding

Authors: *A. I. JANG, J. H. WITTIG, Jr., K. A. ZAGHLOUL;
NINDS, NIH, Bethesda, MD

Abstract: We captured single unit activity from microelectrode arrays in the middle temporal gyrus (MTG) of 5 participants with pharmacologically resistant epilepsy as they performed a verbal paired associates memory task. The microelectrode arrays (Blackrock Cereplex I; 96-electrodes) were implanted during routine surgical placement of intra-cranial electroencephalography (iEEG) contacts used to localize the seizure focus prior to surgical resection. During the paired associates task participants studied pairs of words presented sequentially on a laptop, and were later cued with one word from each pair and instructed to say the partner word out loud. Word pairs were on the screen for 4 seconds, and about 1 second before each pair an orientation cue ("+") was presented for 500 ms. Across five subjects, we recorded activity from a total of 9 sessions of the memory task, where the number of isolated units ranged from 17 to 121 per session. Mean recall accuracy during these sessions was 17±8%. We first examined the mean across-unit spike rate during the encoding period. On average, human MTG units had a lower spike rate during word-pairs that were subsequently remembered compared to those that were subsequently forgotten. This effect was predominant during the orientation cue and about 3 seconds after the word-pair was presented on the screen. Interestingly, we previously reported significant decreases in low-frequency power at these same time points when analyzing iEEG electrode responses over the MTG in a different cohort of patients performing the same task.
Despite seeing an overall trend in single unit activity, the activity patterns of individual units were largely heterogeneous. For example, some units showed decreased rates during the orientation cue of correctly remembered pairs, while others showed increased rates during the orientation cue on the same trials. We therefore used a population-level analysis to quantify the trial-by-trial consistency of the response from all units recorded at the same time. We found that on average, the ensemble response to word pairs that were subsequently remembered was more consistent than the ensemble response to word-pairs that were subsequently forgotten. This finding is in line with our previous report of a more consistent brain-wide distribution of iEEG

power when word pairs are successfully remembered versus those that are forgotten. Taken together, these preliminary findings from single units in the human MTG provide a deeper understanding of the neural mechanisms supporting an important human cognitive function.

Title: Effects of transcranial direct current stimulation (tDCS) on neural oscillations during episodic memory encoding and retrieval

Authors: *B. M. ROBERTS[1], S.-F. WANG[2], M. MONTCHAL[3], A. WADE[1], N. BOUFFARD[1], J. D. RAGLAND[1], C. CARTER[1], C. RANGANATH[1];

Abstract: Research on transcranial direct current stimulation (tDCS) has grown rapidly, but there is controversy regarding whether and how tDCS could impact memory performance. We report two studies that addressed this question by examining the effects of two types of tDCS on subsequent episodic memory performance and concomitant recordings of neural oscillations. In study 1, 20 minutes of anodal tDCS, or sham, was applied over the left DLPFC, and after stimulation, EEG was recorded while subjects performed an item and associative recognition task. Behavioral results indicate that associative memory performance was marginally higher during active tDCS as compared to sham stimulation ($p = 0.059$). Initial EEG analyses indicate that tDCS was associated with increased parietal theta power during both encoding and recognition of object pairs. In Study 2, we investigated the effects of oscillatory tDCS, in which anodal stimulation was amplitude-modulated at theta (5.5Hz) over the left DLPFC. Following stimulation, EEG was recorded as subjects performed a combined item and source recognition task. Behavioral results showed that tDCS had no significant effects on item recognition. Surprisingly, unlike anodal tDCS, oscillatory tDCS impaired source memory performance ($p=0.029$) relative to sham stimulation. Future EEG analyses will examine the relationships between the type of stimulation, oscillatory activity, and episodic memory performance.

Title: How are temporal and cognitive contexts represented by hippocampal subfields?

Authors: *H. ZUCKER[1], M. E. MONTCHAL[2], S.-F. WANG[3], L. A. LIBBY[1], C. RANGANATH[1];
[1]UC Davis Ctr. for Neurosci., Davis, CA; [2]Neurosci., Univ. of California, Irvine, Irvine, CA; [3]Neurosci., Stanford, Palo Alto, CA

Abstract: Although there is general agreement that the hippocampus binds item and context information, little is known about the relative roles of hippocampal subfields (CA1, CA23DG) in representation of different contextual attributes. Here, we used high-resolution fMRI to investigate how hippocampal subfields support representations of incidentally retrieved cognitive and temporal context information. Participants studied visual objects divided into eight lists (temporal context) while making one of four semantic judgments (cognitive context). During high-resolution ($1.5mm^3$ voxels) fMRI scanning, participants made memory judgments on objects and also indicated if they could retrieve their associated temporal and/or cognitive context. We performed voxel pattern similarity analyses to investigate how hippocampal subfields carried information about retrieved temporal and cognitive context . When temporal context was correctly retrieved, voxel pattern similarity carried information about the list in which an object was studied at encoding (temporal context). During successful recollection of cognitive context, voxel patterns carried information about the encoding question (cognitive context). This preliminary evidence supports theories of hippocampal involvement in context reinstatement and suggests that subregions of the hippocampus may differentially bind concurrent temporal and cognitive contextual elements.

Title: Context-dependent decision-making: hippocampal-cortical interactions

Authors: *L. A. LIBBY, N. R. BOUFFARD, C. RANGANATH;
Ctr. for Neurosci., UC Davis, Davis, CA

Abstract: The context in which an event takes place can be used to generate predictions about future events in order to guide adaptive decision-making. However, little is known about the neural underpinnings of context-dependent predictions and decisions in humans. In the current fMRI study, we tested the hypothesis that context-dependent decision-making is associated with functional interactions between a posterior-medial cortico-hippocampal network (the PM system) and regions in prefrontal cortex (PFC). Outside of the scanner, participants learned about eight different food items within four grocery store contexts. For each food item, participants predicted whether a customer would “like” or “dislike” the item, and were then presented with the outcome (a happy face or a disgust face) along with feedback on their prediction accuracy. For half of the food items (context dependent (Cd) condition), outcome was deterministically linked to the store context (p(“like”) = 1 or 0); every item was liked in two stores and disliked in two stores, for an overall “like” rate of 0.5. For the other half of food items (context independent (Ci) condition), outcome was probabilistic (p(“like”) = 0.75 or 0.25) and consistent across every store. The following day, during fMRI scanning, participants again made binary outcome predictions (“like”/”dislike”) about the same set of stores and foods (prediction phase). Next, pairs of food items were presented simultaneously within a store, and participants selected the item that was most likely to be “liked” (choice phase). In both Cd and Ci conditions, prediction phase performance significantly predicted choice phase performance, suggesting that learned context-item-outcome relations generalized to guide decisions. Within each phase, however, performance on Cd trials was not significantly correlated with Ci performance, suggesting the independence of Cd and Ci representations. Preliminary fMRI results suggest differential engagement of the PM system between Cd and Ci trials, and planned analyses will evaluate

multivoxel pattern information in and functional connectivity between PM and PFC regions during context-dependent decision-making.

Title: Human temporal pole mediates attention-based enhancement of memory: a lesion, intracranial EEG, and single-unit study

Authors: *J. H. WITTIG, JR, A. JANG, J. COCJIN, S. INATI, K. ZAGHLOUL; NINDS, Bethesda, MD

Abstract: Humans can remember words that are seen or heard even if barely paying attention, but memory is better when attention is focused. This is true whether attention is focused proactively, before a word is seen, or retroactively, soon after that word has disappeared from sight. fMRI studies have revealed similar activation patterns during proactive and retroactive attention-enhanced memorization, suggesting they share a common neural mechanism. We recently hypothesized that the human temporal pole supports proactive attention-enhanced memorization based on intracranial electroencephalography (iEEG) signals that predicted successful memorization of a to-be-presented stimulus (Haque et al 2015). Here we test the hypothesis on 15 participants implanted with iEEG electrodes to localize epileptic seizure focus prior to surgical resection. Participants viewed lists of serially presented words on a computer screen, and were asked to remember just those words that were immediately preceded or followed by a visual cue. Recognition memory of both cued and non-cued words was assessed about 30 seconds later. Performance satisfied three criteria: cued word performance was significantly better than non-cued word performance; performance on proactive and retroactive cued words was indistinguishable; and non-cued word performance was significantly better than chance. We tested the hypothesis that the human temporal pole supports attention-enhanced memorization using 3 approaches: (1) we compared behavioral performance before and after the temporal pole was resected in 6 participants and found a significant decrease relative to matched controls, (2) we examined iEEG signals in this brain area in 15 participants and found a significant decrease in high-frequency power during the proactive, but not retroactive, attention

cue, and (3) we examined spiking responses of 234 single units in the middle temporal gyrus of 5 participants with microelectrodes (Cereplex I Utah Array) and found significant changes in spike rate during proactive attention, and to a lesser extent, retroactive attention. Single units that encoded proactive attention with a sustained change in spike rate often also encoded retroactive attention, whereas neurons that transiently encoded proactive attention showed no consistent response to retroactive attention. Results from all three approaches support the hypothesis that the human temporal pole mediates proactive attention-enhanced memorization, and to a lesser extent, retroactive enhancement. Our data provide insight into the neural mechanisms that differentiate proactive and retroactive attention-enhanced memorization.

Title: Neural correlates of reality filtering in psychosis

Authors: *R. THÉZÉ[1], A. L. MANUEL[1], F. CHANTRAINE[2], L. NAHUM[1], L. CURTIS[2], A. G. GUGGISBERG[1], A. SCHNIDER[1];
[1]Clin. Neurosciences, [2]Mental health and psychiatry, Univ. Hosp. of Geneva (HUG), Geneva, Switzerland

Abstract: Psychosis is a disorder characterized with symptoms of hallucinations and delusions, which reflect a difficulty to distinguishing things not pertaining to reality. Orbitofrontal (OFC) lesions may also induce a confusion of reality, as evidenced by patients acting upon their confabulations and by disorientation. A surrogate marker of this disorder has been a continuous recognition task with repeated runs, each being composed of the same set of pictures but arranged in different order, in which subjects had to indicate picture repetitions only within the ongoing run. Confabulating patients had an increased rate of false positive as from the second run, indicating that they failed to suppress the interference of currently irrelevant memories. Healthy subjects, when correctly processing a stimulus as new within the repeated runs, displayed a distinct positive frontal evoked potential at 200-300 ms. We refer to this memory and thought control mechanism as “orbitofrontal reality filtering” (ORFi). In this study we explored

whether the reality confusion in psychosis was also characterized with disturbed ORFi. We recorded high-density electroencephalography from 9 patients with mild to moderate psychosis (measured with the Brief Psychiatric Rating Scale, ver. 4) and 10 age-matched healthy controls at rest and while they performed the continuous recognition task. The level of hallucinations correlated with the number of false positives in the second run of the continuous recognition task. Successful treatment of newly presented stimuli of the second run induced a positive frontal potential at 250-300 ms in both groups, as previously observed in healthy subjects. Inverse solutions localized this activity, which was stronger in patients, to the OFC. Electrical potentials of patients then differed at 350-400 ms, when first run repetitions evoked a specific positivity previously suggested to represent a "feeling-of-rightness". Again at 400-600 ms, where new and repeated stimuli were differently processed in controls, the distinction became unclear in patients. Resting state functional connectivity also revealed coherence differences between groups. Patients had higher alpha coherence in right primary auditory and insular area, but lower gamma coherence in OFC. Both measures were inversely correlated with levels of hallucination. These findings indicate that patients with mild-to-moderate psychosis may generate the early orbitofrontal signal associated with reality filtering but that subsequent stimulus processing is abnormal. These processing differences may reflect differences in underlying resting-state connectivity.

Title: Neural representation of value space

Authors: *N. DE HAAS[1], S. THEVES[1], A. NITSCH[2], B. EPPINGER[2], N. W. SCHUCK[3], C. F. DOELLER[1];

[1]Donders Institute, Radboud Univ., Nijmegen, Netherlands; [2]Tech. Univ., Dresden, Germany; [3]Princeton Univ., Princeton, NJ

Abstract: The hippocampal formation (HF) is the key region involved in spatial navigation and in representing the geometry of spatial environments. One major question is whether the HF also supports geometrical computations in non-spatial domains. Here we aim to test the idea that the HF processes value in a geometric fashion, representing distances between objects in a 2D "value space", akin to representation of spatial distances between locations. To this end, we combined high-resolution fMRI with a two-armed bandit task. In the experiment participants learned associations between every-day objects and two choice-dependent outcomes (outcome A and outcome B). Each object can therefore be represented in two ways: ether by jointly representing the value of both outcomes in a "2D value space" or by representing the mean value associated with this object in a "1D mean value space". Results from a behavioural experiment (n=50) showed that even though participants are not aware of any spatial structure while making decisions, our participants formed robust associations between the objects and the values on both axes in value space, as reflected in participants' choices. Before and after the decision task, we presented all objects in randomized order and recorded fMRI data (data acquisition ongoing). This allows us to detect changes of across-voxel pattern similarity for the different types of object pairs as a function of distances in 2D value space and 1D mean value space. We hypothesized that distances in 1D mean value space are processed in prefrontal areas known to process value (especially the orbitofrontal cortex), whereas distances in 2D value space are encoded in the HF. Specifically, following the learning experience object pairs with low distances in value space should show higher neural similarity than object pairs with higher distances in value space, consistent with the recent finding that objects with lower 2D spatial distance in a virtual environment are associated with increased neural similarity (Deuker et al., in prep). This study can help us to elucidate if geometrical computations in the HF support the formation of value space in the service of efficient decision making.

Title: False memory for spatial location activates contralateral visual regions within 400 to 800 milliseconds

Authors: *J. M. KARANIAN[1], S. D. SLOTNICK[2];
[1]Psychology, [2]Boston Col., Chestnut Hill, MA

Abstract: True memory for spatial location reactivates contralateral regions of the visual cortex, which is thought to reflect the constructive nature of memory. In a recent functional magnetic resonance imaging (fMRI) study, we demonstrated that false memory for spatial location was also associated with activity in contralateral early and late visual regions (Karanian & Slotnick, submitted). Given the low temporal resolution of fMRI, the timing of such contralateral false memory activity is still unknown, which is critical to our understanding of false memory construction. In the present event-related potential (ERP) study, we assessed whether false memory activity in contralateral visual regions initially occurred within the 400 to 800 millisecond epoch, which is thought to reflect detailed recollection, or initially occurred within the 1000 to 1600 millisecond epoch, which is thought to reflect post-retrieval monitoring. During encoding, abstract shapes were presented in either the left visual field or the right field during central fixation. During retrieval, abstract shapes were presented at fixation and participants classified each shape as previously in the "left" or "right" visual field. False memories were defined as "left" responses to items previously presented in the right visual field and "right" responses to items previously presented in the left visual field. Preliminary analyses revealed that false memories for the "left" spatial location initially produced activity in right/contralateral visual regions within the 400 to 800 millisecond epoch and this contralateral activity continued into the 1000 to 1600 millisecond epoch. Similarly, false memories for the "right" spatial location initially produced activity in the left/contralateral visual regions within the 400 to 800 millisecond epoch and this contralateral activity continued into the 1000 to 1600 millisecond epoch. The present results demonstrate that false memory effects in contralateral visual regions initially occur in a relatively early time period that is thought to reflect conscious recollection, as opposed to the post-retrieval monitoring period. Such evidence suggests that relatively rapid processing in early visual regions plays a critical role in the construction of detailed false memories for spatial location.

Title: Human genomic signatures of brain oscillations during memory encoding

Authors: *S. BERTO[1], G.-Z. WANG[2], J. W. GERMI[2], B. LEGA[2], G. KONOPKA[2];
[1]Neurosci., [2]UT Southwestern Med. Ctr., Dallas, TX

Abstract: Memory encoding is an essential step for all learning. However, the genetic and molecular mechanisms underlying human memory encoding remain poorly understood, and how these mechanisms give rise to specific patterns of brain oscillations observed during memory encoding is completely unknown. Here, we directly compare intracranial EEG recordings from the neocortex in individuals performing an episodic memory task with human gene expression from the same areas. We identify genes correlated with oscillatory memory effects across six frequency bands. These genes are enriched for preferential expression in neurons, in particular genes encoding synaptic proteins and ion channels, supporting the idea that the genes regulating voltage gradients are involved in the modulation of oscillatory patterns during successful memory encoding across brain areas. These data are the first to identify correlations between gene expression and active human brain states as well as provide a molecular window into memory encoding oscillations in the human brain.

Title: Stimulus-specific memory representations in lateral parietal cortex

Authors: *S. E. FAVILA[1], N. M. LONG[2], B. A. KUHL[2];
[1]Dept. of Psychology, New York Univ., New York, NY; [2]Dept. of Psychology, Univ. of Oregon, Eugene, OR

Abstract: Neural activity patterns that reflect stimulus features during perception are reactivated when that stimulus is retrieved from memory. For example, reactivation of high-level visual category information has frequently been observed in ventral temporal cortex. However, several recent studies indicate that reactivation of event-specific information occurs in lateral parietal cortex. At present, there still remains ambiguity regarding the nature of reactivated representations in lateral parietal cortex and how these representations relate to those in high- and low-level visual cortex. To address this question, we first sought to compare activity patterns in occipital, ventral temporal, and lateral parietal areas across perception and retrieval. Second, we sought to test whether retrieval goals differentially influence stimulus representations reactivated in occipital and parietal cortex. In two separate studies, we asked human subjects to learn word-image associations for 32 unique object stimuli that varied in color and object category membership. After learning the word-image pairs, subjects from Experiment 1 performed two different tasks while undergoing fMRI scanning: perception and cued retrieval. During perception runs, subjects viewed the images (without word cues) while performing an orthogonal target detection task. During retrieval runs, subjects were presented with word cues and recalled the corresponding images. Multivariate pattern analysis showed that, in visual regions, feature sensitivity (sensitivity to colors and object categories) during perception was reinstated at retrieval. Additionally, comparison of neural activity patterns across perception and retrieval revealed item-specific reinstatement within posterior IPS and angular gyrus. Moreover, reinstated item-level patterns in parietal cortex could be predicted from feature-level patterns in visual cortex (independently measured during perception), suggesting a role for parietal cortex in combining visual feature information during memory retrieval. Experiment 2 was similar in structure to Experiment 1, but during retrieval runs subjects were alternately instructed to retrieve either the color or the object category of the cued stimulus. This allowed us to assess the relative sensitivity of reactivation in parietal and occipital cortices to top-down retrieval goals.

Title: Sign language activates different neurocognitive systems during verbal learning between deaf and hearing signers

Authors: *Y. KANAZAWA[1,2], H. YAMAZAKI[1], T. ISHII[2], T. ASO[2], K. OMORI[1], K. NAKAMURA[2];
[1]Otolaryngology, Head and Neck Surgery, [2]Human Brain Res. Ctr., Kyoto Grad. Sch. of Med., Kyoto City, Japan

Abstract: Background: For deaf people, sign language is an essential medium for social interaction and plays a critical role in verbal learning. In particular, language development in those people should rely on the verbal short term memory (STM) via sign language. Most previous studies compared neural activations between sign language processing in deaf signers and spoken language processing in hearing participants. However, it remains unclear (1) how the cross-modal conversion of visual inputs into verbal STM occurs in deaf brains, and (2) whether deaf and hearing signers rely on different neural components in verbal learning. In this study, we examined fMRI activation in deaf and hearing signers using an identical memory span task which would engage verbal STM equally for both groups. **Materials and Methods:** Six deaf signers and 13 hearing signers participated in the present study. On each trial, participants were instructed to memorize a non-word (4-7 syllables in length) presented with fingerspelling and keep the item for 12 seconds. They were then presented with the identical non-word or one-syllable different non-word from the learned item, and decided whether the pair of non-words were the same or different. Echo-planer imaging data were acquired using a Siemens Trio 3 T head scanner with the following parameters: TR = 1.0 s, TE = 30 ms, flip angle = 60°, FOV = 192 mm × 192 mm, multiband acceleration factor = 3, voxel size 3 × 3 × 3 mm, 48 axial slices. Imaging data analysis was performed using SPM8. **Results:** Behavioral analysis revealed that deaf and hearing signers relied on visual and phonological memory, respectively. At the neural level, verbal maintenance broadly activated the left hemisphere language network, including inferior frontal gyrus, supplementary motor area, and inferior parietal lobule in both groups. Interestingly, however, deaf signers more engaged left middle occipital lobule (MOL) and fusiform gyrus (FG) whereas hearing signers more engaged left inferior parietal lobule (IPL) and ventral premotor area (PMv). **Discussion:** We found that the identical verbal STM task using sign language activates different neural systems between deaf and hearing signers. Specifically,

deaf signers relied more on the left MOL and FG, i.e., higher-order visual association cortex, probably reflecting a top-down activation of the visual memory, whereas hearing signers recruited the left IPL and PMv, reflecting their greater reliance on the phonological memory. These findings suggest that deafness influences development of neurocognitive basis for verbal learning and provide novel imaging data to establish an effective verbal learning program for deaf children.

Title: Brain-electrical differences in encoding and delay phases of processing during maintenance and manipulation of information in working memory

Authors: *T. V. ROMÁN-LÓPEZ[1], J. A. FRANCO-RODRÍGUEZ[1], S. A. CISNEROS-LUNA[1], M. MÉNDEZ-DÍAZ[2], O. PROSPÉRO-GARCÍA[2], A. E. RUIZ-CONTRERAS[1]; [1]Lab. Neurogenomica Cognitiva, Fac. Psicologia, UNAM, D.F., Mexico; [2]Lab. de Canabinoides, Depto. Fisiología, Fac. Medicina, UNAM, D.F., Mexico

Abstract: Working memory is defined as the maintenance (Mt) and manipulation of information (Mp) in a goal-directed behavior. Mt involves keeping in mind the information of the stimulus when it is no longer available in the environment, whereas Mp involves the reorganization of the information that is currently maintained. The aim of this study was to evaluate the brain electrical activity, by means of event-related potentials (ERPs), along encoding and delay phases of working memory. Mt and Mp were measured in two independent conditions (Mt vs Mp) in a Delayed Match-to-Sample Task. The Mt condition involves keeping in mind two features, (color and shape) of irregular figures, while the Mp condition involves the mental rotation (180º plane rotation) of these irregular figures. Behaviorally, higher accuracy and faster reaction times were observed for the Mt than for the Mp condition; also, there were marginal differences in

amplitude between Mt and Mp conditions, from 200 to 1000ms post-stimulus-onset in frontal electrodes, only during the encoding phase. On the other hand, when encoding and delay phases were compared as a function of Mt and Mp conditions, higher amplitude between 200-550 ms post-stimulus onset in ERPs was observed. These results suggest that the strategies for encoding information in working memory differ from the delay phase where keeping information "online" was required, regardless of the maintenance and manipulation requirements.

Title: Barcoding neurons for expansion microscopy (ExM) readout of neural projections

Authors: *S. G. RODRIQUES, N. JAKIMO, D. ESTANDIAN, J. JACOBSON, A. MARBLESTONE, E. BOYDEN;
MIT, Cambridge, MA

Abstract: With expansion microscopy (ExM; Science 347(6221):543-548) it is now possible to identify and localize a variety of kinds of biomolecule with multi-color readout, and nanoscale precision, throughout 3-D tissues such as brain circuits. We recently collaboratively initiated the development of a number of different nucleic acid readout technologies, including expansion fluorescent in situ hybridization (ExFISH), which enables the analysis of nucleic acids in the

context of ExM. We here explore how this strategy, applied to nucleic acid barcodes expressed by neurons, may enable the readout of neural morphology. In one proposed method, exogenous nucleic acid barcodes are expressed by neurons. The barcodes are transported along axons and dendrites. Using ExM equipped with nucleic acid readout modifications, we can then attempt to read out barcodes with single-molecule resolution. Using a combination of spatial and spectral information, it may be possible to encode ~25 bits of identity information per neuron, and to read this information out using conventional microscopes in expanded samples. This many bits of information would enable the assignment of a unique barcode to every neuron in a population of millions of neurons, appropriate for the mapping of large-scale neural circuits. As an example application, by matching barcodes at the origin and termination of a neural projection, it may be possible to map long-range neural projections with single-cell resolution. We will discuss the theory of this approach, as well as preliminary data that we are acquiring.

Title: 20-nm resolution imaging of brain circuitry by next-generation expansion microscopy

Authors: *J.-B. CHANG[1], F. CHEN[1], Y. YOON[1], E. JUNG[1], H. BABCOCK[2], J. KANG[2], S. ASANO[1], H.-J. SUK[1], N. PAK[1], P. TILLBERG[1], A. WASSIE[1], X. ZHUANG[2], E. S. BOYDEN[1];

Abstract: Understanding how biomolecules such as proteins are architected in 3-D throughout synapses, neurons, and brain circuits is essential to understanding how such molecular and cellular machines work together to support the operation of normal and diseased neural networks. Earlier, we discovered that biological specimens could be physically magnified by ~4.5-fold by embedding them in a dense swellable polyelectrolyte gel, anchoring key biomolecules to the polymer network, and then adding water to osmotically swell the gel - a process we call 'expansion microscopy' (ExM; Science 347(6221):534-548). We are now creating an improved, next-generation form of expansion microscopy, which can expand specimens up to 20-fold, enabling ~20-nm spatial resolution imaging, using conventional optics. Here, we report the optimization and application of this next-generation expansion microscopy to reveal extremely fine structures that make up brain circuits, including components of the synaptic cleft in intact brain circuits, and Brainbow-labeled neural circuits. Given that conventional, diffraction-limited optics can proceed with very high throughput (e.g., in lightsheet microscopy), the organization of brain circuitry can be revealed with nanoscopic precision over large volumes relevant to behavior and disease, using next-generation ExM. We anticipate that large-volume nanoscopic imaging via next-generation expansion microscopy, because it does not require any special hardware, may support widescale and democratized investigation of the molecular configurations of brain circuits.

Title: 100-fold linear expansion of biological samples for nanoscale imaging

Authors: *D. SARKAR, A. T. WASSIE, A. PAYNE, K. D. PIATKEVICH, D. ORAN, J.-B. CHANG, E. S. BOYDEN;
Media Arts and Sci., MIT, Cambridge, MA

Abstract: Understanding in 3-D how molecules are configured throughout neurons, and how neurons are configured in circuits, may not only enable the discovery of new targets and technologies for treating neural diseases, but could help reveal fundamental principles of neural computation. Since biomolecules are nanoscale, however, and configured with nanoscale precision, this has remained difficult to study. For example, with electron microscopy, fantastic spatial resolution is possible, but it is difficult to identify the biomolecules in a protein complex. Ideally, one would be able to achieve electron microscopy resolution, but with the additional capability of single-molecule biomolecular identification.

While conventional microscopy techniques involve magnification of images of samples, recently, we discovered that it was possible to physically magnify the biological specimen itself (Science 347(6221):543-548). This is done by embedding the specimens in dense swellable polymers, associating key biomolecules or labels with the polymer, mechanically disrupting the sample, and adding water to swell the biomolecule-polymer composite. This process, which we call expansion microscopy (ExM), was originally shown by us to enable ~60 nm resolution, achieved through ~4.5x linear expansion (i.e., a 300 nm diffraction limited lens would now have a resolution of 300 / 4.5 ~ 60 nm), and is in increasingly widespread use because it enables nanoscale imaging of a wide variety of preserved specimens on conventional, diffraction-limited, hardware.

Here we report a new polymeric chemistry that enables 100x linear expansion, which would ideally give an effective resolution of 300 / 100 ~ 3 nm, comparable to that of electron

microscopy. This method does not require any hardware except that found in conventional biology laboratories, and is compatible with existing dyes, fluorophores, and antibodies. Our approach may be useful for analyzing protein complexes and cellular architectures with high precision, thus helping link nanoscale biological mechanisms with large-scale circuit architectures in the brain.

Title: Nanoscale imaging over large volumes via combined expansion microscopy and lattice light sheet microscopy

Authors: *R. GAO[1], S. ASANO[1], T.-L. LIU[3], G. HUYNH[1], E. BETZIG[3], E. S. BOYDEN[2]; [1]MIT Media Lab., [2]MIT Media Lab, McGovern Inst. for Brain Research, Dept. of Biol. Engin., MIT, Cambridge, MA; [3]Janelia Res. Campus, HHMI, Ashburn, VA

Abstract: Conventional fluorescence microscopy suffers from trade-offs in resolution, imaging depth and photobleaching. In this work, we implemented a novel scalable 3-d imaging strategy by combining the physical expansion and clearing capabilities of expansion microscopy (ExM; Science 347(6221):543-548) and the fast and high-resolution imaging volumetric capabilities of lattice light-sheet microscopy (LLSM; Science 346 (6208): 1257998).
Refractive-index matching between expanded samples and the imaging medium allows for deep imaging into samples, with minimal aberration. Physical expansion in combination with the high-resolution of the lattice light-sheet microscope offers effective resolution of approximately ~51 x 51 x 82 nm at an expansion ratio of ~4.5x. In addition, tissue is rapidly imaged at ~7000 um^3 (in pre-expansion units) per minute under these conditions. Finally, the ultra-thin light sheet significantly reduces out of plane photodamage, which enables imaging of expanded volumes of up to ~1 mm x 2 mm x 1 mm. We show that our new imaging strategy, which we call ExLLSM (expansion lattice light sheet microscopy) is compatible with, and enhances the interrogation of, a wide range of biological samples and model systems of different morphologies and origins such as mouse brain slices, Drosophila brains and central neural systems, tumor and lymph node models, and various cultured cells. In particular, the new imaging strategy is ideal for rapid imaging of extended neuronal systems with nanoscopic resolution, high signal-to-noise ratio and low photobleaching.

Title: ExFISH: Nanoscale imaging of RNA with expansion microscopy

Authors: *A. WASSIE[1], F. CHEN[1], A. COTE[2], A. SINHA[1], S. ALON[1], S. ASANO[1], E. DAUGHARTHY[3], J.-B. CHANG[1], A. MARBLESTONE[1], G. CHURCH[3], A. RAJ[2], E. S. BOYDEN[1];

Abstract: The ability to image RNA identity and location with nanoscale precision throughout brain circuits would enable the molecular characterization of cell types, synapses, and signaling pathways, in normal as well as pathological brain states. We have developed a small molecule linker which enables RNA to be covalently attached to a swellable gel synthesized throughout a biological specimen. Then, post-expansion, fluorescent *in situ* hybridization (FISH) imaging of RNA can be performed with high yield and specificity, with single molecule precision, in both cultured cells and intact brain tissue. This process, which we call Expansion FISH (ExFISH), decrowds RNAs and supports amplification of single molecule signals as well as multiplexed RNA FISH readout. ExFISH thus enables super-resolution imaging of RNA structure and location with diffraction-limited microscopes in thick specimens. We deploy ExFISH to image transcripts in mammalian brain circuitry, within cellular compartments such as dendritic spines, which require nanoscale resolution for identification and segmentation. We anticipate that ExFISH can be used for the transcriptomic profiling of neuronal cell-types in-situ, as well as for the super-resolved characterization of neuronal connectivity and synaptic organization in intact brain circuits, key for an integrative understanding of the mechanisms underlying neural circuit function and dysfunction.

Title: Next-generation expansion microscopy with lipid labels for morphological analysis of neurons.

Authors: *J. KANG[1,2], E. D. KARAGIANNIS[1], J.-B. CHANG[1], G. HUYNH[1], A. MARBLESTONE[1], E. S. BOYDEN[1];
[1]MIT, Cambridge, MA; [2]Harvard Univ., Cambridge, MA

Abstract: Expansion microscopy (ExM; Science 347(6221):543-548) is a new modality of imaging that physically magnifies biological specimens in order to enable nanoscale resolution images to be obtained on conventional, high-speed, diffraction limited optics. Recently, we found that biological specimens can be expanded up-to 20-fold by employing a new polymer system, which we term ‘next-generation expansion microscopy’. As next-generation ExM-processed specimens are optically clear, 20-nm lateral resolution can be achieved, with high-speed diffraction limited microscopes, over large volumes. Accordingly, we asked whether this new version of ExM, in combination with novel lipid stains compatible with the ExM context, might be able to support large-scale neural circuit imaging and reconstruction. We applied next-generation ExM to the imaging of mouse brain circuits labeled with polymer-anchorable lipid binding tags developed in our lab, in order to assess whether 20x physical magnification could clearly separate labeled membranes for connectomic purposes. The lipid-binding tags we developed are ExM compatible lipid intercalating labels that can bind to plasma membranes, or any other membranes, of neurons and other cells. Their physical and chemical properties facilitate their fast 3D diffusion within tissue, in aqueous buffers, thus allowing staining of large tissue volumes. Furthermore, the tags contain chemical groups that facilitate the chemoselective conjugation of multiple types of fluorescent labels, important for multicolor and amplified

labeling. We present the chemistry as well as the kinds of data that can be expected with this novel combination of technologies.

Title: Super-resolution imaging of the extracellular space in live brain tissue

Authors: J. TONNESEN[1,2], K. INAVALLI[1,2], *V. U. NÄGERL[3,2];
[1]Univ. of Bordeaux, Bordeaux, France; [2]Interdisciplinary Inst. for Neurosci., CNRS UMR 5297, Bordeaux, France; [3]Univ. of Bordeaux - CNRS, Bordeaux, France

Abstract: All cells in the brain are surrounded by a narrow extracellular space (ECS), which is filled with interstitial fluid (ISF) and the extracellular matrix. The ECS forms a complexly shaped reservoir, which is thought to be critical for metabolite clearance and brain homeostasis and may serve as an important communication channel for chemical and electrical signals. While the volume and diffusive properties of the brain ECS have been measured by various biophysical techniques (radiotracers, iontophoresis etc), virtually nothing is known about its spatial structure, its heterogeneity, and dynamics in live brain tissue. This is because it cannot be visualized by conventional light microscopy, which lacks sufficient spatial resolution. Electron microscopy (EM) using chemical fixation gives the impression that the ECS is a uniformly thin layer (<15 nm) and devoid of larger channels or basins. By contrast, EM based on cryo-fixation indicates that the ECS is much more heterogeneous and larger, which is consistent with the higher ECS

volume fractions reported by iontophoretic techniques in live tissue (15-30%). Here, we present a new and straightforward method to directly visualize the ECS in living brain tissue and to monitor its dynamics by time-lapse imaging. It is based on super-resolution STED microscopy in 3D and labeling of the ISF with a diffusible fluorescent dye (brain interstitial fluid imaging, 'ISF imaging'). The home-built STED microscope uses pulsed lasers for fluorescence excitation and quenching and incorporates a combination of phase plates to improve the spatial resolution of the microscope in all spatial dimensions, including the z-axis. The setup is fully equipped with a recording chamber and micromanipulators to enable electrophysiological experiments in brain slices. We demonstrate the feasibility of this technique to resolve the ECS in live hippocampal brain slice cultures, using Alexa-488 as a fluorescent dye to label the ISF. We show that the spaces between brain cells are highly heterogeneous and dynamic. Moreover, we show that ISF imaging opens up a radically new way to view the complete anatomical organization of living brain tissue, providing sufficient image resolution and contrast to clearly resolve individual axons and spines within the dense neuropil.

Title: Evaluation of refractive index matching agents for super-resolution imaging in thick brain tissue

Authors: *J. ANGIBAUD[1,2], P. MASCALCHI[1,3], C. POUJOL[1,3], V. NÄGERL[1,2];
[1]Univ. of Bordeaux, Bordeaux Cedex, France; [2]Interdisciplinary Inst. for Neurosci., CNRS UMR 5297, Bordeaux, France; [3]Bordeaux Imaging Ctr., UMS 3420 CNRS, US4 INSERM, Bordeaux, France

Abstract: Fluorescence microscopy is the dominant technique in neuroscience to visualize neural morphology and sub-cellular organelles. The development of super-resolution techniques, such as stimulated emission depletion (STED) microscopy, has greatly extended our ability to resolve biological structures on a spatial scale of 100 nm or less, such as dendritic spines, axons

and glial processes, which are often out of reach for conventional light microscopy.
As STED microscopy is highly sensitive to light scattering and aberrations, the ability to acquire super-resolved images is typically restricted to regions close to the surface of the biological sample (<10 μm). However, for many neurobiological questions it is essential to be able to achieve higher depth penetration for super-resolution microscopy. Towards this end, optical clearing strategies that reduce scattering and aberrations and that are compatible with super-resolution fluorescence microscopy hold great promise.
Here, we report on our comparative tests of a variety of mounting media for super-resolution imaging in thick tissue sections (40 μm), including the recent high refractive index clearing agent CFM3 (RI: 1,518) and a common mounting medium (mowiol). We immuno-labelled YFP-positive neurons with Atto647N in fixed brain slices obtained from transgenic animals and imaged their dendritic spines with a STED microscope. Our results indicate that CFM3 helps maintain high spatial resolution and image contrast throughout thick brain sections, largely irrespective of imaging depth. On a downside, photobleaching of Atto647N labelling was more severe when imaging with CFM3 as compared with mowiol.
We are currently optimizing the experimental conditions to improve the photostability of Atto647N, and are systematically investigating the impact of various clearing agents/mounting media on spatial resolution using 3D-STED. Our preliminary results indicate that CFM3 may be a useful mounting media for super-resolution imaging in thick fixed brain slices.

Title: Quantifying transfection artefacts by PALM/STORM imaging and CRISPR/Cas9 gene editing

Authors: ***H. B. BRISMAR**, K. BERNHEM, H. BLOM;
Applied Physics, KTH, Royal Inst. of Technol., Stockholm, Sweden

Abstract: Transient transfection of fluorescent fusion proteins is a key enabling technology in fluorescent microscopy. Transient transfection of proteins may however bypass the normal regulation of expression, leading to overexpression artefacts. With the advent of gene editing techniques many of the potential problems with overexpression can be avoided. In this study we have combined super-resolution PALM/STORM imaging and CRISPR/Cas9 gene editing to analyze to what extent overexpression may compete with normal protein expression. We selected the α_1-subunit of the integral membrane protein Na,K-ATPase (NKA-α_1) as a target for this analysis based on its central role for the integrity of virtually all eukaryotic cells.
A control cell line was generated using CRISPR/Cas9 gene editing where the N-terminus of NKA-α_1 was fused to mMaple3. Single molecule PALM imaging was then used to quantify the density of NKA-α_1 in control cells (23 μm^{-2}). Competitive overexpression was then introduced by transfection of NKA-α_1-pHluorin. Quantification of the endogenous NKA-α_1-mMaple3 during competitive overexpression revealed a time dependent reduction of the endogenous density to 40% of control after 48 hours. The amount of overexpression was quantified in cells transiently transfected with NKA-α_1-mMaple3. The mean density of NKA-α1 increased to 140% of control density. As a complement to PALM based quantification, we also performed STORM based quantification of immunolabeled control and overexpressing cells. The ratio of endogenous and exogenous densities were comparable to the PALM study, but the absolute densities of NKA-α1 were higher (37 μm^{-2} in control cells) due to the differences in mMaple3 conversion rate vs. antibody labeling efficiency.
Na,K-ATPase requires a β_1-subunit for assembly and insertion in the plasma membrane. It has been suggested that expression of β_1-subunit could be a limiting factor for the expression of the full heteromeric Na,K-ATPase in the plasma membrane. Our data suggest that this is not the case. To further analyze this factor we performed 3D-STORM (PRILM) imaging of β_1-subunits in endogenous and competitive α1 expressing cells and found that there is a relatively large pool of β-subunits in the cell that is not exhausted during overexpression.
In conclusion our findings illustrate that care needs to be taken when evaluating localization data gained from overexpressing systems and we demonstrate that CRISPR/Cas9 gene editing provides a good strategy for introduction of fluorescent proteins in single molecule localization microscopy studies.

Abstract: Organism-level systems biology aims to identify, analyze, control and design cellular circuits in organisms. To realize system-level identification and analysis of cellular circuits within intact organs, we developed a whole-organ expansion and imaging protocol, termed CUBIC-X, by performing comprehensive chemical screening, which achieved highly resolved imaging of intact whole organs. CUBIC-X is a simple chemical immersion protocol, which is compatible to fluorescent proteins and enables the whole-organ expansion ~10 times in volume and extremely high optical tissue clearing. Using nucleus stained adult mouse brains, we demonstrated every nucleus counting and phenotyping over the whole brain with the customized high-speed light sheet microscope. The CUBIC-X protocol is also applicable to anatomical and pathological analysis in fine subcellular resolution. These highly resolved information in whole-organ scale will accelerate our comprehensive understanding of the cellular circuits in complex biological systems.

Title: Random access, parallel FIB-SEM imaging of the *Drosophila* brain

Authors: *K. J. HAYWORTH[1], C. XU[2], H. HESS[2];
[1]Howard Hughes Med. Inst., Ashburn, VA; [2]HHMI, Ashburn, VA

Abstract: Previously we reported how heavy-metal stained, plastic embedded brain tissue can be ‘hot knife’ sectioned (using a heated, oil-lubricated diamond knife) into a series of 20 micron thick slabs optimized in size for efficient FIB-SEM imaging; and showed how such slabs can be

computationally ‘volume-stitched’ back together creating a volume suitable for tracing neuronal processes (Hayworth et al. 2015). We have now integrated this technique into a general pipeline for imaging the Drosophila brain across the multiple FIB-SEM machines in our expanding ‘FIB farm’. A Drosophila brain (prepared by the C-PLT method) is epon embedded, trimmed, and then x-ray micro-CT scanned. The brain is then hot knife sectioned into 35 sagittal 20 micron thick slabs. All slabs are flat embedded in Durcupan, sandwiched between a sturdy PET backing film and a 20 micron thick blank of Durcupan which acts as a front mask to reduce FIB streak artifacts. The laminated slabs are individually mounted on metal studs and UV laser trimmed to the tissue dimensions. Each slab is then micro-CT imaged individually. The resulting x-ray volumes (acquired with 0.7 micron voxels) are of significantly higher quality than the whole brain micro-CT since the x-rays need traverse far less tissue. They serve for quality control, and provide sufficient detail to delineate neuropil compartments assisting targeting of subvolumes. In the present study, the 12 slabs spanning the center of the fly brain were micro-CT imaged and used to identify connected neuropil compartments of the fly central complex. Slabs containing the ellipsoid body, fan shaped body, noduli, and parts of the protocerebral bridge were FIB-SEM imaged with 8nm isotropic voxels using two of our custom FIB-SEM machines -a total volume representing over 5 million cubic microns. We will discuss the results of this imaging concentrating on the many technical improvements we have implemented to make such large-scale parallel FIB-SEM possible (closed-loop FIB beam control, FIB beam shape profiling and optimization, electron detection optimization, etc.). We will also discuss an extension to the hot knife procedure called ‘hot-guillotine dicing’ which is designed to allow for efficient 3D subdivision (and hence parallel FIB-SEM imaging) of large volumes of mammalian brain tissue.

Title: Advanced tissue preparation techniques for combined physiology and high throughput 3D transmission electron microscopy

Authors: *J. BUCHANAN[1], A. BLECKERT[2], M. M. TAKENO[2], N. M. DA COSTA[2];
[2]Neural Coding, [1]Allen Inst. For Brain Sci., Seattle, WA

Abstract: The emerging discipline of high resolution connectomics has fueled interest in development of tissue preparation methods for high throughput 3D electron microscopy. Our goal is to combine these methods with multi-photon *in vivo* imaging of Ca^{2+} activity from the cortex of an awake, behaving mouse and investigate the structural – functional properties of local cortical microcircuits. Given the spatial properties of mouse cortical neurons, our current focus is to achieve *en bloc* staining on vibratome sections with 200 um thickness and tissue blocks larger than 1 mm^3.

These methods require tissue processing that produce sharply delineated and intact membranes throughout the sample. Samples must possess sufficient membrane contrast to identify neural processes in consecutive serial sections and allow manual and automated segmentation of the data collected from thousands of serial sections. To avoid the production of artefacts such as precipitate and dirt, we use *en bloc* techniques to avoid post staining of thin sections with heavy metals.

Recent improvements have been made to the reduced osmium ferri- or ferricyanide /OTO bridging technique (Hua et al, *Nat Commun*. **6**, 7923 (2015). Some newly developed methods including wbPATCO- periodic-acid– thiocarbohydrazide-OsO^4 (*Nature Methods*, **9**, 1198, 2012) and BROPA (brain-wide reduced osmium staining with pyrogallol-mediated amplification) (Mikula and Denk, *Nature Methods*, **12**, 541, (2015) have been introduced as well. These protocols are optimized for FESEM, which utilizes either backscattered or in- lens imaging modes to produce images. Our imaging needs differ as we use high throughput Transmission Electron Microscopy with Camera Arrays (TEMCA), which takes advantage of both high speed and the unparalleled lateral resolution of the TEM.

To produce samples more suited to our imaging needs, we have made adaptations to the Hua *et al*. protocol. These include reduction in timing of the critical thiocarbohydrazide step, and using ferricyanide to stain cellular components. We also use a kit epoxy resin and special embedding and blocking techniques to find the region of interest (ROI) in the previously imaged sample. Our protocol consistently produced high contrast samples with well-defined membranes. Using potassium ferricyanide also maintained staining of cellular components, especially microtubules, while preserving translucency of the cytoplasm. Taken together, this protocol has reliably and consistently produced high contrast, well infiltrated samples.

Title: Continued development of an automated TEM specimen loader and precision positioning system

Authors: *J. H. PRICE[1], C. GOODWIN[1], B. GUNDERMAN[1], O. TORRENS[2];
[1]Hudson Price Designs, LLC, Hingham, MA; [2]Coleman Technologies, Inc., Newtown Square, PA

Abstract: Recent advances in generating large-scale serial section image datasets of neural tissues using electron microscopy have enabled dense reconstructions of ever larger and more detailed neuronal circuit structures. As the number of tissue sections being imaged increases to tens of thousands in a single experiment, the need for automated processing, handling, imaging, and analysis becomes apparent. Here we describe an Automated Transport and Positioning System (ATPS) for loading specimens into a transmission electron microscope (TEM) and positioning them for imaging, thereby addressing a subset of these automation needs. This system is a second-generation commercial derivative of an operational system developed for and in conjunction with the Howard Hughes Medical Institute Janelia Research Campus. Leveraging a cartridge-based storage and retrieval system holding up to 512 uniquely serialized grid-mounted sections, the system has demonstrated the ability to automatically pick any grid from a cartridge for subsequent imaging, provide five-degree-of-freedom positioning control of the specimen within the TEM column, and move and settle between adjacent camera fields-of-view in less than 100ms, all while maintaining compatibility with the standard TEM grid format. In addition to describing the architectural and functional design of the system, operational test data will be presented.

Title: Linking functional and anatomical circuit connectivity using fast parallelized TEM imaging

Authors: *A. A. BLECKERT, D. BRITTAIN, J. BORSETH, D. BUMBARGER, J. PERKINS, D. WILLIAMS, M. TAKENO, D. REID, D. CASTELLI, D. SULLIVAN, T. KEENAN, C. REID, N. DA COSTA;
Allen Inst. For Brain Sci., Seattle, WA

Abstract: It is commonly hypothesized that the neocortex is composed of repeated local circuits that implement a set of canonical computations. The ability to readily link functional properties of these local circuits to their underlying connectivity has the capacity to reveal the algorithmic framework of cortical computations. To this end we are in the pursuit of developing the technologies to map and co-register the physiology of neurons measured with calcium imaging to their synaptic connectivity measured with electron microscopy. We intend these technologies to acquire datasets at the spatial scale of cortical microcircuits, which will require an increase in their speed, stability and reproducibility.
We have currently optimized a tissue processing protocol to identify and map live imaging multiphoton microscopy datasets and transition them through EM histology and onto the final EM dataset. In addition, we are working towards a cross imaging registration framework which leverages the surface and descending cortical vasculature to provide a common reference space for co-registration of functionally imaged neurons within the anatomical network.
To acquire the anatomical datasets we are developing a high-throughput platform for fast, parallelized transmission electron microscope (TEM). This is an enhanced version of the original TEM with camera arrays (TEMCA) and current rates of image capture exceed 30 Mp/s (step and settle + imaging + Image QC + corrections) at < 4nm resolution. One extra advantage of this system is that imaging can be multiplexed over several microscopes.

Title: Neural Reconstruction Integrity - a novel connectomics metric sensitive to brain graph connectivity rather than fine image segmentation

Authors: *M. J. ROOS, E. P. REILLY, J. S. GARRETSON, W. R. GRAY RONCAL, D. M. KLEISSAS, M. A. CHEVILLET, B. A. WESTER;
John Hopkins Univ. Applied Physics Lab., Baltimore, MD

Abstract: Volumetric reconstructions of neurons and their synaptic connections, or connectomes (typically derived from electron microscopy image data), are often reduced to brain graphs in which nodes represent neurons and directed edges indicate a synapse between them. Many classic metrics for evaluating the quality of a reconstructed connectome compare the reconstruction to ground truth data at the voxel level—for example, Rank Index, Warping Index, and Variation of Information. In the case of the brain graph, however, the derived graph is insensitive to some types of reconstruction segmentation errors and thus its quality is not well evaluated by classic metrics applied at the voxel level. Here we introduce a novel metric, the Neural Reconstruction Integrity (NRI) metric, which measures how well graphs estimated from reconstructions capture the connectivity structure of the true brain graph. The NRI metric compares ground truth and estimated graphs in which synaptic locations are preserved in the graphs. The fundamental unit of assessment incorporated into the NRI is the presence or absence of a notional intracellular path between a pair of synapses on a given object (putative neuron or neuron fragment). Synapses in the reconstruction are first matched with those in the ground truth volume based on spatial location and polarity (pre- and post-synaptic halves are treated as two different entities). Then, the paths between synapse pairs are identified as True Positives (TP: both synapses are found on a single object in both the reconstruction and the ground truth), False Positives (FP: both synapses are found on a single object in the reconstruction, but not in the ground truth), and False Negatives (FN: both synapses are found on a single object in the ground truth, but not in the reconstruction). The NRI is the harmonic mean (F1 score) of precision and recall scores computed from TP, FP, and FN totals. Taken together, sensitivity of the NRI to both single synapse location and polarization, along with sensitivity to object ownership of synapse pairs, results in the NRI capturing connectivity structure veridicality without being sensitive to image segmentation errors that do not affect the brain graph. The NRI can be applied to evaluate both local (e.g., single neuron) and global (complete network) structure. We evaluated the NRI

on synthetic neural data with simulated reconstruction errors, and demonstrate here the intuitive relationship between single-neuron reconstruction errors and single-neuron NRI scores. We also provide examples of hypothetical network errors and the resulting global NRI scores.

(UNIST), Ulsan, Korea, Republic of; [3]Pittsburgh Supercomputing Ctr., Carnegie Mellon Univ., Pittsburgh, PA; [4]Janelia Res. Campus, Howard Hughes Med. Inst., Ashburn, VA

Abstract: Investigating the dense meshwork of wires and synapses that form neuronal circuits is possible with the high resolution afforded by electron microscopy (EM). However, the imaging scale required to reconstruct the paths of axons and dendrites is more than 10 orders of magnitude smaller than the spatial extents occupied by networks of interconnected neurons—

some of which span nearly the entire brain. Difficulty generating and handling data obtained by nanoscale imaging of relatively large volumes has thus confined most studies to axon and dendrite fragments until recently. These efforts have now been transformed by computing advances and the development of new sample handling and imaging techniques, but examining entire brains at high resolution remains a challenge. Here we present serial-section EM data for a complete larval zebrafish brain and its surrounding head structures. Our approach utilizes multiple rounds of targeted imaging at different scales to reduce acquisition time and data management. We show that the resulting dataset can be analyzed to reconstruct the myelin projectome, consisting of all myelinated processes throughout the brain and periphery. Finally, we provide this dataset as an as an open-access resource for neurobiologists and others interested in the ultrastructure of the larval zebrafish.

Abstract: Analysis of dendritic arbors of gap-junction-coupled spinal neurons in a motor pattern generating microcircuit of adult male Western Mosquitofish, *Gambusia affinis* (Mosquitofish) suggests that the relationship of dendritic arbors and the constituent synaptic proteins found at gap junctions may be linked to the emergence of gap-junction-coupled fast motor pattern generating microcircuits.

In male Mosquitofish, a major restructuring of the spinal motor-pattern generating microcircuit controlling the extremely fast movement of the intromittent organ, gonopodium, occurs concomitantly with a body plan remodeling that results in the development of the gonopodium. Analysis of the dendritic arbors of gap-junction-coupled spinal neurons reveals significant male/female differences in Type-1 motor neuron (MN) dendritic arbors. Male dendritic arbors are longer, wider, and denser than those of females; male dendritic arbors have more branches than do those of females, and male arbor branches are longer than those of females. Adult male Type -1 MN dendritic arbor surface area is three times larger than that of adult females and of Type-2 and Type-3 MNs. The density and frequency of connexin (Cx) puncta, specifically Cx35/36, is higher in males than in females.

These dendritic arbors may be essential for the establishment of synaptic inputs to other spinal neurons. In addition, the relationship of dendritic arbors and the constituent synaptic proteins found at gap junctions may be linked to the emergence of gap-junction coupled fast motor pattern-generating microcircuits, such as that of the adult male Mosquitofish. The increased surface area finding correlates with results suggesting that the location and type of gap junction protein (in this case Cx35/36) expressed have a critical role in controlling MN dendritic arbor length, width, density, and synaptic connectivity.

Title: Automated dense collection of ultrathin sections directly onto silicon wafers

Authors: *T. TEMPLIER[1,2], R. H. R. HAHNLOSER[1,2];
[1]Univ. of Zurich and ETH Zurich, Zurich, Switzerland; [2]Neurosci. Ctr. Zurich, Zurich, Switzerland

Abstract: Silicon wafers constitute ideal substrates for carrying ultrathin biological tissue sections for subsequent imaging using either array tomography, correlative array tomography, or multibeam scanning electron microscopy technology. We developed a method for the automated collection of hundreds of consecutive ultrathin sections directly onto silicon wafers. Hundreds of floating ultrathin sections carrying magnetic material are densely accumulated with remote magnetic actuation at the water surface in a custom diamond knife bath. The sections are subsequently deposited directly onto a previously immersed silicon wafer onto which we routinely collect about 1000 sections of about 1 mm^2 occupying as little space as about 25 cm^2 (40% wafer covering density). The cutting order of the sections is retrieved either using light or electron microscopic imagery by solving a global optimization problem.
We are currently scaling up our approach to the collection of several thousands of sections onto a single large silicon wafer. We hope that our technology will help accelerate volumetric structural research efforts such as connectomics.

Title: Correlative light and electron microscopy for ultrastructural studies of synapses in cultured hippocampal neurons

Authors: *R. SUN[1], C. YIN[1], X. CHEN[2], C. TAO[1], Y. LIU[1], B. ZHANG[1], J. ZHANG[1], P. LAU[1], H. HAN[2], Z. ZHOU[3], G. BI[1];

Abstract: Fluorescence light microscopy (FLM) are commonly used for localizing specific cellular and subcellular targets. Electron microscopy (EM), especially electron tomography (ET) technique, can reveal the three dimensional (3D) details of cellular architectures at nanometer resolution. To combine the advantages of the two techniques for the study of neuronal synapses, we have developed a system of correlative light and electron microscopy (CLEM) capable of visualizing the same sample with ET and FLM. The CLEM system is based on specific patterned substrate, on which dissociated primary hippocampal neurons grow and form synaptic connections. After imaging and localizing specifically labelled synapses with FLM, samples are embedded in Epon resin and sectioned prior to ET analysis. The patterned substrate allows for efficient correlation between FLM and ET images at high precision. Custom software are developed to achieve automated EM image collection and FLM/EM alignment. With this CLEM system, we have obtained high quality tomograms of synapses along dendrites of identified hippocampal neurons and distinguished between excitatory and inhibitory synapses. This technique provides an efficient approach for combing functional study with ultrastructural observation at single synapse level.

Title: Aldehyde-stabilized cryopreservation.

Authors: *R. L. MCINTYRE;
Nectome, Oakland, CA

Abstract: We present a new brain-banking technique for connectomics research, Aldehyde-Stabilized Cryopreservation (ASC), which allows for cryoprotection and indefinite storage of whole, fixed brains at -135°C with no synaptic degradation.
ASC begins with blood washout and rapid chemical fixation using 3% glutaraldehyde, then uses low quantities of sodium dodecyl sulphate (SDS) to permeabilize the blood-brain barrier. Ethylene glycol is added via a recirculating gradient former over 4 hours until 65% of the brain's water is replaced, then the brain is stored at -135°C where it converts to a glassy solid, a process called vitrification.

ASC has several advantages over other brain preservation methods: 1) Vitrification ensures that preserved brains can be stored for essentially unlimited amounts of time. 2) ASC brains can be rewarmed and reperfused, enabling graceful transition to other perfusion-based protocols. 3) ASC can scale to larger brains without substantial modification.
To evaluate preservation quality, multiple rabbit and pig brains were prepared with ASC and then analyzed with extensive electron microscopy across multiple brain regions and by FIB-SEM (focused ion beam milling and scanning electron microscopy) of several selected regions. We found no difference in preservation quality between ASC brains and brains prepared using traditional fixation methods.
The Brain Preservation Foundation has further verified our work as part of their administration of the Brain Preservation Prize.

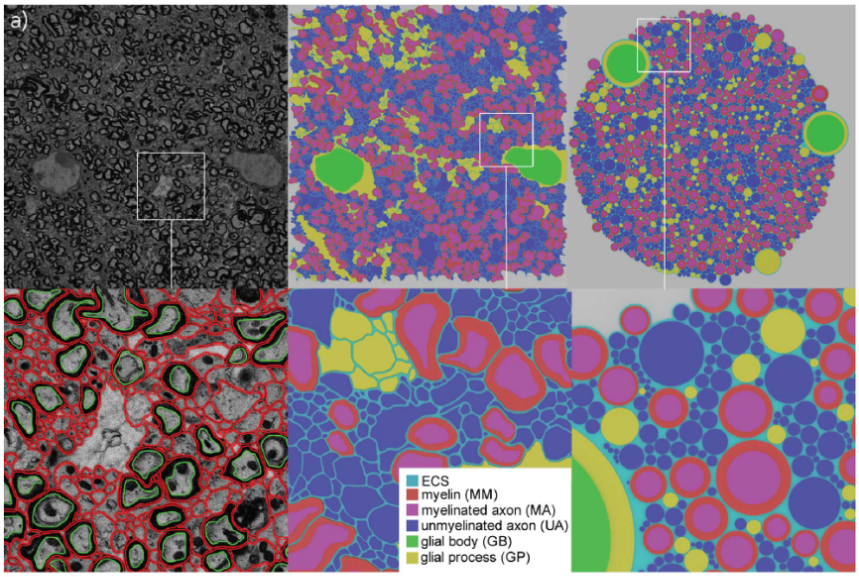
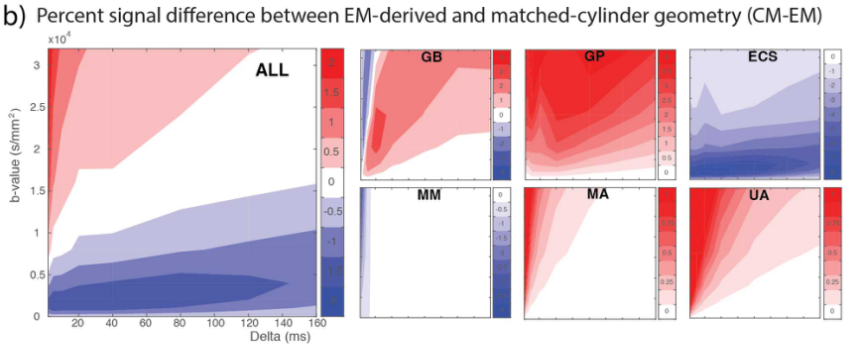
Title: The effect of axon shape and myelination on diffusion MRI signals in a realistic Monte Carlo simulation environment

Authors: *M. KLEINNIJENHUIS[1], J. MOLLINK[1,3,4], E. E. JOHNSON[2], V. L. GALINSKY[5], L. R. FRANK[5], S. JBABDI[1], K. L. MILLER[1];
[1]Oxford Ctr. for Functional MRI of the Brain, [2]Sir William Dunn Sch. of Pathology, Univ. of Oxford, Oxford, United Kingdom; [3]Dept. of Anat., Radboud university medical center, Nijmegen, Netherlands; [4]Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ., Nijmegen, Netherlands; [5]Ctr. for Scientific Computation in Imaging, Univ. of California San Diego, La Jolla, CA

Abstract: Diffusion MRI (dMRI) microstructure techniques, e.g. axon diameter and membrane permeability estimation, are often validated using Monte Carlo (MC) simulations. The geometric substrates are usually oversimplified cylindrical models. This work investigates more realistic geometry derived from electron microscopy (EM) data and aims to showcase how subtle microstructural features can be explored.
An EM section from mouse corpus callosum was segmented into 6 compartments: unmyelinated/myelinated axons; myelin; glial bodies/processes; extracellular space (Figure1a). MC simulations were performed using MCell (Stiles et al., 1996), with DifSim (Balls and Frank, 2009) calculating the dMRI signal from the phase of protons diffusing under a PGSE sequence with diffusion times Δ=2-160 ms, b-values 100-32000 s/mm2 in 30 perpendicular directions. The effects of two tissue features were assessed:
(A) Shape, by comparing EM-derived vs. cylindrical geometry with equivalent radii (Figure1b): The aggregate dMRI signal averaged over directions is similar for EM-derived vs. cylindrical geometry, lending validity to modeling axons in cross-section as circles. Two regimes where shape is relevant: i) short Δ, where lower signal in EM-derived geometry appears driven by irregularly-shaped cell processes; ii) lower b-values, where higher signal in EM-derived geometry might be due to more tortuous diffusion in ECS around realistic cell packings.
(B) Myelination, by comparing EM-derived vs. geometry with myelinated axons replaced by unmyelinated axons under various permeability conditions (Figure 1c): at low permeability, only a modest effect of myelination on the dMRI signal is seen, suggesting myelination does not contribute much to signal attenuation in healthy tissue.
The EM-based geometry and simulation environment presented here has been developed to provide researchers with a flexible tool for investigating the role of a range of tissue features. Here, we have presented two examples: shape and myelination. Ongoing work extends these realistic simulations in full 3D using SBFSEM.





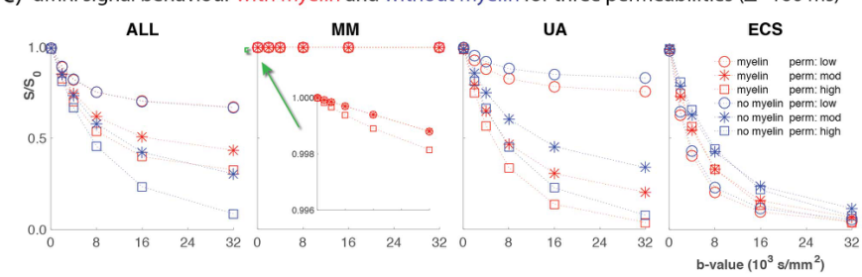


Figure 1a. Electron microscopy segmentation.
top-left) Original section taken from a serial blockface scanning electron microscopy dataset (4000x4000x469; 29.2x29.2x23.5 µm) from the genu of the corpus callosum of a mouse brain in sagittal sections. Acquisition used a Zeiss Merlin Compact Scanning Electron Microscope with a Gatan 3View system. The single section was segmented manually. **bottom-left)** Membranes in contact with ECS (MM/UA/GB/GP: red) and myelinated axons (MA: green). Extracellular space (ECS) was enforced around all objects (no abutting fibres) by eroding objects where they touched. ECS volume fraction is 0.19. **top-middle)** Final segmentation of the section (object counts: 3329 UA; 445 MM/MA; 2 GB; 461 GP). Dilation of the filled mask of all objects in the substrate by 0.0292 µm resulted in an ECS container fitting tightly around the substrate (see bottom-right). **bottom-middle)** A closer look at the compartments (the region in top-middle). **top-right)** Circle packing. Using the areas of the objects in the EM-derived substrate, a homologue cylindrical substrate was created. First, tight packing of circles with equivalent radii yielded an ECS volume fraction of 0.14. To achieve substrates with matched ECS volume the circles' centroids were shifted outward. **bottom-right)** A closer look at the compartments (the region in top-right).
Substrates had a z-dimension (10 µm) to meet the 3D nature of the simulation environment, but diffusion was periodic and free in the constant z-dimension. Diffusivities for ECS, intracellular compartments and myelin were set to [2.0; 0.75; 0.03] µm²/ms and the base rate of 35 particles/µm³ was scaled by concentration factors [0.95; 0.88; 0.50]. The EM-derived substrate is somewhat oversegmented as connections between objects occuring outside the segmented section were ignored. Future 3D tissue modeling efforts will address this shortcoming. Further compartmentalisation and variations in compartment properties (e.g. mitochondria and separate permeabilities of glia and neurons) will add to the accuracy of this model. Fortunately, these improvements are incorporated in a straightforward manner by DifSim.

Title: A genetically encoded marker for light- and electron-microscopic analysis of neuronal cell types

Authors: *M. L. LEYRER[1], D. J. BERG[2], K. L. BRIGGMAN[3], D. M. BERSON[1]; [1]Neurosci., [2]Mol. Biology, Cell Biology, and Biochem., Brown Univ., Providence, RI; [3]NIH, Bethesda, MD

Abstract: Connectomic maps facilitate the understanding of information processing through neural networks. Serial-section electron microscopic (EM) datasets provide the requisite nanometer-scale resolution, but are tedious to reconstruct, permit only indirect identification of cell types, and are limited to small volumes reducing the likelihood of capturing rare cell types. We have developed a novel tool for labeling genetically identified neurons at the light-microscopic (LM) and EM level with spatial and temporal control. We generated a recombinant AAV2 virus to deliver a Cre-dependent construct of membrane-targeted green fluorescent protein (mGFP) fused to an engineered ascorbate peroxidase enzyme (APEX2) (Lam et al., 2014). Cre-specificity of mGFP-APEX2 labeling was validated in retina and/or brain of well-established Cre-driver lines (OPN4-Cre, ChAT-Cre, Rbp4-Cre, and Parvalbumin-Cre). Robust mGFP labeling marked virally infected, Cre-containing cells 2-4 weeks post-injection, permitting detailed confocal reconstruction. After peroxidase histochemistry with 3,3'-Diaminobenzidine (DAB), the same cells labeled with mGFP exhibited an opaque reaction product visible in LM. Following osmication, the reaction product became electron-dense and thus visible in EM. APEX2/DAB-labeled cells were clearly marked in electron micrographs, exhibiting both membrane and cytosolic staining throughout their processes including their axon terminals at distant efferent targets. In wildtype mice, we used a dual viral strategy, combining our vector with a retrogradely transported Cre-expressing AAV, to express mGFP-APEX2 in neurons sending axons to specific postsynaptic targets. Applications of the new method include: 1) serial-section EM analysis of genetically identified neurons, including their somata, dendrites, and local or remote axonal projections; 2) correlated LM and EM cell reconstructions to place small, high-resolution serial EM volumes into a broader anatomical context documented at the LM

level; 3) correlated LM and EM labeling of neurons with identified efferent projections; and 4) enhanced segmentation of EM volumes using APEX2/DAB labeled processes as points of reference.

Title: The genetically encoded peroxidase APEX2 enables cell-type specific labeling for large-scale electron microscopy of mouse cortex

Authors: *M. M. TAKENO[1], T. L. DAIGLE[2], A. L. BODOR[2], A. H. CETIN[2], H. ZENG[2], N. M. DA COSTA[1];

Abstract: Electron microscopy (EM) is perfectly poised to investigate connectivity since it is widely recognized as the gold standard to identify synapses. However at such high resolution it is usually difficult to identify the specific cell types forming the pre- and post-synaptic terminal in any given synapse. Mapping of cortical circuits would benefit from such cell-type specific markers visible at the EM level, and here we report the successful *in vivo* expression of the genetically encoded ascorbate peroxidase, APEX2 (Lam, *et al.* Nat. Methods 12(1):51-4) in mammalian mouse cortex using virus and transgenic mouse reporter line Ai133. APEX2 allows highly sensitive enzyme-based diaminobenzidine (DAB) staining to occur in a pre-embedding step; tolerates a high concentration of glutaraldehyde during the primary fixation step, critical in preserving ultrastructure and suppressing background endogenous peroxidase activity; is not dependent on photoconversion (and therefore, light penetration depth) for visualization; and allows intensification by heavy metals such as nickel and cobalt. We have demonstrated nickel-enhanced DAB (DAB-Ni) staining in tissue sections up to 300 microns thick. EM imaging reveals fine structural details and high-contrast staining, facilitating identification and tracing of processes across serial EM sections.

Title: Mammalian whole-brain preparation for high-throughput electron microscopic connectomics

Authors: *S. MIKULA[1], W. DENK[2];
[1]Electrons - Photons - Neurons, Max-Planck Inst. For Neurobio., Martinsried, Germany; [2]Max Planck Inst. for Neurobio., Martinsried, Germany

Abstract: A comprehensive reconstruction of the mammalian whole-brain 'wiring diagram' is highly desirable because the computations that underlie the control of behaviour involve neuronal circuits that are widely distributed. Currently only electron microscopy provides the resolution necessary to reliably reconstruct neuronal circuits en toto. Substantial progress is currently being made with respect to automated ultramicrotomy and imaging throughput. One of the bottlenecks has been sample preparation. Recently we described a method, which we call BROPA (Brain-wide formamide-Reduced-Osmium staining with Pyrogallol-mediated osmium Amplification), that allows for the preparation of whole mammalian brains with sufficient membrane contrast and ultrastructural preservation for high-throughput electron microscopy-based neural circuit reconstructions (Mikula & Denk, 2015). Here we report on the development of further improvements in mammalian whole-brain sample preparations for electron microscopy based on BROPA and their application to a number of different mammalian brains, including Etruscan pygmy shrew and mouse. By fine-tuning the parameters of the sample preparation, we have resolved issues with whole-brain crack formation, which we routinely diagnose with X-ray microCT and electron microscopy and which appears due to increased sample brittleness resulting from high-concentrations of metal oxides deposited in the sample. We are currently working on further improvements to membrane contrast, scaling our sample preparations to larger mammalian brains, and on high-resolution, high-throughput mammalian whole-brain serial block-face and serial-section electron microscopic mosaic acquisitions that will lead to mammalian whole-brain cellular connectomics (Mikula, 2016).

Title: Serum brain-type fatty acid-binding protein level is elevated in response to mental stress

Authors: ***M. KOGA**, S. NAKAGAWA, Y. WAKATSUKI, K. KITAGAWA, A. KATO, I. KUSUMI;
Hokkaido Univ. Grad. Sch. of Med., Sapporo, Japan

Abstract: There is urgent need to understand pathophysiology of psychiatric disorders such as schizophrenia, bipolar disorder and major depression. To perform this, biomarkers correlated to those disorders and symptoms must be identified. Since the organ mostly involved in psychiatric disorders is the brain, tissue biopsy is generally impossible. Under this condition, identifying molecules which are released from the damaged organ and detectable in peripheral tissue such as blood, urine, etc. are useful approach. However, such kinds of molecules have been poorly

identified in psychiatric disorders. Previous studies have reported that elevated serum levels of brain-type fatty acid-binding protein (B-FABP) was observed in dementia patients and patients with ischemic stroke, thus suggested that B-FABP may be useful biomarker for them. Although analysis of serum levels of B-FABP has been studied in neurological disorders and cerebrovascular disorders, relations between serum B-FABP levels and psychiatric disorders have not been investigated. Unlike conventional neurodegenerative diseases, it is considered that there is no prominent neuronal loss or cell death in psychiatric disorders. However, several previous studies suggested that there were pathophysiologic processes which associate or could lead to neurodegeneration in psychiatric disorders. Therefore, we hypothesize that serum B-FABP levels may be useful biomarker for mental stress which can increase in risk of psychiatric disorders.
Our recent test with using restraint stress model mouse showed substantially higher serum B-FABP levels were observed compared to controls (stressed group, 35.1±13.5pg/mL and control group, 0.0±11.7pg/mL, t-test p=0.0042) and there were duration-dependent effects of repeated stress in serum B-FABP levels. These findings suggested that B-FABP in serum is useful indicator for accumulated mental stress. We preliminarily assessed serum B-FABP levels in patients with schizophrenia, bipolar disorder and major depression. The subjects with psychiatric disorders seemed to have higher serum B-FABP levels than the control subjects. Further numbers of subjects are necessary to investigate associations between serum B-FABP levels and psychiatric disorders subgrouped with clinical status such as duration of illness, symptom assessment scales etc.
The present findings demonstrated that B-FABP may be an indicator of stress levels in the brain and could be a useful biomarker for objective evaluation in psychiatric disorders.

Title: Long-term plasticity underlies antidepressant effects of repetitive transcranial magnetic stimulation

Authors: *C. KELLER[1], W. WU[2], R. WRIGHT[2], N. ICHIKAWA[3], J. HUEMER[4], M. WONG[2], A. YEE[2], K. SARHADI[2], N. ANICETTI[2], L. MCTEAGUE[5], A. ETKIN[2];
[1]Stanford Univ., Mountain View, CA; [2]Stanford Univ., Stanford, CA; [3]Hiroshima Univ., Hiroshima, Japan; [4]Med. Univ. of Vienna, Vienna, Austria; [5]Med. Univ. of South Carolina, Charleston, SC

Abstract: Background: Depression is a highly prevalent and serious mental illness, with unsatisfying success rates for even the best-calibrated combination of pharmacotherapy and psychotherapy. Newer treatments such as transcranial magnetic stimulation (TMS) target specific brain networks and provides a promising non-invasive therapy for those who are medication-resistant or suffer intolerable side effects from antidepressants. However, our understanding of the mechanism by which TMS exerts its antidepressant effect is minimal. Furthermore, importantly, we currently lack a neural circuit biomarker to track and predict clinical outcome.
Methods: We performed a randomized, sham-controlled clinical trial randomizing patients to receive daily 10Hz Left DLPFC repetitive TMS (rTMS) or sham stimulation. Single pulse TMS (spTMS) evoked potentials (TEPs) were recorded before and after treatment to assess the causal network effects of rTMS. Clinical outcome was assessed with MADRS and HAMD screening scores.
Results: Across subjects, daily rTMS elicited significant changes in the TMS-evoked potential across distributed regions, most evident in the later p200 potential. P200 suppression was observed across bilateral medial and lateral prefrontal regions and was highly predictive of clinical outcome, both at the sensor and source level. Importantly, both the baseline strength and the change in strength of the P200 suppression significantly correlated with clinical outcome; that is, the stronger the baseline TEP and the stronger the strength of TEP suppression predicted better clinical outcome. Evoked potential changes were accompanied by a frontal reduction in the early gamma response and a more distributed increase in late alpha power reduction.
Conclusion: Daily rTMS induces long-lasting cortical neuromodulatory effects across broadly distributed regions. These effects are temporally and spatially removed from the onset and location of stimulation, but are highly predictive of clinical outcome.

Abstract: Despite being classified into distinct categories, psychiatric disorders such as schizophrenia (SCZ), major depressive disorder (MDD), obsessive-compulsive disorder (OCD) and autism spectrum disorder (ASD) show clinical overlap, familial co-aggregation, and share genetic risk factors. Therefore, a better understanding of the biological overlap between psychiatric disorders may lead to improved clinical diagnosis and treatment strategies. Geneticist now have a reasonable framework for understanding the basic genetic architecture underlying psychiatric disease; however, the variable expressivity of genetic mutations suggests that environmental factors play a crucial role. In this context, the neural phenotype is the outcome of both genetic and environmental factors, representing a more comprehensive domain to study the cross-disorder overlap. In our previous work, we designed a Control vs ASD classifier based on resting-state functional connectivity magnetic resonance imaging (rs-fcMRI), and showed that the output of the classifier might provide a quantitative measure of "ASD-ness" along one of the biological dimensions in psychiatric disorders. Indeed, based on this new metric we found that SCZ is closer to ASD than other mental disorders. Here we extend this idea by defining cross-disorder dimensions based on datasets that incorporated SCZ (N=98), MDD (N=200), OCD (N=50) and ASD (N=145). For this purpose, we build a classifier for each possible 1 vs. 3 (e.g. MDD vs ASD, SCZ, OCD) and 2 vs. 2 (e.g. MDD, OCD vs ASD, SCZ) combinations of disorders. The classification performance of each classifier is evaluated by stratified 10-fold cross-validation and by the area under the curve (AUC) of the receiver operating characteristic (ROC). We observe that the classification performance is fair to good for each classifier (AUC=0.81±0.04), and that the set of relevant functional connections selected by the machine learning algorithm is independent for each classifier. These results suggest that psychiatric

disorders can be clustered into multiple broader biotypes that depend on the abnormal functional connections taken into consideration. This motivates further studies towards a more continuous representation of these biotypes, and towards a better understanding of the cross-disorder overlap.

Abstract: The diagnosis of psychotic disorders relies on clinical characteristics defined according to DSM criteria. However, there is growing evidence that the DSM classifications have limited overlap with biologically meaningful variables. Recent research suggests that a biomarker-based approach to classify psychoses might be more advantageous for disease understanding than traditional symptom-driven criteria. Here, we examined whether structural brain measures, specifically regional grey matter densities derived from voxel-based morphometry (VBM), would be more accurate when used to classify individuals within the psychosis dimension when these were defined according to DSM criteria or were based on multivariate biomarker profiles – Biotypes (BIO). We analyzed T1-weighted MRI images from the Bipolar-Schizophrenia Network on Intermediate Phenotypes (B-SNIP) sample that includes psychotic probands, their first-degree relatives, and healthy controls. The present analysis focused on 557 probands first grouped by conventional diagnoses [schizophrenia (SZ, n=242), schizoaffective disorder (SAD, n=138), psychotic bipolar disorder (BD, n=177)] and then by Biotype (B1, n=150; B2, n=185; B3, n=222), as well as 251 healthy controls. Classification of the individual MRIs was conducted using L2-penalized logistic classifiers (λ=1) using gray matter density to predict group membership in a repeated cross-validation approach (1000 iterations per analysis). Classification outcomes indicated that healthy controls could be reliably distinguished from probands at rates higher than chance (25%) when every gray matter voxel was treated as a feature. Classification accuracy was highest for the SZ (35%) and B1 (the most impaired Biotype based on cognitive and sensorimotor profiles) (37%) probands. Importantly, the probands could be accurately classified above chance (33%) for both the DSM (42%) and BIO (39%) categories even when healthy controls were not included in the analysis. Classification accuracy further improved, primarily for SZ (39%) and B1 (44%) when the feature set was reduced using an ROI approach (45 bilateral AAL ROIs). This latter result suggests that the application of ROI-based approaches may improve classification. In conclusion, although grey matter densities were able to classify the most severe cases of psychosis (SZ and B1), there was no evidence for superiority for DSM or Biotype models.

Title: ^{14}C-2-deoxyglucose autoradiography screen for mouse brain activity: relating known therapeutics and novel compounds for schizophrenia, depression, and bipolar disorder to brain circuitry

Authors: *A. GIOVANNI[1], S. ENGEL[1], C. BOWEN[1], R. TERRY-LORENZO[1], P. G. JONES[1], L. HARDY[1], T. LARGE[1], T. HANANIA[2], E. V. SABATH[2], V. ALEXANDROV[2,3], M. QUTAISH[3], M. SEAMAN[3], P. CZARNECKI[3], M. SILVA[3], J. SULLIVAN[3];
[1]CNS, Sunovion Pharmaceuticals Inc, Marlborough, MA; [2]PsychoGenics Inc., Tarrytown, NY; [3]InviCRO LLC, Boston, MA

Abstract: The objective of this study was to develop and test a method for screening the acute effect of test articles on ^{14}C-2-deoxyglucose (^{14}C-2DG) concentration in mouse brain, as a representation of glucose uptake due to compound-induced changes in neuronal activity. Eighty C57BL/6 mice were separated into 10 groups of 8 animals. After an overnight fast, each mouse was administered one of 10 test articles while awake via intraperitoneal (IP) injection. Five of the test articles were controls and included water (vehicle), Haloperidol, Desipramine, Ketamine, and Lithium Chloride. The other five test articles were Sunovion compounds in late stage discovery. Fifteen minutes after test article administration, each mouse was administered ^{14}C-2DG intravenously (IV), also while awake. Mice were euthanized at 45 minutes post-injection of ^{14}C-2DG, and their brains were harvested.
Each brain was halved sagittally along the midline and frozen. All 80 frozen brain halves were blocked together in a grid-like configuration for autoradiography. Sagittal 30-µm thick sections of the 80 brain halves were produced using a cryomacrotome. High resolution optical images were acquired prior to each section being taken from the block. Sections were exposed to phosphor imaging plates to measure radioactivity in the tissue and produce autoradioluminograms.
All 2D white light images and autoradioluminograms were reconstructed into 3D volumes. Individual 3D brain volumes were digitally extracted and all 80 brains (white light and autoradiography data) were registered to a common space. Qualitative comparisons and quantitative statistical parameters (vehicle vs. remaining test articles) were generated on the voxel-level and the region-level using the Allen brain atlas.
Changes in raw counts of radioactive signal produced patterns of responses in Regions of Interest (ROI's) that relate test compounds (unknowns) to reference compounds used for the treatment of Schizophrenia (Haloperidoll), Depression (Desipramine), Treatment-Resistant Depression

(Ketamine), and Bipolar Disorder (Lithium).
Comparisons of patterns of response and statistical analysis will be presented as they capture similarities and differences with respect to mouse ROIs's of interest, brain circuits, and behavioral changes between known therapeutics for psychiatric indications and compounds in late stage discovery.

Title: Drug discovery for mental disorders: preclinical studies of Peruvian botanicals

Authors: *C. GALLO, G. POLETTI, A. VAISBERG;
Univ. Peruana Cayetano Heredia, Lima, Peru

Abstract: Mental disorders are multidimensional and severely disabling diseases, with a strong need for pharmacotherapies with better adherence, long-term outcome and patient functionality. Unfortunately, the scientific advancements in the field have not yet led to the introduction of truly novel pharmacological approaches to treatment. One of the possible avenues to achieve this goal is to take advantage of world's ancient knowledge of healing practices to direct search of new lead compounds, with expectedly novel action mechanisms that would lead to better treatment outcomes. For this reason, we have directed our efforts to the search of new pharmaceuticals in Peruvian flora traditionally used for the treatment of mental disorders. Previous studies have led us to collect information on the traditional use of plants for the treatment of mental disorders in several Peruvian localities and geographical regions. We currently have extracts from plant collections corresponding to 265 species from 87 different plant families. These plants are traditionally used for one or more of the following activities:

antipsychotic, antidepressant, anxiolytic and sedative. Importantly, about 60% of those species have never been described in the scientific literature for their potential effects on the modulation of behavior.
Half of our plant extracts have been screened so far to validate their traditional medical use with behavioral tests in mice. We have identified 157 plant extracts having one or more potential psychotropic activity (123 antipsychotic/antimanic, 84 anxiolytic and 38 antidepressant). Additionally, our extracts have been tested for 56 receptor targets in the NIMH Psychoactive Drug Screening Program (PDSP) - University of North Carolina, Chapel Hill (UNC), showing they are potentially active towards several targets of interest (e.g. serotonin 5-HT6 and 5-HT7A antagonists, nocioceptin/orphanin agonists, GPR68 antagonists, among others).

Title: Development of a functional HTS assay for the orphan receptor GPR88

Authors: A. M. DECKER, E. A. GAY, K. M. MATHEWS, R. MAITRA, *C. JIN;
Res. Triangle Inst., RTP, NC

Abstract: GPR88 is an orphan G-protein-coupled receptor (GPCR) highly expressed in the striatum. Genetic deletion and gene expression studies have suggested that GPR88 plays an important role in the regulation of striatal functions and is implicated in basal ganglia-associated disorders. However, the receptor functions of GPR88 are still largely unknown due to the lack of potent and selective ligands. Development of a high-throughput screening (HTS) assay for GPR88 should facilitate the discovery of novel ligands as *in vivo* probes of GPR88 function. Toward this goal, we have developed a CHO-$G\alpha_{qi5}$-GPR88 cell-based calcium mobilization assay. This assay takes advantage of functional coupling of GPR88 with the promiscuous $G\alpha_{qi5}$ protein and consequent mobilization of intracellular calcium, which can be measured in a 384-well format with a Fluorescent Imaging Plate Reader (FLIPR). The assay was validated using the known GPR88 agonist (1R,2R)-2-PCCA (EC_{50} = 297 nM). The assay was deemed robust and reproducible with a Z'-factor of 0.72 and tolerated dimethyl sulfoxide to a final concentration of

2%. A diversity library of nearly 20,000 compounds was screened using this assay to identify novel GPR88 agonist leads.

Title: Effect of substitution on the aniline moiety of the GPR88 agonist 2-PCCA: Synthesis and structure-activity relationship study

Authors: C. JIN, *A. M. DECKER, D. L. HARRIS, B. E. BLOUGH;
RTI Intl., Rtp, NC

Abstract: The orphan receptor GPR88 is richly expressed in both dopamine D_1 and D_2 receptor-expressing medium spiny neurons. Genetic knockout and gene expression studies have suggested that GPR88 plays an important role in the regulation of striatal functions and is implicated in the basal ganglia-associated disorders such as Parkinson's disease and schizophrenia. We have previously reported 2-PCCA inhibits isoproterenol-stimulated cAMP accumulation in a concentration-dependent manner in HEK293 cells expressing GPR88, indicating that GPR88 is coupled to $G\alpha_i$ proteins. 2-PCCA has a high calculated lipophilicity (cLogP 6.2) and was reported to be a P-glycoprotein substrate. In order to elucidate the biological function of GPR88, an in vivo agonist probe appropriate for CNS investigation is required. This poster will present the synthesis, structure-activity relationship and molecular modeling studies of substitutions on the aniline moiety of 2-PCCA with the goal of improving potency and lowering the lipophilicity.

Title: Discovery of highly selective dopamine D3 receptor ligands in a novel series of piperazinylbutyl ureas

Authors: *S. ANANTHAN[1], S. K. SAINI[1], J. V. HOBRATH[1], I. PADMALAYAM[1], L. ZHAI[1], T. ANTONIO[2], M. E. A. REITH[2], M. TAYLOR[3], R. R. LUEDTKE[3];
[1]Southern Res. Inst., Birmingham, AL; [2]New York Univ. Sch. of Med., New York, NY; [3]Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstract: Antagonist or partial agonist at dopamine D3 receptor (D3R) have been proposed as medications for substance abuse and neuropsychiatric disorders. The development of D3R selective ligands as therapeutic agents has been challenging because of the 1) high degree of homology (~80% sequence identity) between the D2 and D3 dopamine receptor subtypes within the helical transmembrane spanning regions and 2) suboptimal physicochemical and pharmacokinetic properties of current ligands. In our earlier effort, we identified a series of D3R preferring amides possessing moderate binding selectivity compared to the D2R. Based on the insights gained from modeling studies, we designed and synthesized a library of piperazinylbutyl ureas. Evaluation of binding affinity of this library of compounds at human D3 and D2L receptors led to the identification of compounds with greater than 400-fold selectivity for D3R over D2R. Functional activity and functional selectivity of selected ligands were also profiled using GTPγS binding assay, β-arrestin-2 recruitment assay, and forskolin-dependent adenylyl cyclase inhibition assay. Docking experiments utilizing the refined crystal structure of D3R and a D2R model, generated using the D3R crystal structure as homology modeling template, indicate that the interaction of the tail groups on the urea nitrogen plays a critical role in imparting differential binding affinity at D3R and D2R. The results of these studies, along with our efforts to identify receptor residues that may play a key role in binding selectivity, will be presented.

Abstract: Our purpose was to identify the gene expression markers of early-onset depression (EOD) in blood by microarray analysis. To exclude bipolar disorder patients who had first episode of depression, we selected EOD patients (N = 10 in depressed state, N = 13 in remitted state) who had no manic episode until elderly (age ≥ 50 years old). Seven hundred ninety seven genes (up; 558, down; 239) with annotation of gene symbol were identified as EOD markers compared to healthy control (N = 30). These genes were cross-matched the microarray data in blood of the depression model mice (676 genes, up; 148, down; 528). In six common genes between patients and mice, five genes were validated as the downregulated-genes in EOD patients by quantitative real-time PCR. These genes may be the biological markers of EOD in blood.

Title: Neural targets of tolcapone enhanced cognitive control in healthy adults.

Authors: *S. G. BHAKTA, G. A. LIGHT, J. A. TALLEDO, A. ALVAREZ, E. HUGHES, B. BALVANEDA, B. K. RANA, J. W. YOUNG, N. R. SWERDLOW;
Dept. of Psychiatry, Univ. of California San Diego, LA Jolla, CA

Abstract: Background: Chronic psychotic disorders, including schizophrenia (SZ), are characterized by significant impairment in cognitive control (CC); a higher cognitive process that broadly impacts goal or context representation and maintenance, attention allocation and stimulus-response mapping, and is essential for decision-making and daily functioning. Impaired CC is thought to contribute significantly to functional impairment in SZ, and is largely unresponsive to antipsychotic (AP) medications. Tolcapone, a reversible catechol O-methyl transferase (COMT) enzyme inhibitor improves neurocognitive performance in healthy subjects (HS) carrying the Val/Val genotype of the COMT gene (SNP rs4680). However, tolcapone's effect on the cognitive control construct is unclear. We used a reverse-translated 5 Choice-Continuous performance test (5C-CPT) with simultaneous electroencephalography (EEG) to study tolcapone's effect on CC in COMT-genotyped healthy adults.
Methods: Healthy adults, between the age of 18-35 years were screened for baseline measures and COMT genotype; effects of a single dose of tolcapone (200 mg or placebo (PBO) p.o.) on neurocognitive performance and event related potential (ERP) measures were tested in a double-blind, randomized, counterbalanced, crossover design. Participants completed two test days separated by one week. Effects of tolcapone on neurocognition and ERP measures were analyzed using repeated measures ANOVA with genotype or gender or median split (low vs. high) baseline (PBO day) d-prime (d') score as between subject factor.

Results: 27 subjects (10 Met/Met and 17 Val/Val) completed the study. Participants were mostly men, young, healthy and educated. Overall, 200 mg dose of tolcapone was well tolerated, however significant elevation of systolic blood pressure ($p<0.05$), and liver function tests were noted with tolcapone suggesting its bioactivity. Tolcapone significantly improved 5C-CPT performance and enhanced activation of frontal electrodes during response inhibition in individuals with low baseline d' scores, but had the opposite effect in the high baseline d' score group.
Discussion: Among healthy adults, tolcapone (200 mg) enhanced cognitive control measured by false alarm rate during non-target trials, and activated frontal electrodes during correct inhibition of response to non-target trials, consistent with its behavioral effects, in specific subgroups. These findings suggest a frontal locus of bioactivity for tolcapone and its regulation of CC.

Title: The preclinical use of Auditory Steady State Responses for drug discovery in schizophrenia

Authors: *B. POUYATOS, C. TOULLER, R. MAURY, C. DUMONT, C. ROUCARD, Y. ROCHE, V. DUVEAU;
Synapcell, La Tronche, France

Abstract: Schizophrenia is a severe psychiatric disorder associated with persistent alterations of diverse neurocognitive functions, leading to life-long psychosocial disabilities. Although schizophrenia has long been considered as a pathology altering specifically the higher-order functions, recent research demonstrated that basic sensory processing was also impaired, especially in the auditory modality.

Neurophysiological approaches including event-related potentials/oscillations and mismatch negativity have provided evidence that most schizophrenic patients show a wide range of clinically measurable dysfunctions in the treatment of auditory stimulations. Here we focus on an alternative method, called Auditory Steady State Responses (ASSRs), which is one the most consistent functional biomarker across schizophrenic patients. ASSRs consist in cortical electrophysiological oscillations entrained to the frequency and phase of a periodic auditory stimulus presented at a rhythm in the gamma range (that is, 30-80Hz). ASSRs are believed to reflect the interplay between cortical pyramidal neurons and parvalbuminergic interneurons. Consistent with the theory of imbalance between cortical excitation and inhibition in schizophrenia, patients show reduced power and phase locking, in particular to stimulations presented at 40Hz.

Here we show that ASSRs can be consistently recorded in the auditory cortex of freely-moving C57Bl6 mice using methods inspired from clinical paradigms, i.e. following series of 2 second trains of 5ms white-noise clicks presented at 20, 40, 60 or 80Hz. Gamma Power and phase locking of ASSRs were altered following treatments with diverse NMDA antagonists (Ketamine, PCP…), as well as in murine models of psychiatric disorders.

Given that these electrophysiological activities are well-conserved across species and can be recorded without the subject attention, ASSRs might constitute a powerful translational biomarker for drug-discovery in schizophrenia.

Title: Electrophysiological profiling of escitalopram in rodents and healthy human subjects

Authors: P. DANJOU[1], G. VIARDOT[1], P. L'HOSTIS[1], N. FAUCHOUX[1], E. CAYRE[2], *C. MACSWEENEY[3], S. C. LEISER[4], L. BREUNING SLUTH[5], S. RAHN CHRISTENSEN[5]; [1]Neurosci., [2]Non-clinical department, Biotrial, Rennes, France; [3]Biotrial Intl. Ltd, London, United Kingdom; [4]Lundbeck Res. US, Paramus, NJ; [5]Lundbeck A/S, Valby, Denmark

Abstract: Serotonin reuptake inhibitors have been the leading class of drugs for the treatment of depression and anxiety for several decades and have been associated with a number of sensitive peripheral and central biomarkers. The central biomarkers include PET transporter occupancy, fMRI and quantified EEG but these methods differ with regard to ease of use. Using EEG in the rat, escitalopram was found to produce a reduction the delta band at 2 mg/kg. We conducted a qEEG study in healthy volunteers which included evoked P300 cognitive potentials, auditory evoked gamma and ERP during a word list memory task (LMT) and the Flanker task focusing on errors (error-related negativity; ERN) and the test was calibrated to produce a sufficient number of errors.

Thirty two healthy male subjects, 18-45 years old, participated in a four-way double-blind cross over study during which they received placebo, escitalopram (15 mg) or two dose levels of a test drug (not reported here) for three days and in a randomized order. Each treatment was administered orally and separated by at least 18 days' wash-out period. Resting and vigilance-controlled EEG was recorded and complete ERP was tested on the day preceding the first dose (baseline) and on days 1 and 3 of dosing.

P300 (amplitude or latency) was unaffected by escitalopram while induced gamma was increased on day 3. Investigation of qEEG power bands in the bipolar leads showed that escitalopram induced an increase in power of the fast waves (β and γ) compared with placebo in both resting and vigilance-controlled conditions. The spread was on most of the 28 electrodes flat maps. This effect was observed in most experimental conditions, in absolute power values as well as in

relative values, and was more pronounced on day 1 than on day 3. A decrease in power of the slow wave (δ) was observed in resting conditions (on day 3 for absolute and relative values) and in vigilance-controlled conditions (on day 1 and day 3 for relative values only). There was no consistent pattern in the pair-wise comparisons of the auditory evoked gamma power or on the ERN or LMT late potential wave amplitude but a mild increase in the Pe (error positivity) potential following ERN was observed.
The human EEG profile was different to that observed in the rat with higher magnitude effects and broader spread over different frequency bands; potential reasons for the species differences will be discussed.

Title: Inhibition of serine racemase as a novel approach to modulating NMDA receptor function

Authors: *C. R. KOULOURIS, S. WALKER, M. ROE, J. ATACK;
Univ. of Sussex, Brighton, United Kingdom

Abstract: The N-methyl-D-aspartate (NMDA) receptors (NMDAR) are a subtype of ionotropic glutamate receptors that are highly expressed in the central nervous system (CNS) and are involved in the excitatory synaptic transmission and synaptic plasticity that form the basis of many critical CNS functions. NMDAR dysfunction has been implicated in Alzheimer's disease, amyotrophic lateral sclerosis (ALS), neuropathic pain, schizophrenia, and depression, among others. Most non-selective NMDAR antagonists (e.g. ketamine) have undesirable side-effects that restrict their clinical utility for relieving symptoms of neuropathic pain and treatment-resistant depression. Modulators of NMDAR function that either act indirectly or

target particular NMDAR subtypes offer the potential to have reduced side-effects relative to the non-selective antagonists. One approach is to inhibit the production of the NMDAR co-agonist, D-serine, which is produced endogenously by conversion of L-serine to D-serine by the enzyme serine racemase (SR). Inhibitors of SR that reduce the production of D-serine may therefore have therapeutic benefits in disorders associated with NMDAR hyperfunction.
Wild-type hSR was expressed with a polyhistidine-tag in BL21 CodonPlus (DE3)-RIL cells and after a two-step purification (immobilized metal affinity chromatography followed by size-exclusion chromatography) was isolated to a high degree of purity (>90%) and yield of ~3mg/L. The presence and purity of SR were verified by western blot, mass spectrometry and crystallography, with the crystal structure of SR in complex with malonate being solved in-house to a resolution of 2.2Å. The conversion of L-serine to D-serine by SR was quantified by a coupled biochemical assay in which D-serine is broken down by D-amino acid oxidase (DAO) and the resulting H_2O_2 takes part in a chemiluminescence reaction with HRP and luminol to produce light. The Km of L-serine was determined to be 6.4 ± 0.5mM and at a substrate concentration of 2mM, the IC50 for the competitive inhibitor malonate was 82μM, in agreement with literature values.
A single-point screen of 3000 fragments (molecular weight <300) has been performed (n=2). Hits have been reordered and IC50s will be determined in the SR assay and counter-screened in the DAO assay (which comprises the second part of the coupled assay). Specific hits will then be confirmed using biophysical methods such as thermal shift, MicroScale Thermophoresis with the ultimate mode of action being established using X-ray crystallography. These structural data will then be used to direct medicinal chemistry efforts aimed at increasing the potency and physicochemical properties of the hits.

Title: Pharmacological MRI platform for pre-clinical CNS drug discovery.

Authors: *A. SHATILLO, K. LEHTIMÄKI, A. NURMI, O. KONTKANEN, P. J. SWEENEY; Charles River Discovery, Kuopio, Finland

Abstract: Pharmacological MRI (phMRI) is a translatable, versatile and powerful MRI technique that allows in-vivo non-invasive mapping of the effects of the pharmacological

compounds in the brain. High temporal and spatial resolution, whole brain coverage and controlled environment render phMRI an invaluable tool for pre-clinical drug testing, allowing fast screening of the novel compounds for modulating neuronal metabolism and hemodynamic response in the brain. Most widely used phMRI modalities are blood oxygen level-dependent (BOLD) signal and regional cerebral blood volume (rCBV) measurements. Multiple experimental paradigms (e.g. acute dosing vs. pretreatment-challenge) combined with different approaches to data analysis gives flexibility to look into specific aspects of test molecule's action. Applied analysis typically produces functional time-series from specific brain areas and statistical parametric maps (SPM) with GLM block modeling. Beyond that, independent component analysis (ICA), functional networks and connectivity analysis with seed-based correlation can be utilized for post-hoc extraction of additional information related to compound-induces changes in the brain. Here we present our wide implementation of the pharmacological MRI platform in high field for pre-clinical drug testing, using both BOLD and rCBV readouts with a number of known psychoactive compounds in anesthetized rats and mice. Functional data were acquired using 7T or 11.7T Bruker MRI system, with single-shot spin echo EPI sequence with 2 seconds time resolution and (if not stated otherwise) 390x390 micrometers in-plane resolution with slice thickness of 1-1.5 mm. Battery of anesthetic protocols, including Isoflurane, Urethane and Medetomidine was used depending on the experiment. Typical duration of single experiment was 1 hour with 20 min baseline and 40 min follow-up after challenge. Every phMRI session was accompanied with physiological monitoring including ECG, respiration, temperature, blood gas analysis and in some cases - continuous blood pressure measurements, which provides additional information about the drug's systemic effects. Results are shown as individual or group-level statistical maps and signal time-series from selected region of interests (ROI). Provided data and methodology established within this study, demonstrates extensive drug testing capabilities using phMRI in various pre-clinical rat and mouse models.

Title: Comparison of protocols for quantitative analyses of membrane protein clustering in lymphocytes in relation to its use as a putative biomarker of depression

Authors: *R. ROMAY-TALLON[1], T. RIVERA-BALTANAS[5], M. A. MITCHELL[2], L. E. KALYNCHUK[3], J. OLIVARES[5], H. J. CARUNCHO[4];
[1]Dept. of Pharm. and Nutr., [2]Dept. of Psychology, [3]Col. of Med., [4]Col. of Pharm. and Nutr., Univ. of Saskatchewan, Saskatoon, SK, Canada; [5]Alvaro Cunqueiro Hosp., Vigo, Spain

Abstract: Protein clustering along the cell membrane of peripheral lymphocytes is altered in depression and has been proposed as a putative biomarker of therapeutic efficacy in major depressive disorder. Here we compared different methods of blood collection and immunocytochemical analyses to determine the best and easiest manner of carrying out this type of analysis in a clinical setting. In our original protocol (protocol A), human blood samples were drawn by a registered nurse. Samples were centrifuged in a Ficoll-Paque-Plus gradient for the isolation of lymphocytes, followed by immunolabeling with a specific anti-serotonin transporter (SERT) antibody. Immunolabelling was performed in small Eppendorf tubes. The subsequent analysis of the clustering was performed using an epifluorescence microscope. In protocol B, we obtained human blood smears from drops of blood generated through pricking the forefinger. The smears were dried for an hour and stored at -80ºC. Immunolabelling was performed directly on the slide using the same anti-serotonin transporter (SERT) antibody. Identification of lymphocytes in the smears was aided by nuclear counterstaining. We then collected pictures with an epifluorescence microscope. For both protocols we used ImageJ software to quantify membrane protein clustering. Protocol A resulted in an average of 63.58 ± 3.22 SERT clusters/lymphocyte, with an average size of 0.11 ± 0.003 μm^2. With protocol B, we found an average of 93.35 ± 3.5 SERT clusters/lymphocyte, with an average size of 0.09 ± 0.002 μm^2. Statistical analyses showed that protein clustering is homogeneous across different patients, but that protocols A and B reveal different overall numbers of clusters and cluster size. This suggests that either of the protocols could be used in a clinical setting, but if one analyses data obtained by the two different protocols, it would be necessary to create an algorithm to convert the numbers from one to the other. Taking into account that protocol B (use of blood smears) is much faster and cheaper that protocol A (drawing of blood samples and isolation of lymphocytes), we would recommend the use of protocol B to further analyse membrane protein clustering in lymphocytes as a putative biomarker of depression.

Title: Gender differences in N100 and P200 evoked potentials and sensory gating in schizophrenia and bipolar disorder

Authors: *S. T. SIDDIQI[1], B. HO[2], J. V. PATTERSON[4], W. E. BUNNEY, Jr.[3];
[1]Psychiatry & Human Behavior, Univ. of California Irvine Sch. of Med., Orange, CA; [2]Psychiatry & Human Behavior, Univ. of California, Irvine, Orange, CA; [3]Psychiatry & Human Behavior, Univ. of California, Irvine, Irvine, CA; [4]Psychiatry & Human Behavior, Univ. of California, Irvine Med. Ctr., Orange, CA

Abstract: Diagnosing mental illnesses such as bipolar I disorder and schizophrenia using standard clinical methods (e.g., DSM-V) can be difficult, especially when presenting symptoms are characteristic of multiple psychiatric disorders. Recent studies have explored the potential of auditory evoked potentials to serve as biological markers that can provide more objective diagnostic tools. Sensory gating, the neurological process of suppressing a response to redundant stimuli, is thought to index brain inhibitory function and occurs in an auditory paired click task when evoked potential peak amplitude is reduced to the second (S2) click stimulus compared to the first (S1). Previous studies have identified sensory gating of negative evoked potentials occurring 100 msec post-stimulus (N100) and positive evoked potentials occurring 200 msec post-stimulus (P200) as potential markers; both bipolar I disorder (especially with psychosis) and schizophrenia may exhibit impaired gating. Few studies have investigated the effect of gender on these potentials and on sensory gating; those that did had conflicting results. Larger amplitudes, worse sensory gating ratios, and weaker sensorimotor gating have been observed in women compared to men; however, other studies have observed no effects of gender. This study investigated the effects of group, gender, and psychosis in N100 and P200 peak measures and sensory gating for controls (n=70), schizoaffective (SczA, n=47), schizophrenia paranoid type (SczP, n=31), and bipolar I disorder (BPI, n=59; n=24 with psychosis). N100 and P200 peak amplitude measures and sensory gating measures (S1-S2 differences, S2/S1 ratios) were measured using an auditory paired click task. It was found that all groups, including control males, differed significantly from the control females for P200 amplitude measures and N100-P200 peak to peak amplitude measures. Differences among groups were not significant for males. Gender effects on the gating ratio were not significant, but SczA, SczP, and the BPI

psychosis groups had larger P200 ratios than the controls (i.e., impaired gating). In addition, both the control and BPI without psychosis groups had larger S1-S2 difference scores than the BPI with psychosis, SczA, and SczP groups. The amplitude difference between S1 and S2 was not significant for the BPI psychosis group for N100-P200 peak amplitude. Latency measures were affected by gender and click. The gating and peak measures that significantly differentiate patient groups may serve as markers for these disorders and help improve future psychiatric diagnosis and treatments. Gender effects on these measures require further investigation.

Title: Identification and development of novel Trace Amine-Associated Receptors ligands for experimental and pharmacological applications

Authors: *R. R. GAINETDINOV[1,2,3], A. GERASIMOV[2], A. LUKIN[4], O. KORENKOVA[2], E. EFIMOVA[2,3], S. ESPINOZA[1], M. Y. KRASAVIN[2];

Abstract: Background. Trace amine-associated receptors (TAARs) belong to G-protein coupled receptors family and respond to trace amines such as β-phenylethylamine (β-PEA) and tyramine. Recently, most of them have been deorphanized as odorant receptors but their other functions are still poorly understood. For example, the TAAR that is the best characterized, TAAR1, represents attractive potential mediator of certain aspects of movement, cognitive and emotional control and thus can serve as potential molecular target for neuropsychiatric disorders such as schizophrenia and depression. Investigation of TAAR receptors requires development of powerful ligand tools for specific modulation of their functions *in vivo*. For this purpose we aimed to create valuable library of effective and potent ligands of TAARs including agonists (full/partial) and antagonists for biological and pharmacological applications. **Methods and results.** All compounds had been designed to incorporate the PEA-like pharmacophore. For functional activity experiments we have used Bioluminescence Resonance Energy Transfer

approaches (BRET). cDNA for TAAR1, TAAR2, TAAR5 and TAAR6 receptors were used. The gene of TAAR1 was modified by N-terminal extension with the first twenty amino acids of bovine rhodopsin, Rho tag or the first nine amino acids of β2-adrenergic receptor for improved membrane localization and were cloned into pcDNA3.1(+) vector. Transfections were carried out using HEK293T cells receptor cDNA vector and EPAC biosensor cDNA vector for evaluation of cAMP production. Then cells were seeded into 96-well plates. On the following day, 70 μl of PBS was added to each well followed by addition coelenterazine-h solution and IBMX solution. After 10-min incubation, either 10 μl of vehicle or 10 μl of compound at concentration 10^{-5} M in PBS was added, and the plate was then placed into a Mithras LB943 instrument (Berthold Technologies, Germany). The BRET signal is determined by calculating the ratio of the light emitted at 530 nm (YFP) to the light emitted at 480 nm (coelenterazine-h). Natural ligands of TAARs were used as positive controls. Several full and partial agonists of TAAR1 and other TAARs have been identified. They have EC_{50} approximately 15 - 200 nM and their chemical structures differ from structures of other TAARs ligands. **Conclusions**. Application of BRET approaches to identify ligands of TAARs should aid in uncovering the pharmacology and signaling of this poorly characterized receptor family. Newly identified TAAR ligands can be perspective candidates for new drugs development.

Title: Another view of the inhibitory-excitatory abnormality in schizophrenia: the role of white matter microstructure

Authors: *X. DU, A. SUMMERFELT, J. CHIAPPELLI, P. KOCHUNOV, L. E. HONG; Maryland Psychiatric Res. Ctr., Catonsville, MD

Abstract: An inhibitory - excitatory (I-E) imbalance has increasingly been investigated as a functional mechanism giving rise to many schizophrenia-related pathophysiology. One of the robust non-invasive measurements of I-E abnormality in schizophrenia is the short-interval intracortical inhibition (SICI) elicited by paired-pulse transcranial magnetic stimulation (TMS). We hypothesized that part of the I-E abnormality, as indexed by SICI, in schizophrenia is likely white matter in origin as precision of signal transmission in the white matter may be critical for the I-E functions. Patients with schizophrenia (n=26) and healthy controls (n=36) completed one diffusion tensor imaging session using a 3 tesla scanner and one TMS session. SICI is measured using TMS to the left motor cortex. Only in patient group, stronger cortical inhibition was associated with better integrity of white matter tracts, such as left anterior corona radiata ($r = -.58$, $p = .002$). Using mediation analysis, we found the relationship between diagnosis and SICI was fully mediated by white matter integrity of left ACR: controlling left ACR caused diagnosis effects on SICI completely disappeared (path C' $p > .05$). To our knowledge, this is the first study demonstrated the importance of circuitry connection integrity in SICI deficits in schizophrenia. Moreover, cortical inhibition also predicted the performance of processing speed in patient group ($r = -.46$, $p = .03$). Those results together suggested that SICI was affected by diagnosis of schizophrenia largely through left ACR and further predicted the behavioral performance of patients. The clarification of the relationship between I-E function and brain white matter may help to reveal the pathology of schizophrenia.

Title: Mutagenesis study of human GPR139 to identify mutant receptors with a gain and loss of function

Authors: *D. NEPOMUCENO[1], G. LEE[2], P. BONAVENTURE[2], C. LIU[2];
[1]Janssen Pharmaceut. Res. & Develop., San Diego, CA; [2]Janssen Pharmaceut. Res. and Develop., San Diego, CA

Abstract: GPR139 (aka GPRg1 or GPCR12,) is an orphan GPCR. The cloning and expression patterns of this orphan GPCR, which belongs to the rhodopsin family of GPCRs, was described in the literature in 2005 (Matsuo et al., 2005). GPR139 has a low sequence similarity (20-25%)

to other members of the GPCR rhodopsin1, 2 family. Human and mouse GPR139 share 94% amino acid homology. GPR139 is highly enriched in circumventricular regions of the habenula and septum. Biochemical and cell-based assays (GTPgammaS binding, calcium mobilization, ERK phosphorylation) demonstrated L-tryptophan and L-phenylalanine activate GPR139 at physiological concentrations (30-300 micromolar), suggesting the receptor may act as a sensor to detect dynamic changes of L-Trp and L-Phe in the brain (Liu et al., 2015). The aim of this study was to develop a mutant GPR139 receptor with an increased and decreased sensitivity to L-Trp and L-Phe. Through random and site-directed mutagenesis, we have identified several mutant GPR139 receptors with both a gain and loss of function. The various mutants were characterized using radioligand binding and calcium mobilization assays.

Title: Alzheimer's disease and aging effects in cortical folding

Authors: *F. HANSEN PACHECO DE MORAES[1], B. MOTA[1], M. CARNEIRO MONTEIRO[2], P. MATTOS[2], F. TOVAR-MOLL[2,3];
[1]Inst. of Physics, Federal Univ. of Rio De Janeiro, Rio de Janeiro, Brazil; [2]Dept. of Neurosci., D'Or Inst. for Res. & Educ. (IDOR), Rio de Janeiro, Brazil; [3]Inst. for Biomed. Sci., Federal Univ. of Rio de Janeiro, Rio de Janeiro, Brazil

Abstract: Recently Mota & Herculano-Houzel (Mota & Herculano-Houzel, 2015 Science) have proposed a model for cerebral cortical folding that predicts a power-law relation between cortical average thickness, exposed and total area, and have shown that this relation, in fact, applies for the cortices of a wide range of mammalian species. In the present work, we aim to investigate the universality of this relation for healthy and diseased human brain and analyze how the inter-species variability in gyrification for humans relates to the inter-specific variation between different mammalian species. The present study is focused on the elderly subjects: healthy controls, mild cognitive impairment, and patients with Alzheimer`s Disease. We have analyzed 3T Magnetic Resonance structural T1 weighted images and extracted the relevant morphological features using a cortical surface reconstruction software (http://freesurfer.net/). In addition to the

comparison between groups we study how aging affects fitted parameters, both constrained and unconstrained by the model; this is done both for each group separately, and longitudinally for subjects as they age where such data is available, to understand how model parameters evolve, improving or decreasing the exponents and residue variance. Moreover, we examine how these quantities vary systematically between the groups, with the aim of characterizing health and disease in the cortex with purely morphological criteria. The control subjects follow collectively a power law with a slope that approaches the predicted theoretical value, while the Alzheimer group presents a significantly lower slope than the controls, suggesting that the exposed area remains constant while the product between thickness and the total area is reduced; this is a measurable morphological effect of the disease in the brain.

Title: Characterizing quantitative MRI changes due to formalin fixation: a longitudinally *Ex vivo* human brain imaging study

Authors: *A. SHATIL[1], K. M. MATSUDA[2], C. R. FIGLEY[3];
[1]Biomed. Engin., [2]Pathology, [3]Radiology, Univ. of Manitoba, Winnipeg, MB, Canada

Abstract: In order to further advance our understanding about MRI signal changes due to formalin fixation over time, we measured different MR properties such as T1- and T2-relaxation, diffusion-based fractional anisotropy (FA), mean diffusivity (MD), and myelin water fraction (MWF) at thirteen different time points. Two neurologically healthy adult female postmortem brains were fixed with 10% phosphate buffered formalin, and four sequences - namely, diffusion tensor imaging (DTI), multi-component T2-weighted myelin water imaging (MWI), and T1-weighted magnetization-prepared rapid gradient-echo (MPRAGE) and MP2RAGE sequences - were acquired in each session using a 3T Siemens MRI system. Image preprocessing pipelines

included a two-stage high-dimensional non-linear warping procedure to normalize the data to the international consortium for brain mapping (ICBM) template. The corresponding FA, MD, T1, T2 and MWF maps were evaluated using five deep white matter (WM) regions of interest (ROIs) (i.e., genu, splenium of corpus callosum, corticospinal tract, optic radiation, internal capsule) and an additional four gray matter (GM) ROIs (i.e., putamen, thalamus, globus pallidus, caudate nucleus).
After plotting the time-course in each ROI at 0, 12, 24, 46, 120, 168, 211, 288, 336, 500, 672, 840 and 1032 hours after initial fixation, we observed that FA, MD and T2 maps remained fairly constant, whereas T1 appeared to increase both in WM and GM regions. Interestingly, MWF maps showed similar increasing trends in all ROIs, with a rapid increase between 46 to 120 hours (except in the caudate nucleus, where the MWF appeared to be more or less unaffected). These linear changes indicate that formalin gradually diffuses inward from the ventricles and cortical surface, and that tissue fixation continues to affect MR properties until, and perhaps beyond our maximum fixation time of 1032 hours (approximately six weeks). Although the underlying mechanisms remain ambiguous, our findings suggest that ex vivo T1-weighted imaging and myelin water imaging should be performed soon after tissue fixation (i.e., to avoid erroneous signals), while diffusion imaging and T2-weighted imaging can be performed reliably after prolonged fixation.

Title: Co-registration of high-resolution structural MRI images for investigating brain functions at submillimeter level

Authors: *Y. CHEN[1], A. CARDENAS-BLANCO[2,1], D. BERRON[1], D. KUMARAN[3,4], E. DUEZEL[1,2,4];
[1]Inst. of Cognitive Neurol. and Dementia Res., Otto-von-guericke-University Magdeburg, Magdeburg, Germany; [2]German Ctr. for Neurodegenerative Dis. (DZNE), Magdeburg, Germany; [3]Google DeepMind, London, United Kingdom; [4]Inst. of Cognitive Neurosci., Univ. Col. London, London, United Kingdom

Abstract: Recent advances in ultra-high field (UHF) magnetic resonance imaging (MRI) allow investigation of brain functions at submillimeter level using functional MRI (fMRI). Studies in

hippocampal subfields and layers of the entorhinal cortex at this scale, for example, greatly furthered our understanding of their roles in cognition, ageing and dementing disorders. The successful application of UHF imaging technique, however, entails a series of methodological challenges, ranging from automatic segmentation to accurate delineation of the interested sub-structures, which have often to be done with multimodal images, including super-high resolution (<0.5x0.5 mm^2 in-plane), anisotropically acquired T2-weighted partial volume (slab) of the brain. Consequently, the co-registration between the T2 slab and the T1-weighted whole brain volume becomes pivotal, as most existing methods, mainly due to the discrepancy in acquisition, fail to co-register reliably or achieve the demanded precision.
Here we propose a new approach to tackle this problem. We based our algorithm on two basic observations: 1. The anatomical boundaries between white and grey matter present exactly reverted gradient vectors in T1 and T2 modalities; 2. The magnitudes of directional gradients reach local maxima at the boundaries. To exploit these properties, we first computed a gradient field for the T2 slab, and then extracted the white matter boundary points in the whole brain T1 volume from a probabilistic segmentation. With these boundary points, we sampled the T2 gradient field and defined an objective function as the mean inner products between these vector samples and their T1 counterparts. We then optimize for a global minimum of the objective function in the transform parameter space, using a combination of gradient descent and multigrid method.
To evaluate the proposed approach, we applied it to two sets of UHF imaging data, of in total 67 subjects, acquired from a 7T scanner with different resolutions. We quantified the coregistration quality in terms of mutual information and cortical segmentation homogeneity. Compared to other existing methods (FSL, ANTs and SPM), our approach exhibited a significant improvement of registration precision and robustness over datasets.
In summary, we present here a novel approach to solve the rigid alignment between multimodal, high-resolution structural images. Our algorithm achieves a submillimeter precision and robust performance over different datasets, and will play a crucial role in facilitating other high-resolution fMRI analyses in complex subfields and cortical layers.

Title: Diffusion kurtosis imaging for the human connectome project

Authors: *A. S. ROKEM[1], E. HUBER[2], P. MEHTA[3,4], R. NETO HENRIQUES[4], M. BALAZINSKA[3], J. D. YEATMAN[2];
[1]eScience Inst., [2]Inst. for Learning and Brain Science, and the Dept. of Speech and Hearing Sci., [3]Dept. of Computer Sci. and Engin., The Univ. of Washington, Seattle, WA; [4]MRC Cognition and Brain Sci., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Diffusion MRI (dMRI) measurements provide detailed information about human brain microstructure in vivo. One of the most commonly used methods to analyze dMRI is Diffusion Tensor Imaging (DTI; Basser et al. 1994). This model approximates diffusion in every voxel as a Gaussian distribution and provides useful information about tissue properties through metrics that summarize this distribution: mean diffusivity (MD) characterizes the mean displacement of water molecules within a voxel, while fractional anisotropy (FA) characterizes the variance in diffusivity across different measurement directions. These parameters from the Gaussian model depend on tissue properties such as the density of the tissue, the myelination of axons, the packing of axons, and the spatial coherence of fiber populations within a voxel. Numerous studies have found that variance in these metrics in specific locations in the brain accounts for variance in human behavior related to psychiatric and neurological disorders, normal development and aging, and psychological traits, providing a close tie between brain tissue properties and behavior. However, in complex tissue, with many barriers to the diffusion process (cell membranes, myelin sheaths, etc.), diffusion can also be non-Gaussian. Diffusion Kurtosis Imaging (DKI; Jensen et al. 2005) is an extension of DTI that accounts for non-Gaussian diffusion. But because it is a more flexible model (21 parameters for DKI versus 6 for DTI), it risks over-fitting to the noise in the data. Using cross-validation, we compared DTI and DKI in the dMRI data provided by the Human Connectome Project (Van Essen et al. 2012). We find that DKI provides a more accurate fit to the data than DTI (smaller cross-validation prediction error). We also find that MD and FA maps are more reliably estimated using DKI than using DTI. We conclude that FA and MD in these data should be calculated using DKI and we provide (1) open-source software to fit the DKI model to data and to calculate MD and FA; and (2) a database of MD and FA maps calculated from HCP data. In addition to its better fit to HCP data, DKI has the additional benefit that it provides additional parameters that lend themselves to a richer biophysical interpretation of the signal.

Title: Frequency distribution of information transfer is task dependent

Authors: *S. E. ROBINSON[1], A. J. MANDELL[2], R. COPPOLA[1];
[1]MEG Core Group, NIH/NIMH, Bethesda, MD; [2]Psychiatry, Univ. of California San Diego, La Jolla, CA

Abstract: We compared the frequency distributions of information transfer using temporo-dynamic symbolic transfer entropy (tdSTE). Transfer entropy (TE) is a bivariate information theoretic measure of directional information flow. This measure was evaluated for 90 centroids in the AAL atlas, giving 8,010 unique pairs. Data were acquired from a 275-channel MEG (CTF/VSM) at a sample rate of 1200 Hz (dc-300 Hz bandpass). For each dataset, a simultaneous linearly constrained minimum variance (LCMV) beamformer was applied to each pair of centroids to obtain estimates of the source time series. The tdSTE was computed for the pair after translation of the sources to symbolic time series, using the rank vector approach. Information transfer rate (ITR) was determined for six 50 Hz wide frequency bands. For three HV subjects, four MEG datasets - *n*-back, p300, clicks, and rest - were acquired in a single session. For each frequency band, the mean and standard deviation was computed for all pairs across the task time period. The rest (task free), p300 (frequent and rare tones), and click (60 bursts of 5 clicks) datasets had similar patterns with the lowest ITR were seen in the 5-50 Hz and 100-200 Hz bands and the greatest transfer rates in the 50-100 Hz and 150-200 Hz bands. By contrast, the *n*-back (working memory) dataset had significantly lower ITR for all frequency bands, with the maxima at 150-200 Hz and 250-300 Hz. One example is presented in the figure, results for the remaining subjects are similar. We expected to observe higher ITRs for the working memory (n-back) task (E/O visual stim with motor response). Instead, it appears that our measure of information transfer is actually reduced in all frequency bands, relative to the resting and auditory datasets (E/C no motor response). A possible cause for this is that each of the 90 nodes is multiply connected with superposition of disparate activity resulting in reduction of TE estimates. Since tdSTE is a bivariate measure, the expected increase in activities for the n-back task result in underestimating TE. A multivariate approach may be necessary to resolve this problem.

Title: Statistically extracting cell-type specific information from human brain transcriptomic datasets captures the effects of age, manner of death, dissection, and psychiatric diagnosis

Authors: *M. H. HAGENAUER[1,2], J. Z. LI[3], F. M. MENG[2], D. WALSH[4], W. E. BUNNEY[4], R. M. MYERS[5], J. D. BARCHAS[6], A. F. SCHATZBERG[7], S. J. WATSON[2], H. AKIL[2]; [2]Mol. Behavioral Neurosci. Col., New York City, NY; [7]Psychiatry and Behavioral Sci., Stanford Med., Stanford, CA

Abstract: Most scientists would agree that psychiatric illness is unlikely to arise from pathological changes that occur uniformly across the entire brain. Despite this fact, the majority of transcriptomic analyses of the human brain are conducted using block-dissected tissue due to the difficulty of conducting single-cell level analyses on donated post-mortem brains. To address this challenge, we compiled a database of more than 3300 transcripts that were specifically-enriched in one of 10 primary brain cell types within published single-cell transcriptomic experiments. Using this database, we predicted the relative cell type composition for 157 human dorsolateral prefrontal cortex samples using Affymetrix microarray data from the Pritzker Neuropsychiatric Consortium, as well as for 841 samples spanning 160 brain regions included in an Agilent microarray dataset from the Allen Brain Atlas. These predictions were generated by averaging normalized expression levels across the transcripts specific to each primary cell type to create a "cell type index". Using this method, we determined that the expression of cell type specific transcripts identified by different experiments, methodologies, and species clustered into three main cell type groups: neurons, oligodendrocytes, and astrocytes/support cells. Overall, the principal components of variation in the data were largely explained by the neuron to glia ratio of the samples. The relative balance of these cell types was influenced by a variety of demographic, pre- and post-mortem variables. In particular, age and prolonged anaerobic conditions around the time of death were associated with decreased neuronal content and increased astrocytic and endothelial content in the tissue, replicating the known vulnerability of neurons to adverse conditions and illustrating the proliferation of vasculature in a hypoxic environment. We also found that the red blood cell content was reduced in individuals who died in a manner that involved exsanguination. When comparing across brain regions, we were able to easily capture canonical cell type signatures - increased endothelial cells and vasculature in the choroid plexus, oligodendrocytes in the corpus callosum, astrocytes in the central glial substance, neurons and immature cells in the dentate gyrus, and interneurons in the globus pallidus. Finally, by including a set of "cell type indices" in a larger model examining the relationship between gene expression and neuropsychiatric illness, we were able to identify more provocative candidate molecules in relationship to major depressive disorder, bipolar disorder, and schizophrenia than using standard methodology.

Title: Mapping of cortex areas from historic and recent studies to the "Atlas of the Human Brain" in standard (MNI-) space

Authors: *J. K. MAI[1], M. MAJTANIK[2];
[1]H-Heine-Univ Dusseldorf, Duesseldorf, Germany; [2]Mr-X-Brain GmbH, Duesseldorf, Duesseldorf, Germany

Abstract: Objective: Many researchers have documented their views of the regional organization of the human cortex with comprehensive 2D images. The interpretation of their results is hindered by the lack of a common framework that allow a comparison with respect to the exact topography and the architectonic properties of distinguished regions. We have registered 2D and surface based maps from many published studies to the 3D-"Atlas of the Human Brain" in standard (MNI-) space to generate high-fidelity correspondence between different maps.
Background: MR-X-Brain® provides a 3D model of the human brain (3D-AHB) with meticulously segmented structures and a software library that allows for automatic registration of the model to the individual brains. Previously we demonstrated the applicability of the software to register the surface-based maps from Brodmann and von Economo and Koskinas to our 3D-AHB. We provided their direct topographic comparison with the cyto- and myeloarchitecure presented in our atlas (Mai et al., Elsevier, 2016) by means of the novel multidimensional data representation as "cortical stripes".
Methods: Our novel way of depicting cortical areal pattern is based on a linear representation of cortical cytoarchitectonic ribbon: the cortical stripe. The cortical stripe is an unfolded linearization of the cortex combined with associated layered parcellation. We have mapped a large number of the published results of detailed architectonic studies (Campbell, Elliot Smith, Sarkissov et al., members of the "Vogt School", Öngür et al.) together with results of recent functional neuroimaging studies. We directly compared between studies and in the context of the cyto-and myeloarchitecture shown in the atlas.

Results and Conclusions: The 3D-representation of the AHB in MNI-space provides a framework for comparing interpretations by different authors on the basis of standard topographic coordinates. Transfer of the 2D maps from different authors to the 3D-AHB allows presentation of each map in coordinated stripes to directly compare the different views ascribed to the homologous cortex region. Because of the linear presentation of x/y in every section (z-coordinate) the numbers of synoptically presented findings

Title: Diffusion tensor distribution function FA boosts power to detect Alzheimer's disease deficits in low resolution data

Authors: ***T. M. NIR**[1], J. VILLALON-REINA[2], A. ZAVALIANGOS-PETROPULU[2], N. JAHANSHAD[2], L. ZHAN[3], A. D. LEOW[4], M. A. BERNSTEIN[5], C. R. JACK[5], M. W. WEINER[6], P. M. THOMPSON[2];

Abstract: In diffusion MRI (dMRI) studies, fractional anisotropy derived from the single-tensor model (DTI-FA) is the most widely used metric to characterize white matter (WM) microstructure despite known limitations with crossing fibers. Due to time constraints, complex diffusion acquisition protocols are rare in clinical studies. However, the tensor distribution function (TDF) can still be used to reconstruct multiple underlying fibers by representing the diffusion profile as a probabilistic mixture of tensors from which a scalar TDF-FA can be calculated. We compared the utility of DTI-FA and TDF-FA to profile deficits in Alzheimer's disease (AD) across various dMRI angular resolutions. 3T T1-weighted and dMRI images were collected from 251 ADNI participants (age: 73.0+/-7.1 yrs; 138M/113F). After distortion corrections, the angular resolution was downsampled from the full 41 gradient directions to optimally distributed subsets of 30, 15, and 7 gradient images. For each angular resolution, we calculated voxel-wise scalar DTI-FA and TDF-FA maps. Subjects' maps were spatially normalized to a common template via ANTs multichannel registration. Voxel-wise random-effects linear regressions tested for FA associations with (1) AD diagnosis (2) CDR-sob cognitive ratings and (3) average hippocampal volume. FDR was used to correct account for multiple voxelwise comparisons. Across all FA metrics, AD diagnosis, greater cognitive impairment, and lower average hippocampal volume, were consistently significantly associated with lower FA. Across resolutions, larger effect sizes and more widespread differences, specifically in the temporal lobes and hippocampal regions, were detected with TDF-FA maps (Figure 1). Ultimately, TDF-FA may be a more sensitive metric than DTI-FA, as it can identify crossing fibers within the tensor model framework. This held true even when the angular resolution was limited to 7 gradients. TDF may be more appropriate than other proposed higher order models for clinical settings where there are time constraints and for low resolution legacy data.

Title: Excluding motion-corrupted resting state fMRI data: is censoring enough

Authors: *R. J. LEPPING[1], H.-W. YEH[2], B. C. MCPHERSON[1,5], R. T. KARCHER[1], M. G. BRUCKS[1], V. B. PAPA[1], A. T. FOX[1], W. M. BROOKS[1,3], L. E. MARTIN[1,4];
[1]Hoglund Brain Imaging Ctr., [2]Biostatistics, [3]Neurol., [4]Preventive Med. and Publ. Hlth., Univ. of Kansas Med. Ctr., Kansas City, KS; [5]Psychological and Brain Sci., Indiana Univ. Bloomington, Bloomington, IN

Abstract: Objective: Head motion in resting-state functional magnetic resonance imaging (rsMRI) corrupts individual volumes within a dataset, and can cause spurious correlations if uncontrolled. The reliability of rsMRI data can be improved by censoring, or 'scrubbing', volumes affected by motion. However, it is a relatively common practice to also exclude subjects in the case of excessive censoring.
rsMRI data are typically assessed for subject-level estimates prior to inclusion in group-level analyses. Datasets that have been heavily truncated due to censoring (i.e., fewer uncensored volumes) yield less-reliable estimates at the subject level. Although censoring removes corruption, it introduces bias to statistical tests resulting in inaccurate estimates and increases financial cost of research. We propose a statistical solution combining standard censoring and weighted regression based on each subject's proportion of uncorrupted to total data. Hence, motion-related noise is adequately removed and datasets with less-reliable subject-level estimates contribute less to group-level statistics.
Methods: We conducted simulations in R to compare statistical power at a range of effect sizes modeled on three scenarios: our weighted regression method; standard motion-censoring; and motion-censoring in conjunction with subject-level exclusions where motion exceeds a certain threshold (i.e., 10%).
Results: Regardless of whether simulated motion was low or high, excluding subjects from group analyses on the basis of trial censorship significantly reduced statistical power. Weighted regression maintained accurate estimates of power across effect size equally well compared to censoring alone.
Conclusion: Based on our simulations, we conclude that subjects should not be excluded from analyses if censoring has been applied. We recommend the application of standard volume-censoring followed by statistical weighting of subject-level estimates based on the proportion of uncensored trial data, as this reduces the impact of less-reliable estimates on group analysis.

Title: Deep learning approach to resting-state networks analysis using fMRI data

Authors: *J.-H. LEE, H. JANG;
Dept of Brain and Cognitive Eng, Korea Univ., Seoul-City, Korea, Republic of

Abstract: Deep learning approaches have recently gained interests in neuroimaging community. For example, the restricted Boltzmann machine (RBM), a single-layer bipartite generative/synthesis model, has been applied to the resting-state fMRI (rfMRI) volumes. There has been, however, no systematic evaluation on the reproducibility of the extracted features. The spatial features using a multi-layer non-linear network model has also not been presented. Our study addressed these two points by using the RBM and greedy layer-wise trained RBMs (i.e. deep belief network, or DBN) to the rfMRI data publicly available via the human connectome project. The FIX-denoised rfMRI data from ten randomly selected subjects were re-sliced to 3mm isotropic voxel (54,885 voxels). The RBM (54,885-150) was trained using a contrastive-divergence-1 approximation of free energy-minimization model. The sparsity level of the RBM weights was measured using a Hoyer's sparseness (0-1; 0 being minimum sparsity; 1 being maximum sparsity). The L1-norm regularization parameter of the RBM weights was adaptively controlled to reach the target sparsity level (i.e. 0.4, 0.6, 0.8, or 0.9). Ten RBM runs were performed using randomly initialized weights for each target sparsity level. The weight vector from the input layer to a hidden node corresponds to a spatial feature. The reproducibility of the resulting 10 sets of 150 spatial features was evaluated using the ICASSO approach. The spatial

features were compared with various representations of rfMRI volumes including the long-term dependency of time series in each voxel. Three-layer DBN (54,885-150-50-10) was then trained with maximal sparsity levels at each layer and the hierarchical organization of the spatial features at the third layer was examined using the spatial features at the first and second layers. The target sparsity of 0.9 at the first layer presented the highest cluster quality index across 150 clusters. The DBN spatial features showed hierarchical organization, in which the 10 spatial features at the third layer consisted of the fine-grained features at the first layer. For example, the default-mode network node in the third layer comprised of the medial superior frontal area, the precuneus and posterior cingulate cortex, and the angular gyrus at the first layer. Our study has a potential to investigate biomarkers of the rfMRI data implicated in the neurologic and/or neuropsychiatric disorders and to develop the machine-learning based systems to conduct automated classification/regression tasks such as to diagnose these disorders.

Title: Detection of peripheral nerve fractions from diffusion weighted image series using two multivariate analyses

Authors: *A. SUDA[1,2], M. TERUMITSU[1], H. MATSUZAWA[2], K. SUZUKI[2], K. SEO[1]; [1]Div. of Dent. Anesthesiol., Grad. School, Niigata Univ., Niigata, Japan; [2]Ctr. for Integrated Human Brain Science, Univ. of Niigata, Niigata, Japan

Abstract: [Introduction]Water diffusion in peripheral nerve is known to provide valuable information on its structural and functional characters and can be quantitatively assessed based on apparent diffusion coefficient (ADC). ADC is estimated from a set of diffusion weighted magnetic resonance imaging (DWI) data as a function of the diffusion weighting factor, referred to as b-value. Since ADC represents the net effect of a complex mixture of diffusion and perfusion components, and hence its signal model is usually unclear, we hypothesize that novel fractions of DWI data would be achieved through decomposition of the data. [Aim] To segregate

multi-b-value DWI data of the trigeminal nerve branches, inferior alveolar nerve (IAN) and lingual nerve (LN), confirming the homonymous artery and vein accompanying IAN as larger capillaries than those in LN. [Methods] Two types of multivariate analysis, cluster analysis and independent component analysis (ICA) with respect to their exploratory decomposition performance were conducted. In healthy men, axial DWI data of eight IAN and four LN were acquired with eight b-values ranging from 0 to 600 s/mm^2 along the anterior-posterior direction. A region of interest was subjected to k-means clustering and ICA. K-means clustering separated the data into three clusters in a voxel-wise manner based on the similarity of b-dependent signal decay profile, while ICA decomposed the same data into a set of spatially independent component (IC) maps. For each cluster, an IC exhibiting the highest correlation between the map patterns was extracted as being potentially relevant. Assuming a double-exponential model for the signal decay of the clusters and ICs, two ADCs, represented as ADCfast (ADCf) and ADCslow (ADCs), as well as the relative fraction f were compared within and between the different decomposition schemes. [Results] Cluster analysis and ICA were segregated into three clusters and ICs, among each of which had different signal decay and map pattern. Among the clusters of IAN, one cluster showed significantly higher ADCf than the others, while no significant differences were observed for ADCs and f. Among the ICs, there were no significant differences in ADCf, ADCs and f. Cluster and IC corresponding high ADCf showed significantly higher f･ADCf. LN showed no significant differences in all fitting parameters among clusters and ICs. [Conclusion] We suggest that one fraction of IAN including a significant perfusion component is segregated, in agreement with histological differences between the two nerves. The remaining fractions would not be characterized and depend on the double exponential model to distinguish them.

Title: Modeling EEG source dynamics associated with emotional responses in a music-listening experiment

Authors: *S.-H. HSU[1,2], Y.-P. LIN[1,2,3], T.-P. JUNG[1,2];
[1]Swartz Ctr. for Computat. Neurosci., [2]Ctr. for Advanced Neurolog. Engin., Univ. of California

San Diego, La Jolla, CA; [3]Inst. of Med. Sci. and Technol., Natl. Sun Yat-sen Univ., Kaohsiung, Taiwan

Abstract: Electroencephalography (EEG)-based emotion classification has drawn increasing attention in the past decade, since EEG is a widely used functional neuroimaging modality with high temporal resolution and real-world applicability. Previous studies focused mainly on developing and optimizing machine-learning methods that consisted of feature extraction, selection, and classification of EEG signals. However, the classification results often had limited interpretability in neuroscience, and the classification accuracy remained far from satisfactory. The critical challenge is that EEG signals associated with emotional responses are still elusive and the responses are nonstationary over time. This study hypothesizes that EEG correlates of different emotional states can be modeled as distinct compositions and modulations of independent sources decomposed from independent component analysis (ICA). This study further proposes a model-deviation index (MDI) to quantitatively assess and track the source dynamics in different emotional states. Specifically, if an ICA model is trained with data under a known emotional state, a low MDI value is expected when the model is used to fit the test data under the same state. On the other hand, if the emotional state has changed, a high MDI value is expected, as the test data deviate from the model. The hypothesis is tested on the EEG data collected from 12 subjects in a music-listening experiment, where each subject sequentially listened to 24 music excerpts (each trial lasted around 37 seconds) and reported one of the felt emotions (happy, neutral, or sad) after each excerpt. Preliminary results on a representative subject showed that the ICA models (trained with EEG data of one happy- or sad-labeled trial) returned lower MDI values in the test trials under the same self-reported emotion than those trials under a different emotion. Furthermore, the differences in the MDI values were more prominent in the beginning of music listening and became less prominent toward the end of music listening. Hence the MDIs from the ICA models could serve as promising features for separating and tracking EEG dynamics of the emotional responses. In summary, the ICA model-based approach incorporating the proposed MDIs not only allows for emotion classification of EEG dynamics, but also provides neurophysiological interpretation to emotion modulations. This approach has online capability that enables applications such as continuous monitoring of emotional states for affective brain-computer interfaces (ABCIs).

Title: Decoupling hemispheres: Comparison of hemispheric specializations using ICA of fMRI statistical maps from Neurovault

Authors: *A. TSUCHIDA[1], B. MILNER[1], G. W. COTTRELL[2], B. CIPOLLINI[2];
[1]Neurol & Neurosur, McGill Univ., Montreal, QC, Canada; [2]Computer Sci. and Engin., Univ. of California San Diego, San Diego, CA

Abstract: The interactions between homotopic regions of the hemispheres are among the most prominent features of the functional network architecture of the human brain. Homotopic functional connectivity is robust and stable across time and conditions, and is thought to coordinate the specialized functions of the hemispheres. Partly reflecting its strength and stability, linear decomposition of brain networks using task-free and task-based fMRI datasets typically recovers networks that are highly symmetrical, especially at a low model order. However, the high degree of interhemispheric interactions may obscure the degree of lateralized network architecture within each hemisphere by treating them as residual to bilateral interactions.

Here we examined the functional networks of the left and right hemispheres by performing independent component analysis (ICA) on each side separately using publicly available statistical maps of fMRI studies. Using the whole-brain ICA components obtained from the same dataset as a reference, we computed spatial similarity scores of each unilateral component and identified the best-matching pair of the left and right component images. We then assessed the functional similarity between the two by decoding the contrast maps associated with the component.

Our analysis shows that overall, unilateral components were reliably matched to the whole-brain components, but with a few notable differences. First, the centroid of some components shifted position relative to their whole-brain counterparts, consistent with unilateral activity being obscured by bilateral analysis. Corroborating this observation, the functional signatures associated with components derived from each hemisphere were overlapping but distinct, even when the components were spatially symmetrical. Second, we found that unilateral and whole-brain approaches showed evidence for hemispheric dominance in a small number of brain networks, suggesting that strongly asymmetric activations show very similar functional signatures. Finally, our unilateral components had greater contrasts than the whole-brain counterparts. This again suggests that bilateral analysis leads to asymmetric activity being treated as “residual” to bilateral activity. Our findings demonstrate the utility of performing hemisphere-specific decomposition analysis to characterize functional symmetry and asymmetry of the brain.

Title: Spectral organization of human brain activity

Authors: *J. S. WYSONG[1], A. C. EVANS[1], J.-M. LINA[2];
[1]Biomed. Engineering, Ludmer Ctr. for Neuroinformatics and Mental Hlth., Montreal Neurolog. Inst., Montreal, QC, Canada; [2]Ctr. de recherches mathématiques, Dept. of Electrical Engin., Univ. de Montréal, École de technologie supérieure, Montreal, QC, Canada

Abstract: D.O. Hebb posited that transiently communicating brain assemblies may generate mental representations. Neural complexity has obscured a fundamental understanding of network mode architecture in active brain networks. MEG signals recorded from healthy human adult brain at rest and while performing a working memory task were studied using a novel framework combining empirical, probabilistic, and theoretical approaches to characterize spectral coupling. In comparison to non informational and random selections of modes, the mode probability and energy distributions in real data exhibit keystones varying across the subject cohort. Here, we report an intricate, but stably self-similar probability distribution of modes that deviates with human intelligence, neural network state, entropy, energy, and order parameter. The data imply that the brain may have adapted resonance coupling common to nonlinear oscillators for the generation of neural information by communicating ensembles in the human brain.

Title: Differential Correlation: A new method to estimate functional connectivity in fMRI

Authors: *W. LIN[1], G. P. KRISHNAN[2], M. BAZHENOV[2], T. J. SEJNOWSKI[1,3];
[1]Salk Inst., LA Jolla, CA; [2]UC San Diego, La Jolla, CA; [3]Howard Hughes Med. Inst., La Jolla, CA

Abstract: Measuring functional connectivity from fMRI is important in understanding processing in cortical networks. However, because brain's connection pattern is complex, currently used methods are prone to produce false connections. We introduce here a new method for estimating functional connectivity. It leverages knowledge from the fMRI transfer function and uses a newly designed differential correlation method to produce better estimation. Benchmarked with a physiologically relevant spiking neural network, our new method's estimation is closer to the ground truth wiring of the network than other commonly used methods. Because our assumptions are simple and the model tested is physiologically realistic, the method has high potential for improving current estimates of functional connectivity.

Title: Inadequate bias correction contributes to discrepancies in structural MRI measures between 8- and 32-channel head coils

Authors: *C. FENNEMA-NOTESTINE[1], R. THEILMANN[2], R. NOTESTINE[3], E. M. MOORE[5], L. A. WETHERELL[3], L. L. STURMAN[1], R. A. CARPER[5], I. FISHMAN[5], R.-A. MÜLLER[5], A. C. GAMST[4];

Laboratory, SDSC, Univ. of California, San Diego, La Jolla, CA; [5]Psychology, San Diego State Univ., San Diego, CA

Abstract: Multi-channel MRI head coils offer improved signal-to-noise ratio (SNR), providing higher resolution images and stronger functional activation. Findings suggest that while global tissue contrast remains similar, SNR and bias fields (i.e., spatially varying intensity gain) differ regionally depending on the number of head coil channels. These effects may impact structural MRI measurements. We compared T1-weighted volume pairs for 22 subjects collected on a 3T General Electric (GE) MR750 scanner using an 8-channel GE and a 32-channel Nova Medical head coil. The 8- and 32-channel volumes were processed independently with FreeSurfer v5.3.0 (using "recon-all -nuintensitycor-3T") for cortical thickness and subcortical volume estimates, and with FSL v5.0.9 (using "fsl_anat --strongbias") for tissue segmentation and subcortical volume estimates. Tissue volume estimates showed a systematic statistical bias when using the 32- relative to the 8-channel coil with less gray (-1.8%) and more white matter (+1.3%) and fluid (+0.8%). Intrasubject differences for all measures were complex and varied by software tool and region. For example, the left and right caudate was slightly larger for 32-channel data (FIRST: +1.7%, +2.1%; FreeSurfer: +0.3, +0.4) while the amygdala was notably larger for FIRST (+19.4%, +8.5%) but smaller for FreeSurfer (-5.0%, -11.1%). To compare summary measures, we used intra-class correlations (ICCs) that incorporated penalties for systematic bias and interactions between measures and head coils. ICCs for commonly reported structures ranged from 0.20 to 0.97 across all measures. ICCs for common subcortical measures ranged from 0.58-0.95 (median 0.89) for FSL's FIRST and from 0.36-0.93 (median 0.64) for FreeSurfer. Although SNR and bias fields both differ between coils, in general, adding Gaussian noise to the 32-channel volumes minimally affected the structural measures. We reviewed ratio volumes of each subject's 8- and 32-channel volumes, which should be relatively uniform after bias-correction. Although both FreeSurfer's and FSL's bias-correction approaches reduced bias overall, FSL's ("strongbias") ratio volume was much more uniform. Finally, multiplying the 32-channel volumes by an estimate of the relative bias field generally improved intrasubject agreement. Our conclusion is that residual bias leads to localized, yet critical, differences in image intensity and intensity gradients between the two volumes. Although effects were variable across software tools and regions, our results caution that 32-channel structural MR data should not be directly combined with or compared to data from lower channel head coils.

Title: Voodoo classification? Biases due to spatial selection and temporal aggregation may hinder the interpretability of MVPA classification accuracy

Authors: *T. GOLAN;
The Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: The application of supervised classification algorithms to neuroimaging data facilitated a series of exciting discoveries in cognitive neuroscience. In addition to the sensitivity gain achieved by optimally pooling data across voxels, MVPA classification seems to offer an intuitive way to convey the strength of an effect: High classification accuracy is commonly interpreted as evidence for well-separable neural responses. This work considers two sources of statistical bias that often render this interpretation invalid.
Selection bias arises when multiple classification problems are evaluated, such as in searchlight classification analysis. While the estimated cross-validated accuracy within each classification-problem may be unbiased, the subsequent statistical thresholding of the resulting accuracy map positively biases the reported results, since locations with favorable noise are more likely to be selected. This issue may affect both within-subject classification of experimental conditions and classification of individuals, as in classification for medical diagnosis.
Aggregation bias arises when the performance of a classifier is evaluated using averaged estimates instead of the original, 'natural' experimental observations. When considering the distinction between classes of task-related neural responses, these natural experimental observations would be single-trial related responses. However, run-wise GLM parameter estimates (beta-values), pooling data across dozens of trials, are often used instead. It is analytically evident that such an aggregation of observations is equivalent with scaling the d' of the tested classifier. Hence in these cases, classification accuracy is in fact a misleading quantity.
The potential impact of these two biases is demonstrated by simulations of realistic analyses. Using the OASIS dataset, a searchlight classification analysis trying to discriminate between T1 MRIs of younger and older individuals showed how selection bias may yield very high performance (up to 100% peak correct classification) given only a weak true separation between the experimental groups. Aggregation bias is demonstrated by a simulation of fast-event related fMRI responses to two experimental conditions. Given a weak (but non-null) single-trial separation between the two conditions, classification accuracy rapidly approaches 100% as the number of aggregated trials within each test-GLM predictor increases.

Although these two biases do not render null results into false-positives, they may still seriously hinder neuroscientific interpretation. Potential remedies and alternative analyses are discussed.

Title: Classifying valence of autobiographical memories from functional magnetic resonance imaging data

Authors: *N. E. NAWA[1,2], A. FRID[3], L. MANEVITZ[3], H. ANDO[1,2];
[1]NICT Ctr. for Information and Neural Networks (CiNet), Suita-Shi, Japan; [2]Grad. Sch. of Frontier Biosciences, Osaka Univ., Suita-shi, Japan; [3]Univ. of Haifa, Haifa, Israel

Abstract: A machine learning-based scheme was employed to predict the valence of the autobiographical memories recalled by human subjects based on the information contained in a single functional magnetic resonance imaging (fMRI) scan. Subjects (N = 11, 6 females, age 21 - 37, average 28.2 years old, right-handed) were asked beforehand to prepare a list of happy and sad events that they had experienced in the past. During scanning, subjects were asked to keep their eyes closed and given auditory cues which indicated whether they should alternate between blocks of (a) counting down numbers and (b) recollecting positive or (c) negative autobiographical memories. Recollection in the memory blocks was self-paced, and subjects were asked to remember as many details as possible of the events. Blocks lasted 32 seconds, and were interleaved with rest periods of 16 seconds; each block type was repeated 3 times in each session. In 6 sessions, subjects switched between tasks (a) and (b), and in the remaining 6 sessions they switched between tasks (a) and (c). All sessions were performed in the same day. One hundred forty seven scans were acquired in each session (TR = 2 s, 33 4-mm slices, in-plane spatial resolution of 3 mm x 3 mm). Each single scan was encoded as a vector containing the blood-oxygen level dependent (BOLD) signal of voxels covering the entire brain. Classification was performed in two steps: first, a subset of 2500 voxels was constructed using a modified version of the Relief algorithm, which assign weights to the features (voxels) according to the average distance to the target group, based on the “k-nearest” neighbors of the exemplar (fMRI scan). Next, a classifier based on a linear combination of one-level decision trees was constructed for each subject using the AdaBoost algorithm. This two-step scheme accomplishes two things (i) it drastically reduces the number of features since only the voxels yielding above

chance level classification are passed to the AdaBoost algorithm, and (ii) it identifies the subset of most informative voxels, as the final classification is determined by a linear combination of the automatically selected features. Within-subject classification accuracy was assessed via cross-validation, with 70% of the data used for training, and 30% for testing. Individual results for the valence classification were in the range of 70.4% and 89.3%. These results represent a substantial improvement from the previously obtained results, and indicate that data-driven methods may help unravel the neural mechanisms involved with complex cognitive-affective processes such as recalling emotional personal events.

Title: Replicability of MEG and fMRI responses to movie stimuli

Authors: *K. LANKINEN[1], J. SAARI[1], Y. HLUSHCHUK[2,5,3,6], P. TIKKA[3,2], L. PARKKONEN[1], R. HARI[1,4], M. KOSKINEN[1,7];

Abstract: Movies, mimicking audiovisual stimuli experienced in everyday life, provide a useful tool to study sensory and cognitive brain functions in naturalistic experimental settings. Despite

the apparent complexity of movies, previous studies with functional magnetic resonance imaging (fMRI), magnetoencephalography (MEG) and electroencephalography (EEG) have shown consistent brain activations time-locked to movie events.
MEG that measures neuronal currents directly and fMRI that reflects hemodynamics related to neuronal activity provide complementary views to human brain function. Here we compared MEG and fMRI signals during presentation of a 15-min black-and-white movie ("At Land" by Maya Deren, 1944) that eight subjects viewed twice during 3-T fMRI and twice during 306-channel MEG recordings. To reveal the replicability of the responses, we computed *intra-subject* correlations of the signal time courses between the two trials and *inter-subject* correlations across subjects; the analysis was made for each anatomical location, separately for MEG and fMRI, as well as cross-modally between MEG and fMRI.
The sources of MEG signals (studied in 12 different frequency bands from 0.03 to 85 Hz) were found by minimum-norm estimation, and the source-level time series and their envelopes were used for correlation analyses. Individual MEG and fMRI data were morphed to the same anatomical space.
For fMRI, both intra- and inter-subject correlations were high (up to 0.7) especially in occipital, parietal and precentral areas. MEG showed intra-subject correlations up to 0.2 in occipital areas, whereas inter-subject correlations were low (< 0.1). Cross-modal correlations between MEG and fMRI were also low (< 0.1).
Our results demonstrate high replicability of the hemodynamic fMRI responses to a movie, both within and between subjects, whereas the electromagnetic MEG responses were replicable only within subjects and poorly replicable across subjects. The low cross-modal correlations were likely due to the differences in the signals' neurophysiological origins, spatial activation patterns, and temporal dynamics. The replicability can be further impaired for instance by inter-individual anatomical differences, inaccuracies of source identification, and different signal-to-noise-ratios of MEG and fMRI. More advanced analysis methods are needed to properly explore the connection between fMRI and MEG signals recorded in naturalistic settings.

Title: Super resolution reconstruction based on orthogonal fusion and sub-pixel shifting techniques for diffusion weighted images

Authors: *H. PENG[1], S. E. CHRIST[2];
[1]Psychological Sci., Univ. of Missouri Columbia, Columbia, MO; [2]Psychological Sci., Univ. of Missouri, Columbia, MO

Abstract: Background: Diffusion weighted (DW) images are inherently characterized by long acquisition times, low spatial resolution, and low signal-to-noise ratio (SNR). Super resolution reconstruction (SRR) techniques have been recently applied to DW images to improve through-plane resolution by combining multiple low resolution (LR) images to reconstruct a high resolution (HR) image. In order to improve both in-plane and through-plane resolution, we propose a new strategy of acquiring LR DW images, which combines the fusion of orthogonal acquisitions and sub-pixel shifting techniques.
Methods: LR DW image datasets ($2mm^3$) of a healthy 43-year-old female volunteer were acquired with a 3T Siemens Trio scanner. Along each of the 3 orthogonal orientations (axial, sagittal, and coronal), DW images were acquired twice with the same parameters except that the second FOV was shifted by 1mm relative to the first acquisition. 2 $b=0s/mm^2$; 12 directions at $b=1000s/mm^2$. The number of slices was chosen to cover the whole brain, varying from 72 to 102 depending on the acquisition orientation. The total acquisition time for the LR DW images was 25min54sec. HR DW images ($1mm^3$) were then reconstructed using SRR with an iterative back-projection approach.
For comparison, we acquired a conventional DW scan with parameters chosen to match the acquisition time of the previous scans: resolution=$1.5mm^3$; 96 slices. 7 $b=0s/mm^2$, 61 directions at $b=1000s/mm^2$, 2 averages. The total scan time was 30min46sce.
Additionally, a dual echo gradient echo field map image was acquired to correct for the image distortion induced by field inhomogeneity.
Fractional anisotropy (FA) and color FA maps were derived from DW images. SNR of the FA map was measured in uniform regions in the corpus callosum (CC) and internal capsule (IC). FA profile was plotted along a line crossing the brain to evaluate the sharpness of the FA maps.
Results: The SRR FA showed overall less noisy and finer structure than the conventional FA. SNR in the region of CC (26.3 vs. 14.0) and IC (11.4 vs. 9.4) was higher for the SRR FA compared to the conventional FA. The SRR FA maps appeared sharper than the conventional FA. Several white matter structures appeared markedly darker in the conventional compared to the SRR FA color maps. Finally, some small white matter structures such as anterior commissure, were clearly visible only in the SRR FA color maps.
Discussion: The SRR DW images have improved in-plane and through-plane resolution. Meanwhile, the SRR FA and color maps were characterized by higher SNR and image sharpness, provided the ability to distinguish smaller white matter fiber structures. Future work will be focus on reducing total scan time.

Title: Scan duration and test-retest reliability of functional connectivity

Authors: *S. M. NOBLE[1], D. SCHEINOST[2], M. N. SPANN[4], F. TOKOGLU[3], R. T. CONSTABLE[2];
[1]Interdepartmental Neurosci. Program, [2]Radiology & Biomed. Imaging, [3]Yale Univ., New Haven, CT; [4]Psychiatry, Columbia Univ., New York, NY

Abstract: Resting state functional magnetic resonance imaging (fMRI) is typically acquired over the course of a 5-minute session and subsequently used to estimate functional connectivity in the brain. However, emerging data suggest that it may be necessary to increase the amount of data acquired for each subject in order to achieve stable subject-specific connectivity maps. Many studies suggest the use of longer scanning durations, but exact recommendations have been varied because different studies employ different definitions of reliability and the dataset required for an accurate assessment of reliability must be comprehensive. Here we assess the reliability of different scan durations using a comprehensive test-retest dataset and Generalizability Theory, an extension of classical intra-class correlation designed to assess the contribution of multiple facets of measurement and their repeated measures on reliability. We acquired resting state fMRI over four months from 12 healthy subjects who were each scanned on four separate sessions. Scans were conducted one to two weeks apart at two 3T scanners. Each session constituted six 6-min multiband acquisitions, enabling high spatial resolution relative to typical acquisitions. In total, 2.4 hours of data was collected for each subject. We then assessed reliability of functional connectivity between all nodes in the Shen-278 functional parcellation atlas ("matrix connectivity"), and separately from PCC nodes to all nodes in the atlas ("PCC seed connectivity"). For matrix connectivity, relative reliability (E_ρ^2) of functional connectivity from a single run was found to be 0.23 +/- 0.18, whereas relative reliability of functional connectivity averaged across all six runs was found to be 0.39 +/- 0.21. For PCC seed connectivity, relative reliability of functional connectivity from a single run was found to be 0.24 +/- 0.16, whereas relative reliability of functional connectivity averaged across all six runs was found to be 0.40 +/- 0.21. We then conducted a Decision Study to assess reliability as a function of different numbers of sessions. Using a single run, fair reliability is achieved over 3-4 repeated sessions, whereas using all six runs, fair reliability is achieved over 2 repeated sessions. We will also examine the reliability of voxelwise connectivity measures (e.g., degree, ICD) as well as the

spatial distribution of reliable measurements. These results suggest that increasing the number of runs acquired is an essential step towards guiding the development of functional connectivity-based analyses extended to the single-subject level.

Title: Metal-induced susceptibility artifact correction for DBS-fMRI using the PSF mapping method combined with reversed gradient approach

Authors: *M.-H. IN[1], H.-K. MIN[1,2,3], Y. SHU[2], M. A. BERNSTEIN[2,3], H. J. JO[1], K. H. LEE[1,3]; [1]Neurologic Surgery, [2]Radiology, [3]Physiol. and Biomed. Engin., Mayo Clin., Rochester, MN

Abstract: Introduction: Deep brain stimulation (DBS) is an effective neurosurgical approach for treating motor disorders. To investigate the underlying mechanisms, non-invasive fMRI is performed. However, the application in patients with implanted DBS has faced metal-induced susceptibility artifacts near the metallic electrode contacts resulting in significant signal dropouts and geometric distortions. We aim to resolve the problems using the point spread function (PSF) mapping-based distortion correction method combined with reversed phase encoding (PE) gradient approach.
Methods: A healthy pig underwent unilateral nucleus accumbens DBS. A PSF data was measured to correct geometric distortions in following DBS-fMRI scan. The PE polarity in echo planar imaging (EPI) was altered, which resulted in a pair of EPI images with opposite geometric distortion, and measured with an 'interleaved' order during fMRI scan. Three fMRI runs were performed using a different stimulation parameter at 3T. From each fMRI run, three BOLD contrasts were calculated from each EPI series with forward and reverse PE polarity and the combined series of the distortion corrected EPI pair.
Results: The overall size of BOLD contrast increased with the increment of the stimulation voltage (Fig. 1A). Due to metallic electrodes, however, strong metal-induced susceptibility artifacts appeared in EPI data. In contrast to stretched distortions, even stronger signal dropouts appeared in compressed areas resulting in the total loss of BOLD contrast. The lost information could be observed from the corresponding EPI with opposite PE polarity due to the opposite geometric distortions. After distortion correction, the geometry of the EPI pair matched very well

with the distortion-free reference image. Therefore, the BOLD contrast from the combined EPI preserved very well both BOLD contrasts from the EPI pair (Fig. 1B).
Conclusions: Our results demonstrate that the proposed approach potentially can effectively resolve the loss of BOLD contrast, which may be beneficial in investigating the DBS mechanisms.

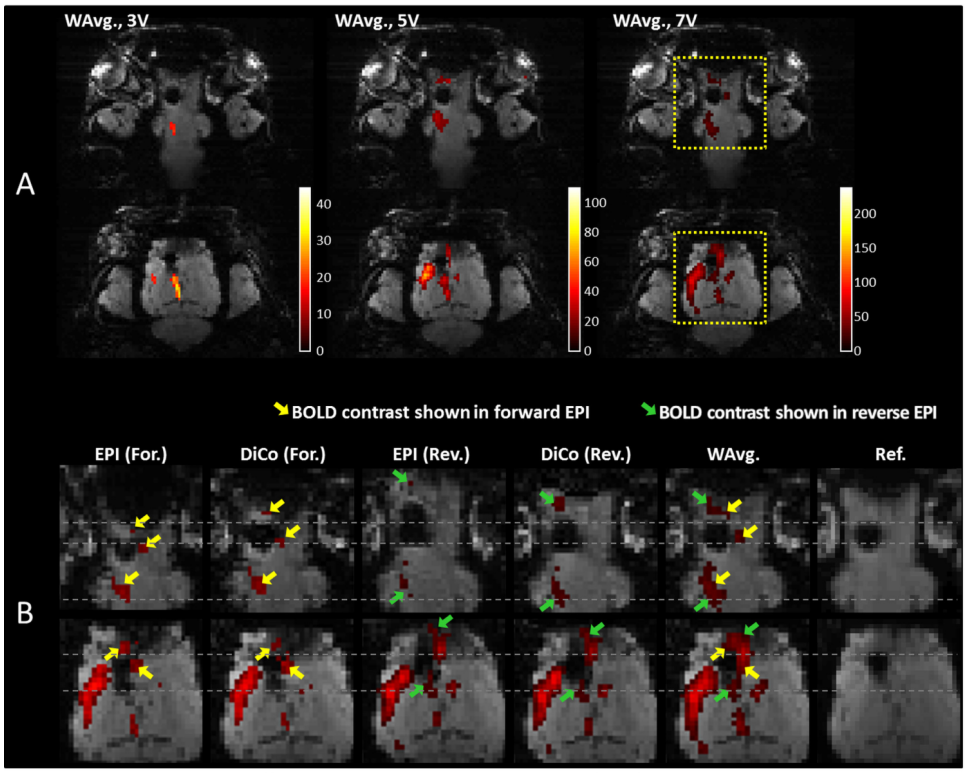

Fig.1. BOLD contrast with different stimulation voltages (A) and PSF-based reverse gradient approach (B). Three different voltages including 3 (left), 5 (middle), and 7V (right) were applied for stimulation and note the different color scale of BOLD contrast in (B). Forward (For.) and reverse (Rev.) phase-encoded EPI images with and without distortion correction (DiCo) and the weighted average of the distortion corrected EPI pair (WAvg.). For comparison, a reference image (Ref.) without geometric distortion was shown. BOLD contrasts were calculated from the corresponding EPI series and overlaid on the mean image. Two slices among 19 were chosen for demonstration purpose and the zoomed areas of the full FOV image (A) were shown in (B). Light-gray dashed lines indicate geometrical difference between BOLD contrasts overlaid on the mean EPI images before and after distortion correction.

Title: Individual brain charting: a neuroimaging database featuring the first functional atlas of the human brain

Authors: *A. L. PINHO[1,2,3], B. THIRION[1,2,3];
[1]INRIA Saclay, Gif-sur-Yvette, France; [2]Neurospin, CEA, Saclay, France; [3]Paris-Saclay Univ., Paris, France

Abstract: One of the most striking endeavors in neuroscience is the accomplishment of a comprehensive functional representation of the human brain in which models concerning its organization could be derived from neuroimaging data. Many studies have extensively addressed high cognitive processes as well as perceptual mechanisms through the analysis of patterns of activity extracted from several imaging modalities. However, the absence of concomitant procedures for data collection, comprising different acquisition techniques with a broad selection of model behaviors, undermines the feasibility of performing generalizations about neural pathways. Particularly, task categories under specific constraints are used in functional Magnetic Resonance Imaging (fMRI) cohorts to assess brain activity involved in putative neurocognitive mechanisms. Yet, inter-subject functional and anatomical deviations arise as great sources of variability and such problems shall be tackled by appropriate registration algorithms that account for various imaging contrasts from different modalities. Here, we present the Individual Brain Charting (IBC) project: a ten-year initiative integrated into SP2 of the Human Brain Project (HBP). The main goal is to develop a multi-modal database pertaining to the topography of both functional specialization and functional connectivity of the human brain. This resource features foremost high-resolution fMRI (1.5mm) maps concerning a limited group of subjects on the performance of several canonical tasks. High resolution anatomical images along with diffusion MRI data will respectively provide a fine segmentation and structural connectivity representation of the brain. The database is complemented by behavioral protocols and task-related data extracted from each subject. These protocols comprise a wide variety of tasks, addressing both perceptual and cognitive functions (e.g. retinotopy, tonotopy, calculation, language processing and social cognition). The unambiguous encoding between task descriptors and brain imaging data allows for a parcellation of the brain volume into functional-specific regions. Such profiles assigned to brain regions designate the functional atlas that carries information on cognitive processes specific to these regions. This facility displays several kinds of post-processed data suitable for various meta-analysis techniques. Raw and processed data are documented and made available online. In addition, IBC datasets are stored in prototypical platforms developed by other HBP partners and unthresholded statistical maps can be accessed through the web-based repository NeuroVault.org.

Title: Stable representation of hubs in functional networks

Authors: *R. MADHAVAN, B. R. SUNDAR, S. E. JOEL;
Med. Image analysis Lab., GE Global Res., Bangalore, India

Abstract: Cortical brain networks have been shown to have few nodes with high density of connections that play a critical role in maintaining the efficiency of the network. These few nodes, termed hubs, have large influence on the network due to their central position and are critical for information flow. “Hubness” can be measured in multiple ways including: (1) Degree: identifies the most connected nodes (2) Betweeness centrality: nodes along the shortest paths (3) Participation coefficient: nodes that participate in multiple sub-networks (modules) of the brain (4) Shapley value: Function of degree of neighbors for each node. While all of these hub definitions are valid, there is no consensus in the field on the definition of “hubness”, and few studies have reported good reproducibility of “hubness” across imaging sessions/subjects. In this study we examined the stability of functional hubs identified using these methodologies across multiple subjects and scans. We collected resting state functional MRI data (rs-fMRI) in 10 healthy controls (10 7-minute scans were obtained over 2 sessions) to examine the functional topological properties of large-scale brain networks. Functional connectivity matrices were generated for each subject at each scanning session (n=100) by parcellating the brain into 90 (or 264) nodes, and constructing networks from the edges between nodes representing correlation coefficient of rs-fMRI time courses. We constructed binary adjacency matrices or graphs over a range of connection densities (2-10%). Hubs were identified on connectivity matrices across all densities using above-mentioned four features. The features were summed over thresholds, subjects and scans to identify nodes that routinely showed high probability of “hubness”. Nodes that showed high summed values and low variance were identified as stable hubs. These hubs were mainly located in regions of the default mode network (DMN) and inferior parietal regions. Surprisingly, on comparing the hubs identified by these 4 definitions, we found a set of nodes that satisfied more than one property of “hubness”. These versatile hubs were located in the inferior parietal gyrus, precuneus and superior frontal gyrus that are part of the executive control, salience and dorsal attention systems. Notably, the DMN regions including the cingulate cortex are only reflected in hubs defined using participation coefficient. Hubs have been shown to be vulnerable nodes in disease. Here, we show the presence of versatile, multi-functional “super-hubs” that are stable across time and subjects, and suggest that damage to these hubs could result in severe cognitive impairment.

Title: Your brain on art: examining the neural substrate of creativity in the arts using mobile brain-body imaging (MoBI)

Authors: ***J. G. CRUZ-GARZA**, A. E. KOPTEVA, A. Y. PAEK, J. L. CONTRERAS-VIDAL; Electrical and Computer Engin., Univ. of Houston, Houston, TX

Abstract: Creativity has been predominantly studied in three major categories: divergent thinking, insight problem solving, and having professional artists perform. Interestingly, the brain regions that are engaged in creative tasks are also known to play a role in cognitive processes not usually associated with creativity such as working memory, attention, and cognitive goal-oriented control. We propose to study the dynamic interaction between these cognitive processes in an unconstrained natural setting when professional artists create art in front of an audience.

Artists who are well experienced and established in their fields participated in this study. They were fitted with mobile brain-body imaging (MoBI) technology and worked collaboratively following the 'Exquisite Corpse' protocol; a creative game developed by the Surrealists in the early 1920's that embraces elements of chance and surprise. The game involved having the three artists collaborate on a work of art that is made up of 3 segments. Each artist takes turns completing a segment for 15 minutes while using only a small cue from the previous artists's work. There were five sessions of three unique participants across different artistic modalities: visual art, dance, music, and creative writing. In order to dissect the multidimensional nature of creativity, the artists provided input to identify significant events in their creative process. The involvement of the artists in the analysis is essential to investigate the neural mechanisms associated with the distinct cognitive processes involved. Both bottom-up and top-down analyses were performed. The experiment was conducted in the presence of general audiences in public spaces at the University of Houston. A real-time visual representation of the artists' brain activity, filtered in the alpha band (8-13Hz) was displayed in real time for the general audience,

while members of the research team explained the evolution of the brain patterns, thus allowing STEAM outreach.
We present our findings regarding the spatial and temporal dynamics in neural activity as the participants engage in an unconstrained creative process. Furthermore, we deploy neural engineering techniques to investigate the cognitive, emotional and motor intent of the artists as they create their art. We aim to reach an understanding for how the brain concurrently processes sensory input and dynamic internal state to produce the aesthetic experience; while at the same time inviting the community to be part of the scientific process by participating as volunteers, asking questions, and observing how the experiment unfolds.
