Title: The role of novel subset of mesencephalic neural crest derived neurons in cerebellar nuclei development in mice

Authors: *M. RAHIMI-BALAEI[1], K. BAILEY[2], N. ASHTARI[1], X. JIAO[1], H. MARZBAN[1]; [1]Human Anat. and Cell Sci., [2]Col. of Med., Univ. of Manitoba, Winnipeg, MB, Canada

Abstract: Introduction: The cerebellum functions in motor coordination and also implicated in non-motor behaviors including emotion and cognition. Purkinje cells (Pcs) are the sole output of the cerebellar cortex and they project to the cerebellar nuclei (CN). The CN provide the main output of the cerebellum. During cerebellar development the CN neurons and Pcs are the earliest born among the different neuronal subtypes. However, they are generated from two distinct germinal zones: the ventrally located ventricular zone, which produces Pcs and the dorsally located rhombic lip, which produces large CN neurons. We found a new subset of the neurons derived from mesencephalon, a new germinal zone, and seems play an important role in cerebellar development.
Methods: In this study we utilized whole mount/section immunohistochemistry, western blotting and primary dissociated cerebellar, embryonic slice and embryonic cultures to examine the origin and role of a new subset of CN neurons in cerebellar development.
Results: It is believed that the isthmus organizer is a signaling center and district mesencephalon from rombencephalon. Our results showed that a subset of CN neurons, which are immunopositive for α-Synuclein (SNCA) and Otx2 (a mesencephalic derived cell marker), originate from the mesencephalon and migrate to the rostral end of nuclear transitory zone. SNCA and p75 neurotrophin receptor double immunostaining suggests that these cells are derived from neural crest cells and form a combination of neurons and nerve fibers that terminate to the subpial surface of putative lobules VI/VII. Interestingly, the $SNCA^{+}/Otx2^{+}/p75^{+}$ cells which divide the cerebellar primordium into rostrodorsal and caudoventral compartments, are cleaved caspase 3 (CC3) and PARP immunopositive. All of these data are in support of the role of these cells ($CC3^{+}$) in proliferation, differentiation, survival and axonal guidance.
Conclusion: The presence of mesencephalic derived early CN neurons in the nuclear transitory zone suggest a regulatory role as a “signaling center” that may play as an intrinsic organizer during early cerebellar development.

Title: Evidence of GDNF receptor alpha-like protein (GFRAL) as a new GDNF family ligand receptor

Authors: *G. WANG, L. XIONG, T. GERASSENKOV, V. KALABOKIS, A. PERSON; Bio-techne, Minneapolis, MN

Abstract: The glial cell line-derived neurotrophic factor (GDNF) family ligands (GFLs) and receptors are major neurotrophic networks in the nervous system. They play important roles in axon guidance, synapse formation, neuronal survival, neural regeneration, and are implicated in a number of neurological diseases. There are four GFLs: GDNF, Neurturin, Artemin, and Persephin. These ligands are known to bind to the co-receptors GFRα-1, GFRα-2, GFRα-3, and GFRα-4, respectively, through which they activate the common signal transducer, receptor tyrosine kinase RET (Rearranged during Transformation). A fifth co-receptor gene, GDNF receptor alpha-like (GFRAL) was identified in 2005, but the function of the orphan GFRAL receptor is currently unknown. We have synthesized recombinant human GFRAL protein and tested the hypothesis that GFRAL interacts with known GFLs to change the dynamics of GFLs and their receptor networks. Both ELISA binding studies, and cell-based assays, were carried out using standard methods. Our results show that Neurturin binds to GFRAL with a high affinity (EC_{50} = 8 ng/ml, n=4). Artemin binds to GFRAL with a low affinity (EC_{50} = 2 μg/ml, n=2). GDNF and Persephin have only minimal or no binding to GFRAL (n=3). Addition of GFRAL proteins at a concentration of 0.5 ug/ml in cell culture media stimulated Neurturin-induced cell proliferation in the SH-SY5Y human neuroblastoma cell line (EC_{50} of Neurturin = 0.5 ug/ml, n=4). This effect of GFRAL is similar to that of GFRα-2 (EC_{50} of Neurturin = 1 ug/ml, n=4), although the maximal response by GFRAL is lower than that of GFRα-2. GFRα-2 dose-dependently increased the effect of GFRAL in stimulating the Neurturin-induced cell proliferation in SH-SY5Y cells (n=2). On the contrary, addition of GFRAL did not affect the stimulatory effect of GFRα-2 on Neurturin-induced stimulation of SH-SY5Y cell proliferation. This is the first study to demonstrate that GFRAL interacts with GFLs, primarily Neurturin and Artemin, and can play a major role in GFLs and receptor networks involved in neuronal processes. These data also demonstrate that biologically active recombinant GFRAL protein can be used to identify new GFRAL ligands, and can also be used as a new tool to investigate GDNF-related signaling mechanisms. The identification of this novel interaction between GFRAL and GDNF family ligands will enhance our understanding of the mechanisms and applications of GLFs, and their receptors, in neurodegenerative and neuropsychiatric diseases.

Title: Transitory expression of vasopressin in developing hippocampus of male rats

Authors: ***M. A. ROQUE**[1,2], R. RUIZ[2], S. HERNANDEZ[2], J. VALDEZ[3], L. ZHANG[4], N. LAJUD[2];
[1]Univ. Autonoma De Mexico, Morelia, Mexico; [2]Ctr. de Investigacion Biomedica de Michoacán, Morelia, Mexico; [3]Ctr. Multidisciplinario de Estudios en Biotecnologia, Morelia, Mexico; [4]Dept. de Fisiología, Facultad de Medicina-UNAM, Mexico, Mexico

Abstract: Arginine-vasopressin (AVP) is a neuropeptide involved in the control of social behavior, learning and memory and stress response in adult animals. During the first two weeks of life AVP receptors type 1A are expressed in the forebrain, including the hippocampus, were they have been proposed to modulate development of excitatory/inhibitory balance; however the developmental trajectory of AVP expression has not been fully described. Therefore the aim of the study was to analyze the expression of AVP mRNA in hippocampus and hypothalamus during the first two weeks of life. Male rat pups were sacrificed at postnatal day (PD) 6, PD12 and PD15. The hippocampus and hypothalamus were dissected and AVP expression was analyzed by PCR. Our results show that hypothalamic expression of AVP was unchanged throughout development. In the hipocampal extracts AVP expression was not detectable at PD6, however we observed a peak of AVP expression at PD12 that decreases at PD15. These results demonstrate a transitory expression of vasopressin during the first two weeks of life. During this time window AVP could be involved in modulating hippocampal development.

Title: Formation of neuronal circuits by interactions between neuronal populations derived from different origins in the *Drosophila* visual center

Authors: *M. SATO[1,2], T. SUZUKI[3];
[2]Inst. for Frontier Sci. Initiative, [3]Brain/Liver Interface Med. Res. Ctr., [1]Kanazawa Univ., Kanazawa, Japan

Abstract: During brain development, various types of neuronal populations are produced from different progenitor pools, and are precisely arranged and correctly connected with their partner to establish a functional neural circuit during brain development. If the neurons produced by these different origins were combined, the neural diversity would be further expanded. This strategy to expand neural diversity by combining neurons produced by different origins has been found in mammalian brain development. However, the molecular mechanisms that specify the identity of each progenitor pool and orchestrate the arrangement of neurons derived from different origins have been obscure. In this study, we utilize the medulla, the largest component of the *Drosophila* visual center, as a model to study brain development and show that different types of neurons are produced from two progenitor pools: the outer proliferation center (OPC) and glial precursor cells (GPC). We also show that Wnt signaling is essential for the regionalization of the medulla through the specification of the GPC, the posterior progenitor pool. We also demonstrate that cell-cell interactions play important roles in precise arrangement of neurons of different origins, OPC-derived and GPC-derived neurons. We found that GPC-neurons migrate tangentially into the developing medulla cortex and that the tangential migration is regulated by Slit-Robo signaling through the interaction between GPC- and OPC-neurons. Our results suggest that conserved signaling pathways such as Wnt and Slit-Robo signalings are involved in the specification of neural progenitor pool and interactions between neurons of

different origins. Similar molecular mechanisms may be conserved in a wide variety of brain development from invertebrates to vertebrates.

Title: Toward a genomic perspective of interneuron lineage specification *In vivo*

Authors: *A. S. NORD[1], M. SANDBERG[2], L. SU-FEHER[3], S. SILBERBERG[2], A. RUBIN[2], I. ZDILAR[3], S. LINDTNER[2], J. L. R. RUBENSTEIN[2];

Abstract: Understanding interneuron specification is of major interest given the critical role interneurons play in the brain and in neurological and neurodevelopmental disorders. Genomic signaling pathways governed by the interaction between transcription factors (TFs), regulatory elements, and chromatin regulate gene expression to give rise to specific interneuron subtypes in the basal ganglia during early brain development. We are dissecting the basis of interneuron specification in the mouse brain. To characterize signaling cascades at a systems biology level, we are combining ChIP-seq with bulk tissue and single cell transcriptomics to profile TF binding, epigenomic state, and gene expression. As an example, we have characterized the activity of Nkx2-1 and Lhx6, TFs that are critical in interneuron specification. Via epigenomic comparison in Nkx2-1 conditional mice, we show that Nkx2-1 binding at distal regulatory elements causes changes in histone modifications and correlated changes in gene expression. Combinatorial binding by Nkx2-1 and Lhx6 at the same set of distal enhancers directs activation of gene expression in a cell- and region-specific manner in cortical migrating interneurons. We are extending this genomic approach to other TF pathways relevant in interneuron lineage specification. In parallel, we are applying single cell transcriptomics to characterize cell identity and transcriptional regulation. By integrating across genetic, genomic, and neuroanatomical

approaches, we hope to decipher the transcriptional wiring guiding interneuron specification at the molecular, genomic, and single cell level.

Title: Pax6 control of gene expression in developing mouse diencephalon

Authors: *I. QUINTANA-URZAINQUI, Z. KOZIC, D. J. PRICE;
Genes and Develop. Group, Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: During embryonic development, the forebrain vesicle expands to form two bilateral telencephalic vesicles that engulf a central diencephalic vesicle. The telencephalon gives rise to the cerebral cortex and the basal ganglia, while the diencephalon's main derivative is the thalamic complex. The formation of such complex structures requires the coordination of multiple molecular networks controlled by a relatively small group of transcription factors. Pax6 is a pleiotropic transcription factor in development. It is a key regulator of multiple aspects of neural development including patterning, neurogenesis, differentiation, cell migration and axon growth. Its mutation causes the small eye phenotype in mice or aniridia disorders in humans. An important role in telencephalic and diencephalic development has also been attributed to Pax6 since small eye mutants display major defects in forebrain structures, brain size and fail to form thalamocortical connections. Pax6 control of gene expression during development has been largely studied in structures such as the eye and the cortex. However, little is known about its molecular actions in the diencephalon, despite the prethalamus being one of the areas of the brain where Pax6 is most highly expressed during development (see Figure). Using RNA-seq we have analysed the changes in gene expression in the developing mouse thalamus, prethalamus and anterior cortex after acute, tamoxifen-induced deletion of Pax6. The computational comparison of the data between the three tissues yielded interesting insights on the common actions of this transcription factor across the brain and, maybe more importantly, on the pathways that Pax6

might be controlling in a tissue-specific manner. Functional analysis indicated that processes such as axon guidance and cell cycle progress were deeply affected after Pax6 deletion in the diencephalon. In this work we present experimental data confirming and expanding some of the hypotheses raised from computational analysis, paving the way towards a better understanding of Pax6 actions in the diencephalon.

Title: FGF8 locally promotes formation of olfactory bulb-like structures

Authors: *E. A. GROVE, S. ASSIMACOPOULOS;
Dept Neurobio., Univ. Chicago, Chicago, IL

Abstract: A major goal in developmental neurobiology is to identify the mechanisms that generate different types of cerebral cortex and regulate their unique circuitry. Fibroblast Growth Factor 8 (FGF8), dispersing from an anterior telencephalic source, forms an anterior to posterior (A/P) gradient setting up the A/P axis of the neocortical area map. We asked whether FGF8 also induces development of the olfactory bulb (OB), the third and most anterior division of cerebral cortex; the OB primordium (OBP) is adjacent to or partly inside the anterior FGF8 source. Using in utero microelectroporation (IUME), ectopic FGF8 was introduced into the lateral cortical

primordium of the mouse at embryonic day (E) 10.5. This procedure consistently produced a remarkable and complex olfactory bulb like structure (OBLS), without an overt migration of endogenous OB cells to the site. At E16.5 and P6, ovoid masses of cells were marked by neuropilin-1 (NRP1) and T-Box 21 (TBX21) immunofluorescence (IFl), which identifies mitral and tufted (M/T) cells, projection neurons of the OB. From the M/T cells, compact axon bundles traveled ventrally to join the lateral olfactory tract (LOT). Guidepost "lot" cells formed a cup shape around the endogenous OB and surrounded the LOT; meanwhile, ectopic lot cells encircled each OBLS and its LOT tributary (tLOT). The FGF8-induced OBLS also contained cells expressing molecules indicative of OB interneurons, suggesting neuroblasts can be diverted from the rostral migratory stream by targets other than sites of injury. Previous studies suggest the LOT develops under strict constraints. Lot cells and Slit/Robo signaling seemed to constrain the LOT to its ventrolateral position, and lot cells appeared to be confined by both semaphorin/neuropilin repellant and netrin attractant signaling to the deep ventrolateral cortical domain. Evidence from explant/slice co-culture experiments previously indicated that M/T axons can grow out of OB explants into the LOT of the host cortical slice, but not into cortical tissue more generally. Yet, M/T cells in FGF8-induced OBLSs placed in various positions in the cortical primordium send out axons to join the main LOT, and lot cells move freely to surround novel masses of M/T cells and their axons. The FGF8-induced OBLS thus breaks rules, suggesting our ideas about OB development need review. More positively, the FGF8-induced OBLS provides a model system in which questions about OB development can be addressed.

Title: Characterization of axon growth repellents in the developing spinal column.

Authors: J. SCHAEFFER, G. M. COOK, *R. J. KEYNES;
Univ. of Cambridge, Cambridge, United Kingdom

Abstract: During amniote vertebrate embryogenesis, the developing nervous system undergoes a segmentation process through the sequential formation of the mesodermal somites along the rostrocaudal axis. Somites differentiate subsequently into dermomyotome (giving rise later to skin and skeletal muscles) and sclerotome (giving rise to vertebral bone structures and cartilage). Sclerotomes split following their antero-posterior intrasegmental boundary, and become polarized into an axon growth permissive (anterior) region and an axon growth repulsive (posterior) region. When outgrowing from the neural tube towards the periphery, motor and sensory axons respond to this binary system and follow a segmented pattern that ensures that the peripheral nervous system develops without obstruction by the future cartilage and bones of the vertebral column.
In this context, repellent molecules from posterior half-somites guide navigating axons by excluding them from “no-go” areas. Among the candidate molecules, peanut lectin-binding glycoproteins, chondroitin sulphate proteoglycans, Eph/Ephrins and semaphorin 3A have been proposed as repellents acting on different receptor systems expressed by axon growth cones. Interestingly, similar repellent molecules are expressed in the adult central nervous system (CNS) by astrocytes. Following brain or spinal cord injury, these molecules are found to be overexpressed and secreted by a population of “reactive” astrocytes recruited at the lesion site, and to impede axon regeneration in this region.
This work presents the results of differential gene expression analysis of anterior and posterior half-sclerotomes, based on RNA-sequencing data. Several candidate genes were highlighted in this study and may play a role in the polarization and differentiation of the somite tissue, in the cell adhesion characteristics of half-sclerotome cells, and in the axon guidance properties of this system.
In addition, the growth cone collapse assay was used to further characterize the axon growth repulsive potential of a tissue or purified candidate proteins. Detergent extracts of rat grey matter and of a cultured line of human astrocytes have been shown to possess growth cone collapse-inducing activity. Furthermore, our experiments indicate that this CNS-derived activity has molecular properties similar to that in somites, so it is possible that this contact-repulsive system has been co-opted in the CNS to play an important role in regulating connectivity and plasticity.

Title: Elucidating the function of GABAergic signaling during neural development in larval zebrafish

Authors: *A. J. VANLEUVEN, S. L. WILLIAMS, B. M. KIDD, R. E. BALL, J. D. LAUDERDALE;
Cell. Biol., Univ. of Georgia, Athens, GA

Abstract: Normal nervous system development and function requires a fine balance of excitatory and inhibitory activity. Γ-Aminobutyric Acid (GABA) is the primary inhibitory neurotransmitter in the central nervous system of all vertebrates. GABA is made by the glutamic acid decarboxylase (GAD) enzyme, which exists in two isoforms, GAD67 and GAD65. The genes *Gad1* and *Gad2* encode these isoforms, respectively, and both function in GABA synthesis. Like mammals, zebrafish have both known *gad* genes; however, our lab has recently found evidence for a *gad1* paralog in zebrafish. These three *gad* isoforms in the zebrafish exhibit differential spatial and temporal expression, which has interesting implications both in terms of neural development and in nervous system function. To further investigate the function of the *gad* genes and to elucidate the role of GABA signaling during development, we are using CRISPR/Cas9 for targeted mutagenesis. So far, we have made *gad1b* -/- mutant zebrafish that show increased and abnormal brain activity in electrophysiological recordings as compared to wild-type animals. We are continuing to make novel alleles for the *gad* genes in zebrafish using CRISPR/Cas9 to address the question of how genetic manipulations in GABAergic signaling affect neural development and neurological activity. We are also using transgenic zebrafish and calcium imaging to better understand the connectivity of inhibitory neural networks and how these networks are altered when GABAergic signaling is altered. These experiments will aid our understanding of the differential regulation of GABA synthesis and the fine-tuning of the central nervous system's inhibitory network during development.

Title: Haploinsufficiency of the homeodomain protein Six3 abolishes male reproductive behavior through disrupted olfactory epithelium development and impaired GnRH neuron migration

Authors: *E. PANDOLFI[1], H. H. HOFFMANN[2], E. L. SCHOELLER[2], P. L. MELLON[2]; [1]UCSD, LA Jolla, CA; [2]UCSD, La Jolla, CA

Abstract: Olfaction is essential in modulating many behavioral responses in mammals, including mating behavior, fear response, and aggression. In mice, odors stimulate sexual behavior and induce neuroendocrine responses necessary for reproduction. The development of neurons in the olfactory system is closely linked to the development of gonadotropin-releasing hormone (GnRH) neurons, which are essential for reproductive function and fertility. Due to the topographical and migratory links between the development of the olfactory system and GnRH neurons, both can be disrupted when migration along olfactory axon pathways is deficient. When axon pathfinding of the main olfactory epithelium (MOE) neurons and migration of GnRH neurons are disrupted, the result is Kallmann's syndrome, a rare genetic disorder of complex genetic etiology, leading to subfertility and hyposmia. The homeodomain gene, *Six3*, is highly expressed in the MOE, main olfactory bulb (MOB), and hypothalamus, areas essential for maintaining reproduction and olfaction. The *Six3* gene has overlapping expression with *Six6*, another gene in the SIX gene family, which is of profound importance in GnRH neuronal development. Here, we study the role of SIX3 in development of olfactory structures and GnRH neurons. We found that GnRH neuron migration was compromised in a dose-dependent matter with complete loss of GnRH neurons in *Six3* KO embryos (*Six3* KO is embryonic lethal), and a 45% loss of GnRH neurons in *Six3* heterozygous (HET) mice. This loss of GnRH neurons during migration was due to effects in the neuronal network along the migratory pathway rather than mediated via effects intrinsic to the GnRH neurons since GnRH neurons actually increased by 30% when *Six3* was deleted only from GnRH neurons in *Six3* Flox x GnRH-Cre mice. In *Six3* HET mice, fertility was absent in male and impaired in female. Downstream reproductive physiology was intact in these mice including normal spermatogenesis and pituitary hormone secretion in response to GnRH administration. However, significant hyposmia led to an inability of males to detect the volatile estrous cues of female mice. This hyposmia resulted in a deficit in mounting, plugging, and litter production by *Six3* HET males. In summary, we found that *Six3* gene dosage is essential in the proper development of olfactory structures, in the migration of olfactory and GnRH neurons, and in the olfactory-based regulation of mating behavior. Our study is the first to address the impact of *Six3* haploinsufficiency in adulthood and demonstrates *Six3* to be a key transcription factor in MOE development and both male and female fertility.

Title: Protocadherin clusters require neural wiring in reticular formation in spinal cord and brainstem

Authors: *T. YAGI[1], S. HASEGAWA[1], A. OKAYAMA[1], R. KANEKO[2], T. HIRAYAMA[1], M. KUMAGAI[1], T. HIRABAYASHI[1];
[1]Osaka Univ., Suita, Japan; [2]Gumma Univ., Maebashi, Japan

Abstract: The clustered protocadherin (*Pcdh*) genes encode cadherin-related transmembrane proteins, which divide into three *Pcdh-a, -b* and *-g* clusters. All isoforms play similar homophilic protein-protein interaction and make dimers together with distinct isoforms beyond different clusters. Therefore it is considering that their isoforms have total function on molecular diversity. Here we were successful to obtain all Pcdhs null mutants by using *trans*-allelic *Cre-loxP* recombination and rescue of *TAF7* transgene. They were died soon after birth with less moving and breathing, and could not respond to any physical stimuli. Increase neuronal apoptosis were found in reticular formation of spinal cord and brainstem after embryonic day 16.5. Loss of *Bax* gene in Pcdh null mutants could avoid their neuronal apoptosis, but did not rescue less moving phenotypes. Administration of neurotransmitters induced their neuronal activity but could not normal coordinated neural activity in motor neurons, suggesting that total Pcdhs display significant for functional wiring in reticular formation.

Title: A neurodevelopmental source of extracellular vesicles.

Authors: *D. M. FELICIANO[1], M. C. MORTON[2], C. M. SELUZICKI[2], J. C. HOLMBERG[2];
[1]Neurosurg., [2]Biol. Sci., Clemson Univ., Clemson, SC

Abstract: Radial glia line the lateral ventricular surface of the embryonic brain and generate immature neurons that laminate the cortex. The anatomical proximity between radial glia and other cell types supports a model for which intercellular communication is critical for cortical development. Extracellular vesicles (EVs) transfer bioactive molecules from donor sources to recipients and mutations effecting EV pathways disrupt brain development. However, the neurophysiological functions of neurovesicles have only started to emerge. It has previously been demonstrated that EVs derived from embryonic cerebrospinal fluid are enriched in miRNAs. Small RNA sequencing has been used to identify EV miRNAs in patients and has further demonstrated that other, hitherto considered sources of EVs exist, likely including choroid plexus epithelial cells. There are other plausible developmental EV sources, however, it is unclear to what extent they regulate development, and their implication in neurpathophysiological states. The data provided here characterize radial glia as an *in vivo* neurodevelopmental source of EVs.

Title: A working module of the neurovascular unit in the sexually dimorphic nucleus of the preoptic area

Authors: *Z. HE[1], L. CUI[2], S. A. FERGUSON[1], M. G. PAULE[1];
[1]Div. of Neurotoxicology, Natl. Ctr. For Toxicology Res., Jefferson, AR; [2]Microbiology & Immunol., UAMS, Little Rock, AR

Abstract: The neurovascular unit (NVU) is conceptually defined as a functional entity consisting of neurons, astrocytes, pericytes, endothelial cells and smooth muscle cells. Although we are in a 'golden era' of bioengineering, there are no modules available as neural chips. The NVU is ideal for the concept of a neural chip; however, it is not known how many cells are contained in actual NVUs or what their size might be. The sexually dimorphic nucleus of the preoptic area (SDN-POA) is a tiny brain structure between 0.001~0.007 mm^3 in rats [He et al., 2012, 2013a, 2013b] with an assessable biological function (i.e., governing male sexual behavior). The present study examined whether there might be identifiable NVUs in the SDN-POA by assessing its vasculature relative to its known neural components. First, a thorough and systematic review of thousands of histologic and immunohistochemical images from 201 weanling and adult rats was undertaken to define the characteristics of the vessels supplying the SDN-POA: its primary supply artery and capillaries were physically inseparable from their neural elements. A subsequent immunofluoresecent study targeting α-smooth muscle actin (αSMA) confirmed the supply artery of the SDN-POA which was delineated using calbindin D28K immunoreactivity. Finally, a schematic of an SDN-POA neurovascular unit was proposed as a working model for the construct of a neural chip. The module could potentially inform development of next generation bioengineered neural transplants and serve the study of neurovascular mechanisms.
Figure 1. Hypothesized NVU working module in the rodent SDN-POA. A: astrocytes, N: neurons, P, pericytes, dashed-circles highlight unknowns and would serve as the focus of future studies.

Title: Roles of transcription factor Runx1 in BMP4-regulated neurite outgrowth and CGRP expression of dorsal root ganglion neurouns

Authors: ***M. YOSHIKAWA**[1], T. MASUDA[2], A. KOBAYASHI[2], S. OZAKI[2], S. AIZAWA[1], T. SHIGA[2];
[1]Nihon Univ. Sch. of Med., Tokyo, Japan; [2]Fac. of Med., Univ. of Tsukuba, Tsukuba, Japan

Abstract: Runx1, runt-related transcription factor, plays important roles in the cell type specification and axonal projections of the nociceptive dorsal root ganglion (DRG) neurons, whereas bone morphogenetic protein 4 (BMP4) is required for axonal growth during neuronal development. Although Runx1 has been shown to be involved in BMP4 signaling in non-neural tissues, the Runx1 function in BMP4-dependent regulation of neuronal development is unclear. To investigate interactions between Runx1 and BMP4 in neurite outgrowth, we cultured DRGs from wild-type (WT) and *Runx1*-deficient mouse embryos in the presence or absence of BMP4. Neurite outgrowth was decreased in BMP4-treated WT DRGs and untreated *Runx1*-deficient DRGs, suggesting the inhibitory effect of BMP4 and facilitatory effect of Runx1 on neurite outgrowth. In addition, the combination of BMP4 treatment and Runx1 deficiency increased neurite outgrowth, suggesting that Runx1 deficiency disrupts BMP4-induced neurite outgrowth inhibition. We next analyzed neurite number in cultured DRGs. In contrast to neurite length, the neurite number was not changed by Runx1 deficiency or BMP treatment of WT DRGs. However, neurite number was increased by BMP4 treatment in *Runx1*-deficient DRGs. These results showed that neither BMP4 treatment nor Runx1 deficiency alone affects neurite number of DRGs, but the combination of these two increased it. Both BMP4 treatment and Runx1 deficiency increased calcitonin gene-related peptide (CGRP)-positive neurons, and CGRP expression was not increased by BMP4 treatment in *Runx1*-deficient mice, suggesting that Runx1 contributes to BMP4-induced CGRP expression in DRG neurons. Thus, Runx1 appears to play important roles in neurite outgrowth and CGRP exprssion via BMP4 signaling in DRG during the embryonic stages.

Title: cAMP-induced activation of PKA and p190B mediates down-regulation of plasmalemmal TC10 activity and neurite outgrowth

Authors: *S. KOINUMA[1,2], T. NANAO[1], N. WADA[3], T. NAKAMURA[1];
[1]Tokyo Univ. Of Science, RIBS, Noda-Shi, Japan; [2]Ctr. for Animal Dis. Models, Noda-shi, Japan; [3]Tokyo Univ. of Science, Fac. of Sci. and Technol., Noda-shi, Japan

Abstract: cAMP plays a pivotal role in neurite/axon growth and guidance.Furthermore, in vivo studies have shown that cAMP elevation strongly promotes axon regeneration. Neurite outgrowth requires membrane expansion through the exocytosis of plasmalemmal precursor vesicles at growth cone. TC10 is a Rho family GTPase and has been shown to play a significant role in the exocytosis of certain membrane proteins by tethering vesicles to the plasma membrane. Recent studies including ours have shown that TC10 and its effector Exo70, a component of the exocyst tethering complex, contribute to neurite outgrowth through the membrane addition. We further propose a model that GTP hydrolysis of vesicular TC10 near the plasma membrane promotes neurite outgrowth by accelerating vesicle fusion by releasing Exo70. TC10 could be involved in axon regeneration because TC10 mRNA level increases following axotomy. In this study, we tried to find a mechanical linkage between cAMP and TC10 activity in neuronal cells. Firstly, by using a FRET sensor, we have shown that TC10 activity at the plasma membrane decreased abruptly following dbcAMP treatment both in PC12 and Neuro2A cells, whereas no change in TC10 activity was observed in dbcAMP-treated HeLa and COS-7 cells. TC10 depletion lead to a significant decrease in neurite outgrowth in dbcAMP-treated PC12 cells. Although exogenous expression of wild-type TC10 could rescue the decrease in neurite outgrowth by TC10 depletion, constitutively active TC10 could not. These results are consistent with our model for the mechanical implication of GTP hydrolysis of TC10. Drug and RNAi experiments have shown that dbcAMP-induced inactivation of plasmalemmal TC10 was principally mediated by PKA in neuronal cell-lines. Next, we found that RhoA activity at the plasma membrane was decreased following dbcAMP addition. Thus we checked the possibility that GAPs which are thought to inactivate RhoA also down-regulate TC10, and found that depletion of p190B abolished down-regulation of both TC10 and RhoA in dbcAMP-treated PC12 cells. Furthermore, p190B depletion markedly reduced dbcAMP-induced neurite outgrowth. Because p190B does not have canonical PKA phosphorylation motif, we tried to find a factor(s) which links PKA and p190B. Expression of dominant-negative mutant of Rac1 reduced dbcAMP-induced TC10 inactivation. Furthermore, the depletion of STEF/Tiam2 also reduced dbcAMP-induced TC10inactivation. Together with our previous study for efficient activation of STEF by PKA, we presume that PKA-STEF- Rac1-p190B pathway plays a major role in neurite outgrowth following cAMP treatment.

Title: ERK/MAPK hyperactivation leads to altered corticospinal neuron connectivity and motor learning deficits

Authors: *G. R. BJORKLUND[1], L. T. HEWITT[1], L. XING[2], V. NIKOLOVA[3], S. S. MOY[3], W. D. SNIDER[2], J. M. NEWBERN[1];

Abstract: Several well defined genetic mutations in components of the RAS/RAF/MEK/ERK (ERK/MAPK) pathway cause neurodevelopmental deficits in a family of syndromes known as RASopathies. A majority of these mutations result in ERK/MAPK hyperactivation, however, the impact of enhanced ERK/MAPK signaling on the development of cortical connectivity is poorly understood. We employed a conditional genetic approach to define the effects of ERK/MAPK hyperactivation on the developing mouse motor cortex. Excitatory-neuron specific overexpression of constitutively active MEK1 (caMEK1) throughout the cortex led to an increase in the levels of phosphorylated ERK1/2, particularly in developing axons. We tested whether enhanced ERK/MAPK altered the extension and arborization of axons derived from layer 5 subcortical projection neurons. Anterograde viral tract tracing revealed that caMEK1 expression led to a decrease in the elongation of corticospinal axons in the spinal cord. Importantly, when caMEK1 expression was restricted to layer 5 excitatory neurons, a similar alteration in corticospinal elongation was observed. These data demonstrate that the changes in axonal growth following ERK/MAPK hyperactivation are layer 5 neuron autonomous. The arborization of axonal projections in the hindbrain, striatum, and contralateral cortex were also compared to control mice. We examined whether cortical excitatory-neuron specific caMEK1 mutants exhibit deficits in locomotor activity and motor learning. Mutant mice did not show a change in global locomotor activity in the open field test when compared to controls. In contrast, we observed significant differences in skilled motor learning in the accelerating rotarod assay and single-pellet reaching task. Our data reveal alterations in corticospinal axon outgrowth and branching that coincide with impairments in motor learning following cortical excitatory neuron specific ERK/MAPK hyperactivation. These findings suggest that the aberrant development of

cortical long-range projection neuron connectivity contributes to motor delay and possibly learning abnormalities in RASopathies.

Title: Muscarinic acetylcholine receptor type-1 antagonists modulate post-translational modifications of $Ca^{2+/}$calmodulin-dependent protein kinase kinase β in adult dorsal root ganglion neurons

Authors: *P. FERNYHOUGH[1,2], M. G. SABBIR[2];
[1]Univ. of Manitoba, Winnipeg, MB, Canada; [2]Div. of Neurodegenerative Disorders, St Boniface Res. Ctr., Winnipeg, MB, Canada

Abstract: Muscarinic receptors mediate the metabotropic action of acetylcholine (ACh). Lesions in the central ACh-mediated system are now considered to be a major factor in neurodegenerative disorders. Previously we have shown that pirenzepine (PZ) and muscarinic toxin-7 (MT7), selective antagonists of muscarinic acetylcholine receptor type-1 (M1R), can induce neurite outgrowth in cultured adult rodent dorsal root ganglion (DRG) neurons. However, the exact mechanism of their effect on neurite outgrowth is unknown. Muscarinic receptor activation can directly/indirectly regulate many signaling pathways including $Ca2^{+}$ signaling. Previously, we have shown that M1R antagonism can raise AMPK phosphorylation and resulted in increased mitochondrial activity. Ca^{2+}/calmodulin-dependent protein kinase kinase β (CaMKKβ) is a potential target of muscarinic antagonism as an upstream activator of AMPK and it is strongly expressed in peripheral neurons. Therefore, in the present study, we used iso-electric focusing to identify the post-translational modification (PTM) of CaMKKβ upon PZ/MT7 treatment in adult DRG neurons as well as M1R-GFP transiently over-expressed cells. Our results indicate that CaMKKβ undergoes significant PTMs upon MT7 or PZ treatment, however, the extent and nature of the modifications differed. In primary DRG neurons, CaMKKβ was found significantly relocated from the perikarya to neurites within 1hr of treatment with

PZ/MT7. In addition, MT7/PZ treatment significantly altered the association of CaMKKβ with several multiprotein complexes which may be due to the differential PTMs.

Title: Cell autonomous and non-cell autonomous functions of Vax1 in mouse embryo

Authors: *K. MIN[1], Y. SUNG[2], N. KIM[1], H. LEE[2], J. KIM[1];
[1]KAIST, Daejeon, Korea, Republic of; [2]Yonsei university, Seoul, Korea, Republic of

Abstract: *Ventral anterior homeobox1 (VAX1)* is a homeodomain transcription factor, which is known for its role in the development of vertebrate ventral forebrain. *VAX1* mutations in human and mice cause various malformation of ventral midline brain structures including anterior commissure, corpus callosum and optic chiasm. Previously, it was reported that Vax1 not only regulates transcription of genes in the brain areas but also promotes retinal axon growth as a translational regulator via the intercellular transfer. However, it still remains unclear about the physiological importance of the cell autonomous versus non-cell autonomous functions of Vax1 in the development. To investigate this, we generated $Vax1^{KR/AA}$ mutant mice, in which conserved lysine and arginine residues that binds to heparin sulfate proteoglycan (HSPG) of retinal axons are replaced with two alanines. We then examined the brain and eye development of mice that have six different Vax1 gene contents; $Vax1^{+/+}$, $Vax1^{+/AA}$, $Vax1^{+/-}$, $Vax1^{AA/AA}$, $Vax1^{-/AA}$, and $Vax1^{-/-}$. The $Vax1^{-/-}$ and $Vax1^{-/AA}$ failed to form the midline structures of forebrain and were perinatally lethal due to the palate cleft. In contrast, $Vax1^{AA/AA}$ also lacked of the commissures but had normal palate. However, the $Vax1^{AA/AA}$ mice develop abnormal retina-optic stalk boundary with the proximal expansion of Pax6, similar as the $Vax1^{-/-}$ and $Vax1^{-/AA}$ mice. Together, we demonstrate that different levels of cell autonomous and non-cell autonomous activities of Vax1 are necessary for brain and eye development.

Title: Molecular controls over corticospinal motor neuron axonal branching at specific spinal segments

Authors: *Y. ITOH, V. SAHNI, S. J. SHNIDER, J. D. MACKLIS;
Dept. of Stem Cell and Regenerative Biol., Harvard Univ., Cambridge, MA

Abstract: Corticospinal motor neurons (CSMN, and related cortico-brainstem motor neurons; together "CSMN") are located in layer V of the neocortex, and make synaptic connections to motor output circuitry in the spinal cord and brainstem. CSMN axons form the corticospinal tract (CST), the major motor output pathway from the motor cortex. CSMN and the CST critically control voluntary movement. CSMN are also clinically important. CSMN degeneration in amyotrophic lateral sclerosis (ALS), along with degeneration of spinal motor neurons, causes spasticity and paralysis. In humans, damage to the corticospinal tract in spinal cord injury is the principal cause of loss of voluntary motor control. Previous studies in our lab have identified combinatorial molecular controls over the specification and differentiation of CSMN.
CSMN themselves exhibit striking anatomical and functional diversity: Some CSMN extend axons to innervate cervical spinal cord targets, and control forelimb movement, while others extend far more caudally to innervate lumbar segments, and control hindlimb movement. The underlying molecular basis for this diversity is strongly suggested by the stereotypic organization of these populations in the sensorimotor cortex, which is largely conserved from rodents to primates, and by their precise topographic pattern of connectivity in the spinal gray matter. We are investigating molecular mechanisms underlying segmental specificity of this connectivity. We have identified a set of candidate molecular controls over development of this diversity and specificity of CSMN segmental connectivity. We selectively isolated cervical- and lumbar-projecting CSMN ($CSMN_C$ and $CSMN_L$, respectively) at three critical time points of CST development, and identified differentially expressed genes between these two subpopulations of CSMN during development. Using gain- and loss-of-function analyses, we identified a secreted proteoglycan expressed specifically by $CSMN_C$ that non-cell-autonomously limits $CSMN_L$ axonal collateral branching in the cervical spinal cord. These results represent a novel mode of

control over circuit connectivity, via non-cell-autonomous regulation of $CSMN_L$ axonal branching by $CSMN_C$, thus over development of segmentally and functionally specific corticospinal circuitry.

Title: Transcriptional mechanisms governing serotonin neuron axonal architecture

Authors: *L. J. DONOVAN, E. DENERIS;
Neurosciences, Case Western Reserve Univ., Cleveland, OH

Abstract: Serotonin (5-HT) is a major neuromodulator in the brain and disruption of 5-HT signaling has been linked to neurodevelopmental psychiatric disorders including depression, anxiety, suicide, and posttraumatic stress disorder. Although significant progress has been made in understanding the neuron-type specification of 5-HT neurons, far less is known about the regulatory factors that act in subsequent developmental stages to control acquisition of their mature morphological and functional characteristics. Surprisingly, little is known about the intrinsic regulatory factors that control 5-HT axonal growth and guidance despite the fact that 5-HT axons innervate nearly all regions of the brain and spinal cord. The LIM-homeodomain (LIM HD) transcription factor (TF), Lmx1b, plays an essential role in 5-HT neuron terminal differentiation through its activation of 5-HT genes that determines 5-HT neuron transmitter identity. Notably, serotonergic expression of Lmx1b continues throughout life after the acquisition of 5-HT neuron identity. This continual expression led us to hypothesize that Lmx1b regulates other genes responsible for further features of 5-HT neurons such as their expansive axonal projections. To investigate this, Lmx1b floxed mice were crossed with transgenic mice expressing Cre recombinase specifically in newborn 5-HT neurons. Further, the Ai9 reporter was crossed into this mouse line to mark 5-HT axons with Td-Tomato. Our findings with $Lmx1b^{fl/fl;ePet\text{-}Cre;Ai9}$ conditional knock out ($Lmx1b^{cKO}$) mice reveal mispositioning of 5-HT cell bodies in the dorsal raphe and a severe disruption of forebrain 5-HT axonal innervation patterns. Confocal imaging revealed a lack of Td-Tomato$^+$ axonal innervation in the $Lmx1b^{cKO}$ hippocampus. In addition, we found Td-Tomato$^+$ hyper-innervation of thalamic and other regions in $Lmx1b^{cKO}$ mice. These findings suggest a major intrinsic role for Lmx1b in 5-HT axonal development and cell body positioning in the raphe. A further goal is to identify Lmx1b

regulated genes involved in shaping 5-HT neuron connectivity. *Lmx1b*^{cKO} 5-HT neurons are being sorted at different developmental time points and analyzed by RNA-sequencing to identify axon growth and pathfinding-related genes controlled by Lmx1b. 5-HT neuron transcriptome databases previously generated in the lab with fetal to postnatal 5-HT neurons have revealed potential intrinsic 5-HT axonal growth and pathfinding genes and are being used to guide Lmx1b studies. These experiments will elucidate the mechanisms by which Lmx1b builds 5-HT axon architecture and advance our understanding of how complex 5-HT axon connectivity is achieved during development.

Title: A heterogeneous population of nuclear-encoded mitochondrial mrnas are present in the axons of primary sympathetic neurons

Authors: *A. ASCHRAFI[1], A. N. KAR[2], J. GALE[1], A. G. ELKAHLOUN[3], A. E. GIOIO[1], B. B. KAPLAN[1];
[1]Lab. of Mol. Biol., Natl. Inst. of Mental Hlth. USA, Bethesda, MD; [2]Univ. of South Carolina, Columbia, SC; [3]Natl. Human Genome Res. Inst., Bethesda, MD

Abstract: Mitochondria are enriched in subcellular regions of high energy consumption, such as axons and pre-synaptic nerve endings. Accumulating evidence suggests that mitochondrial maintenance in these distal structural/functional domains of the neuron depends on the “in-situ” translation of nuclear-encoded mitochondrial mRNAs. In support of this notion, we recently provided evidence for the axonal targeting of several nuclear-encoded mRNAs, such as cytochrome c oxidase, subunit 4 (COXIV), ATP synthase, H+ transporting and mitochondrial Fo complex, subunit C1 (ATP5G1). Furthermore, we showed that axonal trafficking and local translation of these mRNAs plays a critical role in the generation of axonal ATP. Using a global gene expression analysis, this study identified a highly diverse population of nuclear-encoded mRNAs that were enriched in the axon and presynaptic nerve terminals. Among this population of mRNAs, fifty seven were found to be at least two fold more abundant in distal axons, as compared with the parental cell bodies. Gene ontology analysis of the nuclear-encoded

mitochondrial mRNAs suggested functions for these gene products in molecular and biological processes, including but not limited to oxidoreductase and electron carrier activity and proton transport. Based on these results, we postulate that local translation of nuclear-encoded mitochondrial mRNAs present in the axons may play an essential role in local energy production and maintenance of mitochondrial function.

Title: Axonal trafficking of mitochondrial ATP synthase mRNA

Authors: N. SALES, J. GALE, S. S. SCOTT, C. CHEN, A. ASCHRAFI, *A. E. GIOIO, B. B. KAPLAN;
Lab. of Mol. Biol., NIH, NIMH-, Bethesda, MD

Abstract: Previously, a diverse population of nuclear-encoded mitochondrial mRNAs was identified in axons of primary sympathetic neurons cultured in multicompartmented Campenot chambers. Evidence suggests that the local translation of these mRNAs is vital for the maintenance of mitochondrial function in this distal neuronal compartment. In addition, it was shown that mRNA encoding ATP5G1 synthase subunit 9 (ATP5G1), an essential component of Complex V in the electron transport chain, is present in distal axons and is locally translated. Furthermore, when axonal ATP5G1 levels are diminished via siRNA methodology, there is a significant reduction in local ATP levels and conversely, an increase in the production of reactive oxygen species (ROS). Reduction of axonal ATP5G1 expression also results in attenuation in the rate of axonal growth, establishing that the trafficking and local translation of axonal ATP5G1 is important in both the maintenance of mitochondrial function and axonal health (Natera-Naranjo et al., 2012). In this investigation, we address the mechanism of trafficking of this mRNA to distal axons. Our preliminary findings indicate that mRNA localization is mediated by cis-acting elements located in the 3' UTR of the mRNA. RNA secondary structure analysis using MFold (Zuker, 2003) suggested that this regulatory sequence was situated in a putative stem-loop structure. Taken together, these findings extend our

knowledge concerning the regulation of mRNA trafficking to the axon and mediation of local mitochondrial activity.

Title: Mitochondrial dynamics in retinal ganglion cell development and regeneration

Authors: *A. KREYMERMAN[1], J. WEINSTEIN[2], D. BUICKIANS[3], T. TRAN[3], N. SUN[3], L. BAZIK[3], M. STEKETEE[4], J. L. GOLDBERG[1];
[1]Ophthalmology Dept., Stanford, Palo Alto, CA; [2]Ophthalmology, Louisiana State Univ., New Orleans, LA; [3]UCSD, San Diego, CA; [4]Ophthalmology, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: A major underlying problem in the central nervous system (CNS) is a failure to regenerate neurons and their projections in disease or after injury. In recent decades, mitochondrial dynamics including volume change, fission-fusion, positioning or transport, and biogenesis have been investigated in models of neuronal health and degeneration. Little is known about how these mitochondrial events change in development, during periods in which axons are growing or maturing, or about how manipulating mitochondrial dynamics influences axon growth or regeneration. We have been investigating mitochondrial changes in the retina and optic nerve during development and manipulating mitochondrial fission and fusion in growing retinal ganglion cell axons. We found that suppressing mitochondrial fission (increasing fusion) blocks RGC axon growth inhibition normally elicited by chondroitin sulfate proteoglycans in early postnatal RGCs in vitro. To identify whether mitochondrial fission/fusion and or transport mechanisms also influence axon regeneration in vivo, we are manipulating mitochondrial dynamics in studies of retinal ganglion cell regenerative therapies. We found that axon growth-suppressing Kruppel-like transcription factors (KLFs) increase the expression of mitochondrial fission process 1,18 kDa (MTP18), a positive regulator of Mt fission, supporting the hypothesis

that increased fission is inhibitory for axon growth in RGCs. **Thus we hypothesize that axon regeneration is dependent on the regulation of mitochondrial dynamics.** We further find that mitochondrial axon localization changes during retinal ganglion cell development. Together these data support a mechanism in which axon growth and guidance responses are regulated by mitochondrial fission-fusion dynamics, and suggest suppressing fission as a potential therapeutic strategy for improving axon regeneration after CNS trauma**.**

Title: Simultaneous imaging of ATP levels and membrane potential in mitochondria during axonal transport

Authors: *R. SUZUKI, K. HOTTA, K. OKA;
Keio Univ., Kouhoku-Ku, Yokohama, Japan

Abstract: Adenosine triphosphate (ATP) is a major energy source produced by mitochondria, and is used in muscle contraction, neuronal activity, organ development, and many other physiological phenomena. In neurites, mitochondria are known to be transported bidirectionally, and ATP produced by locally anchored mitochondria has been suggested relationships with neuronal major activities including firing, neurotransmission, and morphogenesis. In addition, mitochondrial transports also play an important role as quality control of mitochondria: recall of unhealthy mitochondria and supply of new healthy mitochondria. As some neurodegenerative diseases accompany dysfunction of mitochondrial transports, to check and control mitochondria quality is essential for neurons to manage their functions normally and properly.
One previous research investigated mitochondrial membrane potential, one of indicators of mitochondrial quality, revealed that ~90% of mitochondria with high potential were transported towards growth cones (GCs) and ~80% of mitochondria with low potential were transported towards cell bodies (Miller KE and Sheetz MP, 2004). However, no mitochondrial ATP levels

has been directly measured, and it is not clear whether mitochondrial ATP and membrane potential correlate. Furthermore, a question whether ATP levels of mitochondria transport to anterior is high or not has remained unanswered. In this study, we quantified mitochondrial ATP level and membrane potential simultaneously and analyzed relationships between mitochondrial ATP, membrane potential, and transport within axons in dorsal root ganglion (DRG) neurons. We transfected a genetic mitochondrial ATP sensor into DRG neurons and stained the neurons with tetramethylrhodamine ethyl ester, an indicator for mitochondrial inner-membrane potential, and conducted time-lapse fluorescent imaging under physiological conditions. Acquired images were processed by an original algorithm to analyze mitochondrial ATP levels, membrane potentials and mitochondrial mobilization quantitatively.
Mitochondria are classified into 3 types: retrograde, anterograde, and pause depending on their movement. Although no difference of membrane potential was found between 3 types, ATP levels of anterograde mitochondria were high compare to that of pausing mitochondria. Furthermore, mitochondria in GC showed higher both ATP levels and membrane potential than that of mitochondria in the axon. These results suggest, in extending neurites, mitochondria with high activity were transported towards GC where needs a lot of energy to elongate.

Title: Axonal transport mediates exosomes derived from cerebral endothelial cells on axonal growth

Authors: *Y. ZHANG[1], M. CHOPP[1,2], C. LI[1], X. LIU[1], X. WANG[1], L. ZHANG[1], Z. ZHANG[1]; [1]Neurol. Res., HENRY FORD HOSPITAL, Detroit, MI; [2]Dept. of Physics, OAKLAND UNIVERSITY, Rochester, MI

Abstract: Exosomes play essential roles in intercellular communication by transferring their cargo between source and target cells. We have demonstrated that exosomes harvested from post stroke rat cerebral endothelial cells (sCEC-exosomes) promote axonal growth. The present study

tested the hypothesis that axonal transport mediates sCEC-exosome-enhanced axonal growth. Embryonic cortical neurons were cultured in a microfluidic device which separates distal axons, axon bodies and their parent cell bodies into three isolated compartments. Tracking intra-axonal vesicles, we found that application of sCEC-exosomes ($3x10^7$) into the distal axon compartment significantly ($P<0.05$) increased vesicle velocity (2.3±0.2 vs 0.7 ±0.1 μm/s in control), which was associated with an increase in growth cone extension (29±1 vs 12±1 μm/h in control, $p<0.01$). Application of emetine, a global protein synthesis inhibitor, into the axon body compartment completely abolished transport proteins, kinesin and dynein, in this compartment and suppressed exosome-augmented vesicle velocity (0.2±0.0 μm/s) and axonal growth (5±1 μm/h). RT-PCR analysis showed that the distal axonal exosomal treatment significantly increased a set of pre and mature miRNAs, including miR-19A, 27A, 195, and 298 in distal axons and somata, with elevated levels of these miRNAs ~10 times higher in distal axons than in somata. Emetine eliminated exosome-elevated pre-miRNAs and reduced mature miRNA levels in distal axons, but did not affect pre- and mature miRNAs in somata. Western blots revealed that the distal axonal exosome treatment robustly reduced protein levels of Sema6A, PTEN and RhoA in distal axons, whereas emetine only partially suppressed the effect of the exosomes on these proteins that are targeted by aforementioned miRNAs. To further examine whether sCEC-exosomes enhance axonal growth after blockage of vesicle transport between the soma and distal axon by emetine, sCEC-exosomes were applied to distal axons immediately after termination of emetine treatment. Under the control condition, axonal growth recovered 12h after end of emetine treatment. However, the exosome treatment led to full recovery and doubling of axonal lengths 3 and 12h after ending emetine, respectively. Together, our data suggest that in addition to mature miRNAs delivered by sCEC-exosomes, the exosomes applied to distal axons amplify axonal transport to deliver pre-miRNAs from somata to distal axons, leading to enhanced-axonal growth by suppressing axonal inhibitory genes via elevated mature miRNAs. Thus, the present study provides new insights into axonal transport in mediating sCEC-exosome-promoted axonal growth.

Title: apl1 intracellular domain overexpression affects axonal guidance in c elegans gaba neurons

Authors: *J. JENKINS[1], R. EL BEJJANI[2];
[1]Davidson Col., Savannah, GA; [2]Biol., Davidson Col., Davidson, NC

Abstract: The amyloid precursor protein (APP) is best studied for its role in Alzheimer's disease. However, APP is expressed in normal brains and its role in neurons remains unclear. The intracellular domain of the mammalian gene APP is highly conserved with the *Caenorhabditis elegans* gene *apl-1*. We have integrated a transgene to overexpress the intracellular domain of *apl-1* (AICD) in the GABA neurons of *C. elegans*. We show that AICD overexpression causes a significant number of axons to be misguided compared to the wild type ($p<0.0001$). In mammalian species, APP is trafficked through the plasma membrane by retromer, suggesting that retromer trafficking may affect the function of AICD in axonal guidance. We found that *rab-6.2* does not affect the defect in axon guidance caused by AICD, suggesting that retromer does not affect *apl-1* trafficking in *C. elegans*. Alternatively, the PIKfyve complex is involved with *apl-1* signaling in other *C. elegans* tissues. It also shows that the *Drosophila apl-1* ortholog, *Appl,* is required for correct axonal guidance, APPL forms a complex with the PCP complex to activate Wnt signaling. Suggesting that *apl-1* may affect guidance via *Wnt*. We are currently testing the involvement of the PIKfyve and PCP Wnt complexes on the defect in axon guidance caused by *apl-1* overexpression. We will also perform a genetic screen to discover additional pathways that are involved with this defect.

Title: Understanding axon regeneration: regulatory roles for RNA binding proteins

Authors: *M. ANDRUSIAK[1], P. SHARIFNIA[2], Y. JIN[2];
[1]Div. of Biol. Sci. - Neurobio. Section, UCSD, San Diego, CA; [2]UCSD, La Jolla, CA

Abstract: Acute injury to the nervous system, as observed following spinal cord injury or stroke, triggers a number of cellular stresses. Injury-related cellular stresses lead to impaired nervous system function and brain cell loss. We are examining how a neuron regulates which cellular machinery to produce to respond to cellular stress induced by acute axon injury. Using an established laser axon injury model in the roundworm, *C. elegans*, we can examine how a neuron responds to stress in an intact organism. We have identified a conserved RNA-binding protein that impairs a neuron's ability to respond to stress. Loss of function in this RNA binding protein results in an increase in axon regeneration. Time-course analyses show that the protein likely acts during the early regenerative response. We are performing in-depth genetic and genomic analyses to identify functional relevant targets. Increasing studies have shown that RNA regulation plays diverse roles. In understanding of how a neuron responds to stress, we hope to be able to 'fine-tune' this response in order to optimally respond to acute nervous system injury.

Title: The role of type iii nrg 1 in cortical axon outgrowth

Authors: *A. LUSSENDEN[1], L. W. ROLE[2,3], D. A. TALMAGE[4,3];
[2]Dept. of Neurobio. and Behavior, [3]Ctr. for Nervous Syst. Disorders, [4]Dept. of Pharmacol. Sci., [1]Stony Brook Univ., Stony Brook, NY

Abstract: Neuregulin 1 has been shown to be a key regulator of neuronal development, including cell survival, receptor trafficking, and neurite outgrowth. Type III Neuregulin 1 (Type III Nrg1), a neuron-specific isoform of Nrg1, functions as both a ligand and a receptor for its signaling partners, the ErbB family of receptor tyrosine kinases. In response to neuronal activity and/or ErbB4 binding to Nrg1, two "back-signaling" networks are engaged. In one, the intracellular domain (ICD) of Type III is cleaved by gamma secretase and then translocates to the nucleus. The second results in activation of PI3K/Akt signaling. Relatively little is known

about how each of these signaling mechanisms contributes to overall Nrg1 function during development of the nervous system. Type III Nrg1 signaling regulates cortical dendritic and axonal outgrowth, however we do not know the contribution of each signaling pathway. Here, we are asking whether ICD nuclear translocation and PI3K/Akt signaling regulate distinct developmental processes, and whether either ICD nuclear translocation and/or PI3K/Akt operate in distinct cellular compartments. To answer these questions, we are using cortical neuronal cultures to examine single axon dynamics. Stimulating Type III Nrg1 back-signaling increases axonal outgrowth. The effect on axonal growth is blocked by PI3K inhibitors but not by gamma secretase inhibitors. We then asked whether stimulating Type III Nrg1 back-signaling selectively in the axonal vs the somatodendritic compartment would affect axonal length. Indeed, selectively stimulating axonal Type III Nrg1 results in increased axon growth whereas stimulating somatodendritic Type III Nrg1 does not. These findings suggest a role for axonal, but not somatodendritic, Type III Nrg 1-mediated PI3K/Akt signaling in cortical axon outgrowth. Title: KSRP RIP-seq reveals targets important for neuronal development and function

Authors: *A. S. GARDINER[1], G. PERALES[1], S. L. OLGUIN[1], A. SUNDARARAJAN[2], J. MUDGE[2], F. D. SCHILKEY[2], J. L. TWISS[3], N. I. PERRONE-BIZZOZERO[1];
[1]Dept. of Neurosciences, Universtiy of New Mexico, Albuquerque, NM; [2]Natl. Ctr. for Genome Resources, Santa Fe, NM; [3]Dept. of Biol. Sci., Univ. of South Carolina, Columbia, SC

Abstract: RNA-binding proteins (RBPs), including the KH-type splicing regulatory protein (KSRP), are critical mediators of post-transcriptional regulation of gene expression. KSRP is involved in such diverse functions as mRNA splicing and stability, and we have shown that it is essential for controlling neuronal outgrowth, implicating it in neuronal development and regeneration. Through its KH4 RNA binding domain, KSRP binds to AU-rich instability

elements in the 3'UTR of mRNAs, causing destabilization of such targets and recruitment of the exosome, ultimately resulting in a reduction of translation. KH RNA binding domains 1-3 mediate binding to targets other than AU-rich mRNAs. In order to obtain a global representation of neuronal targets during development, we performed RNA immunoprecipitations followed by next-generation sequencing (RIP-seq) using cortical tissue from E18 KSRP knock-out (KO) and wild-type (WT) mice. DESeq analysis identified approximately 5000 mRNAs that were significantly more abundant (FDR corrected $p<0.05$) in the WT RIP compared to the KO RIP. Top hits included mRNAs encoding Ksrp and other RBPs such as Hu proteins, Ddx proteins, Celf1/2, and Mbnl1/2. Other targets included Sox transcription factors, translation initiation factors, cell cycle regulators, and genes involved in cytoskeletal structure. Ingenuity Pathway Analysis of KSRP targets revealed canonical pathways such as cell cycle regulation, ephrin receptor signaling, and axonal guidance signaling. Molecular and cellular functions included gene expression, cellular function and maintenance, and cellular assembly and organization. Finally, physiological system functions included nervous system development and function, embryonic development, and organismal development. We examined the effect of KSRP on hippocampal morphology using Thy1-GFP mice crossed with both KSRP KO and KSRP Het mice. We found that the lack of KSRP resulted in an increase in mossy fiber outgrowth. This was opposite to the effect we observed with Thy1-GFP/HuD KO and Thy1-GFP/HuD Het mice, in which the lack of HuD, an RBP that stabilizes mRNAs, resulted in a decrease in mossy fiber length. Supporting these morphological findings, KSRP KO mice showed alterations in the attentional set-shifting task (ASST) and novel object recognition (NOR) behavioral tests. Overall, our results support a role of KSRP in brain development and function.

Abstract: The cellular and molecular mechanisms that govern targeting of discriminative touch receptors to specialized peripheral targets have not yet been identified. High-acuity skin areas, including whisker follicles, fingertips and touch domes in hairy skin, are enriched in epidermal Merkel cells that are contacted by slowly adapting, Aβ mechanoreceptors. Our objective is to elucidate mechanisms of Merkel-cell afferent targeting. As a first step, we analyzed the spatiotemporal organization of Merkel cells and their innervation during embryogenesis. We performed immunohistochemistry on cryosections and whole-mount preparations from mice ranging from embryonic day 14.5 (E14.5), when Merkel cells appear in the skin, to postnatal day 21 (P21), when afferents are functionally mature. Afferents were visualized by labeling with antibodies against Neurofilament-Heavy (NFH) or by their expression of TrkC-TdTomato in transgenic reporter mice. Merkel cells were labeled with antibodies against Keratin 8. We found that NFH^+ neurons diffusely tiled the upper, or papillary, dermis at E14.5 but did not penetrate the epidermis. At E16.5, NFH^+ and TrkC-$TdTomato^+$ afferents penetrated the interfollicular epidermis (between hair follicles) to contact Merkel cells but did not cross the basement membranes of hair follicles or glabrous skin. These findings confirm that Merkel-cell specification occurs independent of innervation. By E18.5, some touch-dome afferents projected past Merkel cells into the upper layer of the epidermis. Other afferents targeted hair follicles at this stage. At P1, touch-dome afferents refined to make specific contacts with Merkel cells, whereas others formed collars around hair follicles. These results establish touch-dome Merkel-cell afferents as the earliest tactile afferents to innervate their targets during development. We next investigated the developmental localization of cell types that could release cues to guide innervation. Since NFH^+ afferents innervate touch domes in mice that lack Merkel cells, we conclude that Merkel cells are not required for initial targeting of afferents. Keratin 17 (K17) is expressed by columnar keratinocytes that are tightly juxtaposed to Merkel cells in mature touch domes. We observed that interfollicular $K17^+$ keratinocytes selectively localized to touch domes at all developmental stages assessed. Thus, they are well poised to govern targeting of Merkel-cell afferents during development. Ongoing studies include *in vitro* and *in vivo* assays to determine whether $K17^+$ keratinocytes are sufficient to promote neurite outgrowth from dorsal root ganglion neurons.

Title: Neurite guidance and elongation on anisotropic micropillar arrays

Authors: ***M. PARK**[1], K. KANG[2], I. S. CHOI[1];
[1]KAIST, Daejon, Korea, Republic of; [2]Dept. of Applied Chem., Kyung Hee Univ., Youngin, Korea, Republic of

Abstract: Topographical cues can affect neurite outgrowth in a variety of ways. Control over neurite directionality, in particular, has been extensively researched through the use of aligned nanofibers, grooved substrates, and even cell-mimetic scaffolds. However, most studies have relied on the use of continuous, line-based topographies to guide neurite outgrowth, and the use of interrupted topographies is rare, despite their unique effects on primary hippocampal neuron behavior. In this work, we designed anisotropic micropillar arrays to successfully control the directionality of neurite outgrowth in primary hippocampal neurons. We found that the degree of anisotropy in the micropillar arrays was correlated to the fidelity of neurite alignment, and that the rate of neurite elongation was affected as well. We also explored the three-dimensional interactions between neurites and micropillars. This topographical platform can contribute to both studies in fundamental neuron behavior, as well as the practical development of neuroregenerative scaffolds.

Abstract: Altered synaptic bioactive lipid signaling has been shown to augment neuronal excitation in the hippocampus of adult animals by activation of presynaptic LPA_2-receptors leading to increased presynaptic glutamate release. Here we show that this results in higher postsynaptic Ca^{2+} levels and in premature onset of spontaneous neuronal activity in the developing entorhinal cortex leading to reduced axon growth velocity of neurons giving rise to the perforant path projecting to the hippocampus. This was due to Ca^{2+}-dependent molecular signaling to the axon affecting stabilization of the actin cytoskeleton. The spontaneous activity affected the entire entorhinal cortical network and thus led to reduced overall axon fiber numbers in the mature perforant path which is known to be important for specific memory functions. Our data show that precise regulation of early cortical activity by bioactive lipids is of critical importance for proper circuit formation.

Title: Midline radial glial-like cells promote longitudinal growth of dorsal column axons during development

Authors: *K. KRIDSADA[1], J. NIU[1], P. HALDIPUR[2], K. MILLEN[2], W. LUO[1];
[1]Neurosci., Univ. of Pennsylvania, Philadelphia, PA; [2]Pediatrics, Seattle Children's Res. Inst. Ctr. for Integrative Brain Res., Seattle, WA

Abstract: The ability to regenerate the central nervous system is limited to only a subset of vertebrates, such as amphibians and fish. In these robustly regenerating species, radial glial cells (RGCs) in the spinal cord are thought to construct stereotyped channels that precede neurite outgrowth, providing a growth permissive environment during both regeneration and development. In rodent spinal cords, RGCs similarly grow a fibrous network of highly conserved compartments during embryonic stages when axon tracts begin to form. However, whether mammalian RGCs play similar roles in developmental longitudinal axon growth, and whether this mechanism can be harnessed to promote spinal cord regeneration, remains largely unknown. By studying mechanisms underlying CNS development, we hope to provide novel insight into regeneration. Our lab has identified a population of roof plate-derived radial glial-like cells that migrate into the dorsal midline of the mouse spinal cord during embryonic growth of dorsal column (DC) axons from E14.5. These $Zic2^{+}$ radial glial-like midline cells (ZRGCs) lie in close apposition to the longitudinally growing DC fibers, which are the ascending axons of mechanoreceptors in the dorsal root ganglia. Their proximity to the fibers suggests a potential cell-axon interaction in promoting growth. By examining a mouse line carrying a mutation in *Lmx1a*, a gene required for roof plate development, we show here that ascending DC fibers are shortened in *Lmx1a*-null mice, and fail to reach their targets in the medulla. Additionally, *Lmx1a*-null mice exhibit ectopic crossings across the midline, suggesting a physical/chemical barrier role for ZRGCs to maintain left-right segregation in the spinal cord DC. These deficits, in conjunction with their scaffold-like morphology, suggest that ZGRCs provide mechanical and/or chemical support to promote longitudinal growth and pathfinding of developing DC fibers. Using deep sequencing analysis of enriched gene expression in ZGRCs at E14.5, we determined that ZGRCs express a number of growth promoting factors, such as extracellular matrix molecules, growth factors, and guidance cues. Our findings reveal a novel developmental mechanism in the mammalian system for long distance growth and guidance throughout the spinal cord.

Title: Identification of a novel axon guidance factor expressed in Cajal-Retzius cells

Authors: *J. TANG, J. PENG, Z. LUO;
Lab. of Synaptic Signaling, Inst. of Neuroscience,Chinese Acad. of Scien, Shanghai, China

Abstract: It is still unclear that why homotopic callosal axonal projection could reach to contralateral cortex layer II/III and stop there. We identified a novel axon repulsive factor tex264 directly regulate this process. Co-staining of tex264 protein and Reelin showed tex264 expressed in the Cajal-Retzius cells (CR cells), a population of transient neurons located in the marginal zone of developing cortex. Using explant co-culture and axon turning assay, we found tex264 strongly repulsed axonal growth in vitro, which could be mediated by tex264 induced growth cone collapse. Tex264 forebrain cKO mice showed multiple projection defects. Using SMI312 staining and BDA injection to trace the cKO mouse callosal projection, we found lacking of the repulsive cue tex264, more axon passed by contralateral cortex layer II/III and projected to layer I. Thus, tex264 should be considered as a novel axon guidance which is essential for connectome integration of neocortex superficial layers.

Title: Involvement of ecto-nucleotide pyrophosphatase/phosphodiesterase 1 (ENPP1) in regulation of insulin-induced neurite outgrowth in sensory neurons

Authors: *K. NISHIDA, R. IKEDA, A. HOSODA, R. HIRAI, A. OHISHI, K. NAGASAWA; Kyoto Pharmaceut. Univ., Kyoto, Japan

Abstract: Insulin functions as a trophic factor *via* insulin receptor (IR) in sensory neurons, and their signaling induces neurite outgrowth. However, regulating mechanisms under which induction of the neurite outgrowth are poorly understood. ENPP1, an ATP metabolizing ecto-enzyme, is reported to be one of the molecules to regulate insulin signaling by interacting with IR in the liver. In this study, we examined whether ENPP1 was involved in regulation of insulin-induced neurite outgrowth or not. On Western blotting, expression of ENPP1, IR-alpha and IR-beta was detected in fraction of sensory neurons and rat dorsal root ganglion (DRG). By immunohistochemistry, ENPP1-immunoreactivity was found in the small- and medium-sized sensory neurons in DRGs, and ENPP1 was colocalized with IR-alpha in soma of sensory neurons. Insulin dose-dependently enhanced the neurite outgrowth in primary cultured sensory neurons. Moreover, in the IR-expressing, but not IR- and ENPP1-coexpressing, PC12 cells, treatment with insulin increased the neurite outgrowth and the phosphorylation levels of IR. These results suggest that ENPP1 might negatively regulate insulin-induced neurite outgrowth in sensory neurons.

Title: Differential fasciculation of ipsilateral and contralateral retinal ganglion cell axons

Authors: *A. A. SITKO[1], F. FIEDERLING[2], F. WETH[2], C. A. MASON[3];
[1]Dept. Neurosci., Columbia Univ. Press, New York, NY; [2]Zoologisches Inst., Karlsruher Inst. fuer Technologie, Karlsruhe, Germany; [3]Neuroscience, Pathology and Cell Biology, Ophthalmology, Columbia Univ., New York, NY

Abstract: Fasciculation is a key mechanism in axon guidance during neural development. It has been most well studied in early axon tracts, in which young axons extend along pioneer axons, aided by cell adhesion molecules expressed along the pioneers. Fasciculation may also be an important mechanism of organizing axons in developing tracts. In the mouse visual system, ipsilaterally- and contralaterally-projecting (ipsi and contra) retinal ganglion cell axons are segregated from each other in the retinogeniculate pathway, specifically in the optic nerve and tract. We hypothesize that fasciculation contributes to this segregation of retinal axon cohorts. Specifically, we propose that ipsi axons have a greater preference to self-fasciculate than contra axons. To test this hypothesis, we use an *in vitro* retinal explant culture system to compare the fasciculation behaviors of ipsi and contra retinal axons. We find a difference in intrinsic fasciculation preferences between the two cohorts, and are testing how exposure to chiasm cues affects relative fasciculation behavior of ipsi and contra neurites. In additional, we have developed a novel retinal explant system to compare inter-explant fasciculation between neurites extending from pairs of like (i.e., ipsi/ipsi or contra/contra) or unlike (ipsi/contra) retinal explants. Finally, in order to better understand the molecular underpinnings of differential fasciculation behaviors of ipsi and contra axons, we assess the role of EphB1, a receptor tyrosine kinase expressed by ipsi and not contra retinal ganglion cell axons, and which is required for correct ipsilateral projection at the optic chiasm. This work not only provides insight into the mechanisms underlying pre-target axon organization in the developing retinogeniculate system, but also provides a new *in vitro* platform for testing the effects of candidate molecules on retinal axon fasciculation and axon-axon interactions.

Title: Differential expression of axon-sorting molecules in mouse olfactory sensory neurons

Authors: *H. TAKEUCHI, N. IHARA, A. NAKASHIMA, Y. IKEGAYA;
Grad. Sch. of Pharmaceut. Sciences,, The Univ. of Tokyo, Tokyo, Japan

Abstract: In the mouse olfactory system, the axons of olfactory sensory neurons that express the same type of odorant receptor (OR) converge to a specific set of glomeruli in the olfactory bulb (OB). It is widely accepted that expressed OR molecules instruct glomerular segregation by regulating the expression of axon-sorting molecules. Although the relationship between the expression of axon-sorting molecules and OR types has been analyzed in detail, those between the expressions of axon-sorting molecules remain to be elucidated. Here we collected the expression profiles of four axon-sorting molecules from a large number of glomeruli in the OB. These molecules demonstrated position-independent mosaic expressions, but their patterns were not identical in the OB. Comparing their expressions identified positive and negative correlations between several pairs of genes even though they showed various expressions. Furthermore, the principal component analysis revealed that the factor loadings in the principal component 1, which explain the largest amount of variation, were most likely to reflect the degree of the cyclic nucleotide-gated (CNG) channel dependence on the expression of axon-sorting molecules. Thus, neural activity generated through the CNG channel is a major component in the generation of a wide variety of expressions of axon-sorting molecules in glomerular segregation.

Title: Effect of maternal obesity on fetal brain development: impairment in the expression of axon guidance cues

Authors: *N. MERABOVA[1,2], G. TATEVOSIAN[1,2], S. G. BOURET[3], S. PARK[3], N. DARBINIAN[1,2], A. E. EDLOW[4], R. A. SIMMONS[5], L. GOETZL[1,6];

Institute, Developmental Neurosci. Program, Children's Hosp. of Los Angeles, Keck Sch. of Medicine, Univ. of Southern California, Los Angeles, CA; [4]Mother Infant Res. Institute, Dept. of Obstetrics & Gynecology,Tufts Med. Ctr., Boston, MA; [5]Pediatrics; Div. of Neonatology, Univ. of Pennsylvania, Philadelphia, PA; [6]Dept. of Obstetrics & Gynecology, Philadelphia, PA

Abstract: **Introduction**: Epidemiologic studies suggest that maternal obesity (MO) is associated with an increased risk of long term pediatric neurodevelopmental and metabolic sequelae. The complex underlying neurodevelopmental processes require further investigation. We hypothesized that in-utero exposure to MO would alter expression of genes involved in axonal growth. We therefore investigated expression of class 3 Semaphorins (*SEMA3A-G*) and their receptors and co-receptors; Plexins (*PLXNA1-4*) and Neuropilins (*NRP1* and *NRP2*) respectively.
Methods: We performed an IRB-approved, matched case-control study in women with singleton fetuses undergoing elective pregnancy termination in the second trimester (GA 15 - 21 wks). MO cases ((6♂/6♀), BMI >30) were compared to lean controls (6♂/6♀, BMI <25). Subjects were matched for gestational age, race and fetal gender. Total RNA was isolated from snap-frozen fetal brain tissue. RT-qPCR was performed with specific primers. The ΔΔCt was calculated following GAPDH normalization and fold change calculated relative to controls. Changes in gene expression levels with $p<0.05$ were considered statistically significant.
Results: Our results show a significant up regulation in fetal mRNA expression of *SEMA3E* and *PLXNA3* transcripts with MO in both males and females (**Table 1**). We observed gender specific changes: Semaphorin-3F (*SEMA3F*) and its receptor Neuropilin-1 (*NRP-1*) were up regulated in brain tissue from males (↑1.8 ($p=0.05$) and ↑1.5 ($p=0.02$) folds respectively), with no effect in females.
Conclusions: Our data suggest that in utero exposure to MO is associated with potentially clinically significant, sex-specific alterations in fetal brain expression of genes related to axon guidance. These molecular alterations may provide a mechanistic link between MO and neurodevelopmental and behavioral outcomes.

Title: A novel developmental requirement for NMDA receptors in axon guidance is disrupted by hypoxic injury

Authors: *J. BONKOWSKY[1], J. GAO[2], T. STEVENSON[2];
[1]Dept. of Pediatrics, Univ. of Utah Sch. of Med., Salt Lake City, UT; [2]Univ. of Utah, Salt Lake City, UT

Abstract: Hypoxic injury in the developing human brain is a major cause of chronic neurodevelopmental impairments in part through loss of normal connectivity although the mechanisms are poorly understood. We found that hypoxic injury down-regulates N-methyl-D-aspartate receptor (NMDAR) expression in the developing brain. NMDARs are glutamate-gated heteromeric ion channels that play key roles in excitatory synaptic transmission in the adult brain and in synapse stabilization. We found that commissural axon pathfinding is disrupted by pharmacological inhibition of NMDARs. We demonstrate that the NMDAR NR1 subunit is expressed in commissural axons, and that *vglut1*, the biosynthesis enzyme for glutamate, is expressed in neurons adjacent to the commissural axons. We further show that an NMDAR agonist can rescue hypoxic-induced commissural neuron pathfinding defects. In summary, we report an unexpected developmental role for NMDARs in axon pathfinding, and show that disruption of normal NMDAR function by hypoxia contributes to connectivity disruption.

Title: Neurexin restricts l4 columnar targeting through promoting ephrin clustering

Authors: *L. LIU, Y. TIAN, J. HAN;
Southeast Univ., Inst. of Life Sci., Jiangsu, China

Abstract: Columnar restriction is commonly observed in vertebrates and invertebrate nerve system, which helps to form non-overlapping receptive fields and preserve the spatial sensory information from the periphery. Columnar restriction is thought to be mediated by contact-dependent repulsive interactions that are regulated by cell surface proteins. Neurexins are cell adhesion molecules involved in synapse formation and synaptic transmission. However, the potential roles of Neurexin in neural early development are unclear. Here, we showed that Neurexin is expressed in *Drosophila* laminar neurons and accumulated in their growth cones. Depletion of Neurexin from L4 neurons results in their axons project into neighboring columns. Using yeast two-hybrid screening, we identify that Neurexin interacts with Ephrin, a key molecule involved in axonal targeting. We further demonstrated that Neurexin mediates L4 columnar restriction through promoting Ephrin clustering, which is essential for L4 columnar

restriction. Our study reveals novel roles of Neurexins in mediating Ephrin clustering and columnar restriction, and supports a model in which L4-expressed Ephrin cooperates with gila-derived EPH to restrict L4 axons in column.

Title: Celsr3 modulates visual development and function in mice

Authors: *L. ZHOU;
GHM Inst. of CNS Regeneration, Jinan Univ., Guangzhou, China

Abstract: Visual function is highly dependent on the integrity of the complicated visual network. Celsr3, a member of atypical cadherin family, is critical for brain wiring such as in forebrain, hippocampus and spinal cord. However, its role in visual development and function is still not known. Here we study this issue by inactivating *Celsr3* in different retinal cells. Using Celsr3-GFP transgenic mice, Celsr3 is identified to be expressed in different retinal cells including ganglion cells (RGCs), bipolar cells and amacrine cells. Upon Isl1-Cre activation, *Celsr3* is conditionally removed in some ganglion cells and most bipolar cells. In *Isl1-Cre;Celsr3$^{f/-}$* mutants, the visual function is abnormal using dark/light box test, the raster discernibility is significantly decreased by optomotor test, and papillary reflex is diminished, compared to the control. Electroretinogram (ERG) shows abnormal a and b waves in *Isl1-Cre;Celsr3$^{f/-}$* mice but unaffected oscillating potentials (Ops), compared to control mice. Mutant mice have normal retinal laminar organization by histology studies, comparable cell number of amacrine cells and horizontal cells, but significant reduction in RGCs, compared to control samples. Furthermore, RGC projections to the superior colliculus (SC) and lateral geniculate nucleus (LGN) are impaired in mutant mice. Using ChAT-Cre and PCP2-Cre to specifically

inactivate Celsr3 in amacrine cells and bipolar cells respectively, we found the local circuit in the retinas was disrupted. Thus, Celsr3 is required for the formation of normal visual function probably via regulating RGC projections and retinal local network establishment.

Title: Study of genes critical for retinal axon navigational error associated with ocular albinism

Authors: *S. GUHA, Y. HE, D. FARBER;
Ophthalmology, Jules Stein Eye Institute/ UCLA, Los Angeles, CA

Abstract: Mutations in the Ocular Albinism 1 (OA1) gene are responsible for the disease, ocular albinism, characterized by abnormal melanosome biogenesis and navigation error of the retinal ganglion cell (RGC) axons to the brain. How the reduced pigmentation of the RPE exerts its effects on the RGCs to influence the misrouting of their axons remains unsolved. We hypothesized that microarray analysis of gene expression changes between control and *Oa1*$^{-/-}$ mouse embryonic eyes would identify genes influencing normal/abnormal decussation at the chiasm. Here, we report that 51 genes were differentially expressed in embryonic day 15 (E15) RPEs/retinas- in *Oa1*$^{-/-}$ vs control B6/NCrl mice. QPCR, Western blot and immunohistochemistry showed that Creb binding protein (Crebbp), Doublecortin (*Dcx)* and Transcription factor 2 beta (Tfap2b) were down-regulated in the embryonic and postnatal eyes of *Oa1*$^{-/-}$ mice. These data suggest that Crebbp, Dcx and Tfap2b may have a critical role to play during a precise embryonic period in the axon guidance defects associated with ocular albinism.

Title: Dysregulation of *Dscam* mRNA localization and local translation in Down syndrome model mice

Authors: *S. JAIN[1], K. WELSHHANS[2];
[1]Dept. of Biol. Sci., Kent State Univ., Kent, OH; [2]Dept. of Biol. Sci. and Sch. of Biomed. Sci., Kent State Unviersity, Kent, OH

Abstract: Down syndrome cell adhesion molecule (DSCAM) plays an important role in many neurodevelopmental processes such as axon guidance, dendrite arborization and synapse formation. DSCAM is located in the Down syndrome trisomic region of human chromosome 21 and implicated as one of the genes directly contributing to the Down syndrome brain phenotype, which includes a reduction in the formation of long-distance connectivity. We have previously found that overexpression of DSCAM in mouse cortical pyramidal neurons results in a decrease in axon outgrowth and branching. This finding implicates DSCAM as a contributor to the formation of improper neuronal connectivity in Down syndrome. Thus, it is of significant interest to understand the underlying molecular mechanisms by which *Dscam* regulates axon pathfinding and how these processes may be dysregulated in Down syndrome. The local translation of a select group of mRNA transcripts within growth cones is necessary for the formation of appropriate neuronal connectivity. We find that *Dscam* mRNA is localized to growth cones of C57BL/6J mouse hippocampal pyramidal neurons. Furthermore, stimulation with the axon guidance molecule, netrin-1, results in an increase in locally translated DSCAM protein in growth cones. This increase in locally translated DSCAM requires deleted in colorectal cancer (DCC), a netrin-1 receptor. When examining these processes in a mouse model of Down syndrome (Ts65Dn), we find dysregulation of the localization and local translation of *Dscam* mRNA in early postnatal neuronal growth cones. Furthermore, study of neuronal connectivity formation in Ts65Dn mice reveals the disruption of appropriate interhemispheric connectivity formation during development. Taken together, these results have implications for Down syndrome, because dysregulated local translation of *DSCAM* during embryonic development may contribute to inappropriate neural connectivity and the etiology of this neurodevelopmental disorder.

Title: Stage II retinal waves promote glutamate release in developing rat retinas

Authors: *C.-Y. YANG[1], C.-T. WANG[1,2,3,4];
[1]Inst. of Mol. and Cell. Biol., [2]Dept. of Life Sci., [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan; [4]Genome and Systems Biol. Program, Natl. Taiwan Univ. and Academia Sinica, Taipei, Taiwan

Abstract: Early in the development of vertebrate visual system, the patterned, correlated, spontaneous bursts of action potentials display in immature retinal ganglion cells (RGCs) and propagate through the developing visual system termed retinal waves. The stage II waves, occurring during birth to postnatal day 9 (P9) in rodent, are crucial for refining visual circuits from retinas to central brain. The waves are mediated by periodic spontaneous depolarizations in starburst amacrine cells (SACs), releasing acetylcholine and γ-aminobutyric acid to neighboring SACs and RGCs. Previously we found that the Syt I-mediated increase in wave frequency acts through promoting exocytosis in RGCs and this effect is abolished by bath application of ionotropic glutamate receptor antagonists. However, whether stage II retinal waves promote glutamate release during the first postnatal week remains unclear. To solve this problem, we expressed the intensity-based glutamate-sensing fluorescent reporter (iGluSnFR) in developing rat RGCs. We found that bath application of 100 μM glutamate increased the fluorescence intensity of iGluSnFR in RGCs, suggesting that iGluSnFR can serve as an effective sensor for glutamate release in developing rat retinas. We subsequently observed the changes in the fluorescence intensity following pharmacological treatments. First, high KCl (119 mM) was used to depolarize retinal neurons, thus inducing Ca^{2+}-dependent exocytosis. Second, adenosine $A_{2A}R$ agonist (5 μM CGS21680) was applied to increase the wave frequency and cAMP/PKA activity. We found that application of high KCl or CGS21680 alone increased the intensity of iGluSnFR in developing RGCs. The intensity of iGluSnFR was profoundly increased in the presence of both KCl and CGS21680. These results suggest that glutamate release can be promoted by increasing the frequency of stage II retinal waves.

Title: Distinct roles of pro- and mature bdnf signaling in retinotectal axon remodeling in the developing xenopus visual system

Authors: *E. KUTSAROVA, M. MUNZ, A. SCHOHL, A. WANG, O. BILASH, Y. ZHANG, C. LEE, E. S. RUTHAZER;
Montreal Neurolog. Institute, McGill Univ., Montreal, QC, Canada

Abstract: Sensory experience is required to build precise topographic representations of the sensory world in the brain. Specific patterns of neuronal activity can instruct the stabilization of appropriate and the pruning of inappropriate connections between neuronal partners. Brain-derived neurotrophic factor (BDNF) is synthesized as precursor protein (proBDNF) and its mature form (mBDNF) is derived by cleavage of the pro-domain. Tissue plasminogen activator (tPA) and plasmin are believed to be crucial for extracellular conversion of proBDNF to mBDNF. BDNF is an important player in modifying synaptic efficacy, with proBDNF likely signaling through p75NTR to facilitate synaptic weakening and mBDNF signaling through TrkB to facilitate synaptic strengthening. Using *in vivo* multiphoton imaging of RGC axonal growth in the developing visual system of *Xenopus laevis* tadpoles, combined with a visual stimulation protocol allowing us to stimulate the retinal ganglion cells (RGC) either in synchrony or out of synchrony with neighboring inputs, we are able to identify distinct activity-dependent components that underlie structural developmental plasticity. Our preliminary experiments involving depletion of mBDNF by TrkB-Fc suggest that mBDNF signaling is necessary for Hebbian (synchrony-induced) stabilization of axonal branches. In contrast, presynaptic knock-down of p75NTR prevents axonal branch loss, in line with the idea that proBDNF and mBDNF could act in opposition in activity-dependent circuit refinement. Inhibition of the tPA/plasmin

system impedes axonal branch elaboration, suggesting that the conversion of proBDNF to mBDNF may be crucial for neural circuit remodeling.

Title: Investigating the electrical and morphological changes of Cajal-Retzius cells during cortical development

Authors: *L. SUN[1], Y. BAI[2], X. WANG[2];
[1]Inst. of Biophysics, Beijing City, China; [2]Inst. of Biophysics, Beijing, China

Abstract: Cajal-Retzius (CR) cells were identified and demonstrated by Ramón y Cajal and Retzius in the late 19th century. CR cells were born at very early developmental stage, then migrated tangentially from different brain regions to the marginal zone and covered the whole neocortex gradually. It is well known that CR cells played a key role in the structural and functional organization of the neocortex by secreting reelin. But the role of electrical and morphological change of CR cells during the cortical development were still poorly understood. Taking advantage of the EBF2-GFP mouse, CR cells were easily targeted. By Combining the patch-clamp recording, immunostaining and confocal microscopy, we investigated the functional and structural properties of CR cells from P1 to P14. We found that the change of electrical characterize of CR cells were consistent with the morphological changes. The axon of CR cells showed a long range extension and multiple branches which would indicate the role of CR cells in the communication between different cortical regions.

Title: Tuning mouse embryonic stem cell-derived motor neurons' activity using optogenetic stimulation

Authors: G. PAGAN-DIAZ[1,2], C. CVETKOVIC[1], R. BASHIR[1], *P. SENGUPTA[1,2];
[1]Dept. of Bioengineering, [2]Beckman Inst. for Advanced Sci. and Technol., Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: Characterization of distinct neuronal lineages derived from progenitor cells is important for studies aimed to develop biological models that can recreate basic functions of neurons of the central nervous system. These models are particularly important for studies on neurological disorders aimed at understanding disease pathways and for high throughput testing of drug candidates. Furthermore, developing a model system with embryonic stem (ES) cell-derived spinal cord motor neurons (MN) can be attractive for development of a neuromuscular junctions in a biological soft-tissue robotic systems. The critical first step towards building a useful model with MNs require a thorough investigation of spontaneous and stimulation-evoked tuning of electrical activity of developing MN networks. We used TdTomato tagged Channelrhodopsin-2 (ChR2-TdTom) expressing mouse ES cells for this study which were differentiated for 9 days (D9) to form MN embryoid bodies (MEBs). The MEBs are about 200-400 micron in size, and the cells at the interior undergo apoptosis resulting in a fluid-filled cavity surrounded by viable cells on the outside. Differentiation of ES cells into MEBs was monitored by the production level of eGFP with a MN specific Hb9 promoter. The MEBs were then plated on collagen type-I coated custom-designed micro-electrode chips fabricated in-house for measurement of their electrical activity. Electrical signal from MEB networks, both slow potential and action potentials, was measured for 6 days (D9 to D9+6) using a Multi-Channel Systems amplifier. Network firing patterns were evaluated for bursting activity and spectral content using analysis algorithms developed in MC_Rack and MATLAB. The developing MEBs were characterized, in parallel, for synapse density and neuronal protein content using confocal microscopy. Our results demonstrated that differentiated MEBs are spontaneously electrically active and they exhibited an inherent oscillatory network firing pattern that slowly developed in

these networks. The activity across different electrodes exhibited synchronized periodic behavior. Optical stimulation of MEBs with light pulses from a blue LED (470 nm) induced activity in these networks, affected the firing patterns and changed network oscillation timescales. Moreover, a daily optical stimulation regimen for these developing MEBs enhanced their maturation and altered their sensitivity toward stimulation. These findings are a milestone in the efforts of developing MN circuits from ES cells that can potentially be used to actuate and control skeletal muscle tissue in the development of higher order soft-tissue robotics.

Title: Synaptotagmin III in developing retinal ganglion cells regulates patterned spontaneous activity and visual circuit development

Authors: *W.-C. SHU[1], C.-T. WANG[1,2,3,4];
[1]Inst. of Mol. and Cell. Biol., [2]Dept. of Life Sci., [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan; [4]Genome and Systems Biol. Program, Natl. Taiwan Univ. and Academia Sinica, Taipei, Taiwan

Abstract: During a developmental critical period, patterned spontaneous activity is essential for establishing functional neural circuits. This patterned spontaneous activity propagates through the developing visual system termed retinal waves. Stage II retinal waves, occurring during birth to postnatal day 9 (P9) in rodents, are critical for establishing the eye-specific segregation of retinogeniculate and retinocollicular projections. These waves are generated by starburst amacrine cells (SACs) spontaneously releasing acetylcholine (ACh) and γ-aminobutyric acid (GABA) to neighboring SACs and retinal ganglion cells (RGCs). We previously found that the expression level of synaptotagmin III (Syt III), a calcium sensor protein in vesicle release, is significantly increased in P4-P6 rat RGCs (P4-P8 in rodents as the critical period for eye-specific segregation). Syt III in neonatal RGCs increases the frequency but decreases the spatial correlation of retinal waves via calcium binding to its C2AB domains. However, how and why Syt III in RGCs modulates stage-II waves remain unclear. Since RGCs secrete glutamate and Syt III serves as a calcium sensor in transmitter release, we propose that Syt III in developing RGCs

may promote glutamatergic transmission between SACs and RGCs, thus regulating the spatiotemporal properties of stage II retinal waves. To verify our hypothesis, we overexpressed Syt III and Syt III-C2AB*(a mutant harboring the abolished calcium binding sites) in RGCs. During 3-4 days after *exo vivo* transfection, we performed live calcium imaging to measure the changes of wave properties in the presence of ionotropic glutamate receptor antagonists. We found that the frequency of wave-associated calcium transients was decreased to the same level in retinas overexpressing control, Syt III, or Syt III-C2AB*, suggesting that Syt III in developing RGCs may promote glutamate release, thus affecting the wave properties. Moreover, by using *in vivo* electroporation, we transfected P3 rat RGCs with Syt III and found the alteration in contralateral retinogeniculate projections. Thus, our results suggest that Syt III in developing RGCs may regulate patterned spontaneous activity and visual circuit development.

Title: An unanticipated role for activity in olfactory circuit assembly and stability

Authors: *B. THROESCH[1,2], K. N. JAMES[1,2], W. DAVINI[1], S. A. SILVER[1], K. T. EADE[1], N. TORABI-RANDER[1], K. K. BALDWIN[1];
[1]Mol. and Cell. Neurosci., TSRI, San Diego, CA; [2]Neurosci., UCSD, La Jolla, CA

Abstract: Neural circuit assembly and maintenance are shaped by two main mechanisms: genetic programs and neural activity. Defining the balance between these two forces is critical to understanding how the brain assembles itself. The olfactory bulb is a highly dynamic system where newly born interneurons are integrated throughout the lifetime of an organism. The largest population of these interneurons are called granule cells. While granule cells are present at birth, additional granule cell precursors are produced in the subventricular zone and migrate into the olfactory bulb where they mature and integrate into the first-order olfactory processing circuitry. Mature granule cells receive excitatory input from and form inhibitory synapses with second-order projection neurons, mitral and tufted cells, continuously reshaping and organizing the olfactory bulb circuit. Therefore, the olfactory system is an attractive model system to study the roles of activity in governing neural circuit formation and maintenance.

Using transgenic mice expressing tetanus toxin to selectively block vesicular release from either olfactory sensory neurons or mitral and tufted cells, we find that loss of second-order mitral and tufted neuron signaling has a dramatic impact on the structure of the olfactory bulb. The increased disorganization of the olfactory bulb is due to delayed maturation and increased cell death of most populations of inhibitory interneurons, including granule cells, while excitatory olfactory sensory neurons and mitral and tufted cells were spared. Single cell tracing analyses of granule cells show these neurons exhibit decreased dendritic complexity and branching as well as decreased spine density, resembling immature granule cells. These studies establish a new role for non-sensory neuronal activity in shaping and maintaining odor processing circuits.

Title: Dysbindin, a schizophrenia susceptibility gene, regulates patterned spontaneous activity in the developing rat retina

Authors: *M.-H. LU[1], C.-T. WANG[2,3,4,5];
[1]Sch. of Med., [2]Inst. of Mol. and Cell. Biol., [3]Dept. of Life Sci., [4]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan; [5]Genome and Systems Biol. Program, Natl. Taiwan Univ. and Academia Sinica, Taipei, Taiwan

Abstract: Dysbindin is encoded by a schizophrenia (SCZ) susceptibility gene that is associated with SCZ pathogenesis. Previous studies revealed that dysbindin regulates neuronal function, including exocytotic kinetics, receptor trafficking, and dendritic spine formation. However, how dysbindin affects neural circuit development remains unknown. Prior to visual experience, patterned spontaneous activity propagates throughout the developing vertebrate visual system. This robust activity, also known as “retinal waves”, exhibits unique spatiotemporal properties which are essential to visual circuit refinement. Here, we study the role of dysbindin in regulating the spatiotemporal properties of retinal waves. Immunofluorescent chemistry revealed that dysbindin was expressed in the ganglion cell layer (GCL) and inner plexiform layer (IPL) of the P0-P2 rat retina. During 60-80 hr after *exo vivo* transfection, calcium imaging was performed

in the dysbindin-overexpressing or -depleting neonatal rat retinas. The imaging data were analyzed with MATLAB code, allowing simultaneous analyses of >100 cells in the GCL. Our results showed that the frequency of wave-associated spontaneous calcium transients was decreased by overexpressing dysbindin but increased by depleting dysbindin. Moreover, both overexpression and depletion of dysbindin decreased the pairwise correlation of calcium transients, suggesting the expression level of dysbindin may regulate the spatial correlation of retinal waves. The decreased spatial correlation in the dysbindin-overexpressing or -depleting retinas may be attributed to a decrease in larger wave events which recruit more neighboring cells in the GCL. Therefore, dysbindin is important for regulating the spatiotemporal properties of retinal waves, implying its potential role in establishing visual circuits from the developing retina to central brain.

Title: Independent regulation of 'feedforward' and 'feedback' E-I ratios following visual deprivation in a canonical V1 microcircuit

Authors: ***N. J. MISKA**, G. G. TURRIGIANO;
Neurosci., Brandeis Univ., Waltham, MA

Abstract: Monocular deprivation (MD) during the critical period for ocular dominance plasticity induces a stereotyped sequence of changes in visual cortex. Brief (2d) MD is thought to induce thalamocortical (TC) and intracortical (IC) LTD that together suppress firing, but during longer deprivation (6d), homeostatic potentiation of excitation contributes to a restoration in firing rates despite continued deprivation. Whether dynamic changes in inhibition also contribute to this biphasic response to prolonged MD is unknown. Here, we used optogenetics to probe for changes in the E/I ratio in 'feedforward' TC circuits and 'feedback' IC circuits within L4 of monocular V1. We virally labeled the LGN with Channelrhodopsin-2 (ChR2), which allows us

to use pulses of blue light to stimulate TC afferents within V1 while recording from layer 4 pyramidal neurons in acute cortical slices. Unexpectedly, brief MD increased the TC E/I ratio, and this shift reversed during extended MD. Consistent with reports that TC synapses undergo LTD during brief MD, we found that optogenetically evoked, desynchronized TC quantal amplitudes onto L4 pyramids were depressed following brief MD, and LTD induction was occluded. This suggests that in order to increase TC E/I ratio, TC-driven feedforward inhibition onto L4 pyramids must depress even more than direct TC excitation. These data also suggest that the suppression of firing is not driven by changes in the feedforward TC circuit, but might instead be due to changes in the feedback IC circuit. To investigate this we combined a mouse line expressing CRE recombinase in L4 pyramidal neurons with local viral injection of a floxed-ChR2 transcript to selectively label and stimulate L4 pyramidal neurons, while recording from other nearby L4 pyramidal cells. Preliminarily, brief MD reduced the E/I ratio at IC synapses. Hence, our data suggest that the E/I ratio shifts in opposite directions in 'feedforward' and 'feedback' L4 subcircuits following brief MD. Presently, we are recording from L4 PV+ interneurons as well as neighboring L4 pyramidal cells while stimulating TC afferents to determine whether relative changes in TC synaptic strength onto PV+ interneurons vs. pyramidal neurons could account for the observed shift in TC-driven E/I ratio.

Title: Action potential firing by neighboring inputs promotes branch elaboration of developing retinotectal axons

Authors: *T. N. RAHMAN[1,2], M. C. MUNZ[2], E. S. RUTHAZER[2];
[1]McGill, Montreal, QC, Canada; [2]Montreal Neurolog. Inst., Montreal, QC, Canada

Abstract: The precise wiring of neuronal circuitry is established through the action of molecular guidance cues and further refined by activity-dependent mechanisms. However, it remains

poorly understood how the precise patterns of activity within a network alter circuit refinement. Here, we utilize the developing retinotectal circuit of translucent albino Xenopus laevis tadpoles to study the influence of activity-dependent mechanisms on axon branch dynamics by performing in vivo, time-lapse imaging. All retinal ganglion cells (RGC) in the Xenopus tadpole normally project their axons to the contralateral optic tectum, but in a small fraction of animals, one or two RGC axons are instead misguided ipsilaterally. In such animals the pattern of activation of a single cell relative to all its neighbouring inputs in an intact animal can be manipulated independently by presenting flashes of light to either the ipsilateral or contralateral eye. Using in vivo two-photon microscopy while simultaneously presenting visual stimulation, we observed that contralateral, but not ipsilateral, eye stimulation was sufficient to increase branching of the ipsilateral axon. Thus, increased activity of neighbouring axons, presumably cooperatively acting to drive postsynaptic firing of tectal neurons, is sufficient to promote activity-dependent axonal elaboration. Stimulation of the specific axon by itself was not sufficient to enhance its growth. However, we find that firing of the ipsilateral axon did upregulate the rate of its branch tip retractions. These results confirm that patterned visual input plays an instructive role in mediating changes in branch dynamics and that axon elaboration and extension are promoted non-cell autonomously.

Abstract: Although the optically and genetically accessible nervous system of *C. elegans* is ideal for neurophysiology with fluorescent probes, the embryo's sensitivity to phototoxicity, small size, entangled body posture, and rapid movements in three dimensions confounds image acquisition and analysis. We have addressed this problem using an inverted Selective Plane Illumination Microscope for high-speed volumetric calcium imaging at high resolution. Using this platform, we imaged calcium dynamics in muscles and neurons. In muscles, we observed spreading correlated calcium waves in the four body wall muscle bundles, revealing how they

drive early twitching and later coordinated behavior. With a strain expressing nuclear-localized GCaMP from a panneuronal promoter, we tracked global brain dynamics at single cell resolution in freely behaving embryos. Current work is aimed at unambiguously identifying the active cells. We used a sparser cytoplasmic GCaMP label to monitor calcium dynamics in compartments of known neurons. As has been observed in the adult, we found that backward movement of the embryo correlated with calcium transients in reversal command interneurons, AVAL and AVAR. Thus the embryo is capable of coordinated behavior mediated by a similar circuit as in the adult. Functional imaging of the embryo will add a valuable layer of information to cross-reference with the rich anatomical and gene expression datasets already available.

Abstract: Graphene, a 2D material consisting of sp2-hybridised carbon atoms organised in a hexagonal lattice, has already impacted with its extraordinary physicochemical characteristics the fields of photonics and electronics but holds the potential to revolutionise specific areas of neuroscience and nanomedicine [1]. Biomedical research, and neuroscience in particular, are in fact increasingly focusing on graphene based materials (GBM) to successful design multifunctional neuro-devices able to modulate brain cells and neuronal network activity via direct interaction to these materials. The wider proposal of revolutionary biomedical devices based on the design of these 2D planar nanostructures towards interventions in the central nervous system (CNS), requires an accurate understanding of their interactions with the neuronal

milieu. In this direction we recently demonstrated that GBM in form of supporting, single layer, substrates and of sub-micrometric flakes, might interact in the biological microenvironment with subcellular structures of dissociated hippocampal cells of rat resulting in unexpected modulation (down- or up-regulation) of their electrical activity. In particular, we demonstrated the ability of a chronic treatment by graphene oxide nanoflakes to down-regulate neuronal signalling in the absence of cell toxicity [2]. From the other hand, surprisingly, neuronal networks developed on a single layer of graphene show higher electrical activity when compared to controls (glass and gold) or to multilayer GBM, revealing graphene interfaces ability to up-regulate network activity.Our results describe the potential of GBM to alter different modes of neuronal communication systems in the CNS hinting at opportunities for novel applications in synaptic engineering, network repairing or neuronal prosthesis.

Title: Mechanisms of spontaneous electrical activity in the developing cerebral cortex - subplate zone

Authors: *M. B. SINGH[1], S. D. ANTIC[2];
[1]Dept. of Neuroscience, UCONN HEALTH, Farmington, CT; [2]Inst. of Systems Genomics, Dept. of Neuroscience, UConn Hlth., Farmington, CT

Abstract: During cortical development, elemental processes such as neurogenesis, migration, neurodifferentiation and synapse formation are regulated by spontaneous calcium and electrical

activity. Environmental cues affect electrical activity at the early stages of brain development, which then controls gene expression. The aim of this work is to investigate the cellular mechanisms contributing towards the generation of spontaneous electrical activity in the mammalian cortical mantle. We are focused on a group of neurons located in the subplate zone (SP). SP neurons govern the path-finding of incoming axonal projections and establishment of cortical connections and cortical columns. The selective disruption of SP neurons has been implicated in mental retardation and schizophrenia. SP neurons, in both rodent and human cerebral cortex, exhibit spontaneous electrical activity comprising of highly irregular sustained (plateau) depolarizations crowned with action potentials. We performed whole-cell recordings, immunolabeling and calcium imaging from positively identified SP neurons in acute brain slices obtained from the newborn mice (P01 - P06). The spontaneously-occurring outbursts of electrical activity were challenged with drugs that block voltage-gated and ligand-gated membrane conductances. These experiments established that the spontaneous activity in SP neurons was not solely mediated by synaptic activity. A significant portion of spontaneous depolarizations seems to be linked to intact functioning of connexin-based pores and purinergic receptors. Immunostaining performed on brain sections from young mice (P1-P3) detected connexins 26 and 45. The high sensitivity of SP neurons to lanthanum or gadolinium, lack of sensitivity to pannexin channel antagonist probenecid, together with a partial decrease of activity upon blockade of purinergic receptors, prompted a working hypothesis that spontaneous flickering of connexin hemichannels causes initial depolarizations along with release of ATP that stimulate spontaneous electrical activity in cortical SP zone.

Title: Postnatal activation of Erk1/2 in astrocytes promotes excitatory synaptogenesis in immune challenge-induced seizure susceptibility

Authors: *J. CHEN[1], H. QIN[1], L. MOU[1], Y. HE[1], Y. YAN[2], H. ZHOU[1], Y. LV[2], J. WANG[2], Y. SHEN[1], Z. YUDONG[1];
[1]Dept. of Neurobio., Mail Box 22,Zhejiang Univ. Sch. of Med., Zhejiang, China; [2]The First Affiliated Hosp. of Wenzhou Med. Univ., Wenzhou, China

Abstract: The highest incidence of seizures occurs in early life, suggesting that seizure activities may be related to deficits in brain development. Immune challenges not only affect brain development, but also promote epileptogenesis, implying immune activation is one of the key factors linking epilepsy to abnormal brain development. Here we report that activating astrocytes by systemic lipopolysaccharide (LPS) challenges in the second postnatal week promotes excitatory synapse development, leading to enhanced seizure susceptibility in mice. Toll-like receptor 4 (TLR4) activation in astrocytes increased astrocytic Erk1/2 and phospho-Erk1/2 levels in a myeloid differentiation primary response protein 88 (MyD88)-dependent manner. Constitutively activating Erk1/2 in astrocytes was sufficient to enhance excitatory synaptogenesis without activating TLR4. Deleting MyD88 or suppressing Erk1/2 in astrocytes rescued LPS-induced developmental abnormalities of excitatory synapses and restored the enhanced seizure sensitivity. Thus, we provide direct evidence for a developmental role of astrocytes in shaping a predisposition to seizure generation..

Title: Outcomes with environmental enrichment therapy for autism

Authors: *M. A. LEON[1], E. ARONOFF[2], R. HILLYER[3];
[1]Univ. California, Irvine, CA; [2]Mendability, American Fork, UT; [3]Mendability, LLC, American Fork, UT

Abstract: Two randomized clinical trials have shown that environmental enrichment can ameliorate the symptoms of autism spectrum disorder, and in this project we determined its efficacy under real-world circumstances. 1002 children were given daily environmental enrichment by their parents, guided by an online system. The parents were asked to assess the symptoms of their child with a comprehensive questionnaire in regular intervals for 7 months. An intention-to-treat analysis showed significant gains for a wide range of symptoms that included: learning, memory, anxiety, attention span, motor skills, eating, sleeping, sensory processing, self-awareness, communication, social skills, and mood/autism behaviors. The

children of compliant caregivers were more likely to have significant improvement in their symptoms. The treatment was effective across a wide age range and initial symptom severity. There was also equal progress for males and females. Environmental enrichment in the form of Sensory Enrichment Therapy, delivered via an online system, therefore appears to be an effective, low-cost means of treating a wide range of autism symptoms across different ages, gender, and symptom severity.

Title: Longitudinal development of social visual engagement in infants later diagnosed with autism spectrum disorder

Authors: *L. OLSON[1,2], A. KLIN[2], S. SHULTZ[2], W. JONES[2];
[1]Joint Doctoral Program in Clin. Psychology, SDSU/UCSD, Decatur, GA; [2]Pediatrics, Marcus Autism Center/Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Background: From birth, typically-developing infants preferentially attend to the social signals, such as eye gaze, of their caregivers (Haith et al., 1977). Recent findings from our laboratory revealed that infants later diagnosed with autism spectrum disorder (ASD) exhibit decline in eye fixation from 2 until 24 months of age and that the decline is already underway

within the first 6 months after birth. In contrast, typically-developing infants show an increase in eye fixation from 2 to 6 months (Jones & Klin, 2013). These findings represent the earliest known indicators of social disability in infancy.
Objectives: Measure growth charts of social visual engagement from 2-24 months in TD infants and infants later diagnosed with ASD.
Methods: 106 infants were enrolled as risk-based cohorts: N = 40 at low risk (22 males) and N = 66 at high risk for ASD (41 males). Risk status was based on having either a full biological sibling with ASD (high) or on not having ASD among 1st, 2nd, or 3rd degree relatives (low). Diagnostic status was ascertained at 36 months. Of the HR sample, at outcome 13 received a diagnosis of ASD (9 male); 13 showed symptoms of the Broader Autism Phenotype (BAP, 11 male), and 40 (20 male) were confirmed non-ASD. Infants were shown scenes of naturalistic caregiver interaction as in Jones & Klin (2013). Eye-tracking data were collected at 10 time points (months 2, 3, 4, 5, 6, 9, 12, 15, 18, and 24). Longitudinal looking profiles for this cohort were compared with those of the earlier sample (2013) for eyes, mouth, body, and object regions within and between diagnostic group categories. Cohorts 1 and 2 were also combined for larger sample analyses.
Results: Analyses of the TD and ASD replication cohort by functional ANOVA are consistent with earlier results: longitudinal looking profiles for eyes, mouth, body, and object were not significantly different between cohorts 1 and 2 (all $F < 2.4$, $P > 0.14$). Across outcome groups, typically-developing children show increasing eye fixation; non-ASD siblings show increasing eye fixation; siblings with subthreshold (BAP) symptoms show neither increasing nor decreasing eye fixation, and infants later diagnosed with ASD show declining eye fixation. Similar spectrum effects are observed for body fixation (Fig. 1).
Conclusions: Our results replicate earlier findings showing that infants later diagnosed with ASD show decline in eye fixation from 2-to-24 months. Spectrum effects emerging in the first 6 months give early indication of social disability in infants later diagnosed ASD. Future analyses will include longitudinal looking profiles for female infants.

Title: Gaze behavior and joint attention in dynamic scenes of school classes by children with autistic spectrum disorders; an eye-tracking study for early diagnosis and intervention

Authors: *T. HIGUCHI[1], Y. ISHIZAKI[2,4], A. NORITAKE[3], Y. YANAGIMOTO[2], H. KOBAYASHI[2,4], K. NAKAMURA[3], K. KANEKO[2,4];
[1]Pediatrics, Kansai Med. Univ. Takii Hosp., Osaka, Japan; [2]Pediatrics, [3]Physiol., Kansai Med. Univ., Osaka, Japan; [4]Dept. of Developmental Pediatrics Donated by Nabari City, Kansai Med. Univ., Mie, Japan

Abstract: Children with autism spectrum disorders (ASD) often have difficulty in keeping up with school classes. Previous studies suggest that the skill to share a common focus on objects with others, joint attention (JA), is impaired in the ASD. This may lead them to less gaze at objects pointed by a teacher, thereby, less understanding of the class compared to children with typical development (TD). However to date, gaze behavior of children with ASD in such class scenes remains poorly explored. To address this issue, we measured eye movement of children with ASD (n = 23, median 7 y, range 3-14 y) and age-matched children with TD (n = 23, median 7 y, range 2-13 y) while they performed a free-viewing task of class-scene movies. In the task, there were two types of class scenes: Japanese and arithmetic class scenes. In the Japanese class scenes, a teacher pointed at cartoons of a person's face and body on a blackboard; in the arithmetic class scenes, he pointed at geometric figures. For each class scene, the participants viewed six movies which were sequentially presented on a LCD display. In the analysis, we defined the regions of interests (ROI): the teacher's face and finger, the cartoon characters and geometric figures at which the teacher pointed, and the rest of the space including the area with no objects such as walls. We then compared total gaze time in each ROI and frequency of JA, gaze at the pointed objects by referring to the teacher's face or finger, between the children with ASD and TD by two-way ANOVA. The children with ASD showed three characteristics in gaze behavior in class-scene movies compared with the children with TD. First, their JA frequency was less in both class scenes ($p < 0.05$). Second, they spent less time in gaze at the cartoon characters pointed by the teacher ($p < 0.001$) while they spent time as long as those with TD in gaze at the geometric figures, inconsistent with previous reports that children with ASD tended to gaze at geometric figures. Third, the children with ASD spent more time in gaze at the space including no object in both class scenes ($p = 0.001$). These results indicate that children with ASD do not necessarily show preferential looking at geometric figures in class scenes. They instead assign their attention to irrelevant objects or space due to JA failures. Nevertheless, we also observed that they spent more time in gaze at the pointed objects when the gaze direction of the teacher was congruent with that of his finger. We conclude that the gaze-behavior analysis in class scenes can be a potent tool for reliable and objective diagnosis of children as ASD, which may also leads to early intervention for children with ASD to improve their understanding of the content in classes.

Abstract: Background: Individuals with autism spectrum disorder (ASD) often find it difficult to recognize bodies and faces. Interestingly, such issues are more pronounced in children than adults. The occipito-temporal cortex contains regions, such as the extrastriate body area (EBA) and the fusiform face area (FFA), that are critical for recognition of the body and face. If difficulties in body and face recognition originate from dysfunction of these regions, activation in these regions might be more abnormal in children with ASD than in adults with ASD. **Methods:** We performed functional magnetic resonance imaging while children and adults with ASD and age-matched typically developed (TD) individuals observed objects divided into the following categories: face, body, car, and scene. To examine various aspects of EBA and FFA

activation, we performed individual region of interest (ROI) analysis, as well as conventional random effect group analysis. At individual ROI analysis, we examined 1) the ratio of participants showing a category-sensitive response, 2) the size of regions (i.e. number of activated voxels), 3) location and its variability, and 4) activation patterns among the four object categories.**Results:** Adults with ASD showed no abnormalities in activation of the EBA and FFA. By contrast, children with ASD showed abnormal activation in these regions. Specifically, a smaller percentage of children with ASD showed face-sensitive activation of the FFA than TD children. Moreover, the size of the EBA was smaller in children with ASD than in TD children.**Conclusions:** Our results revealed abnormalities in both the FFA and EBA in children with ASD but not in adults with ASD. This result indicates that severity of such abnormalities of children with ASD might differ from adults with ASD, which is a first important step toward elucidating maturation of brain region associated with face- or body- recognition for individuals with ASD.

Title: Amygdala responses to subliminal and supraliminal faces in adults with high function autism spectrum disorder: A MEG study

Authors: *T. MAEKAWA[1,3], K. OGATA[2], T. YAMASAKI[2], M. TANAKA[2], S. TOBIMATSU[1];
[2]Clin. Neurophysiol., [1]Kyushu Univ., Fukuoka, Japan; [3]Psychiatry, Amekudai Hosp., Naha, Japan

Abstract: Background: Autism spectrum disorder (ASD) is a set of heterogeneous neurodevelopmental conditions characterized by early-onset difficulties in social communication

and unusually restricted, repetitive behavior and interests. Magnetoencephalography (MEG) is used in ASD research for its noninvasive nature of recordings and for its excellent temporal and spatial resolution. Purpose: The aim of this study was to investigate the amygdala responses to subliminal and supraliminal faces in adults with high-functioning ASD. We hypothesized that the responses in ASD were weaker that those in healthy adults without ASD (HC) because ASD was characterized by deficit of understanding emotional meanings of human faces. Method: Eighteen adults with ASD and 18 HC were participated in this study. At first they were checked their intelligence quotient (IQ). MEG experiment: Subjects were seated in front of 23 inch monitor and visual stimuli were presented at the center of the monitor. Stimuli were fearful or neutral faces and objects which image resolutions were filtered by broad, low or high spatial frequency. Stimuli were randomly presented 17 or 300 ms duration with 1~1.2 s inter-stimulus intervals. Subjects were instructed click the mouse as soon as the target stimulus (a picture of train) was presented on the monitor. Magnetic brain responses were recorded by 306-ch whole head MEG machine (Neuromag®, Elekta, Co. Ltd. Helsinki). Each subject's structural brain image was taken by a 3T MRI equipment (Achieva 3.0T TX, Philips, Japan). MEG data were analyzed by adaptive beamformer method. Results: All subjects carried out the experiment. FIQ of all subjects was over 80 and there was no statistical difference of FIQ between the ASD and HC groups. AS our expectation, MEG responses to the subliminal faces at the amygdala in ASD were weaker than those in HC. However, MEG responses to the supra liminal faces and objects at the amygdala in ASD were not. Conclusion: The amygdala weak responses to the subliminal faces in adults with ASD are potentially responsible for lack of ability to insight other's face emotion.

Title: Tactile temporal resolution might correlate with the degree of hypersensitivity in individuals with autism-spectrum disorders

Authors: *A. YAGUCHI[1,2], M. IDE[1,3], M. WADA[1];
[1]Dev. Disord. Sect., Dept. of Rehabil. for Brain Functions, Res. Inst. of NRCD, Tokorozawa, Saitama, Japan; [2]Dept. of Psychol., Rikkyo Univ., Niiza, Saitama, Japan; [3]Japan Society for the Promotion of Sci., Chiyoda, Tokyo, Japan

Abstract: Some individuals with autism-spectrum disorders (ASD) dislike touch to their skin of specific materials, because they insist that such materials cause unpleasant impression (e.g., prickle or strong impression). As for the hypersensitivity to touch, a previous study has reported that the individuals with ASD have increased detection sensitivity to vibrotactile stimuli around a certain frequency (200 Hz), comparing with typically developing (TD) individuals. This result indicates that lower threshold of neural activity at a level of peripheral nerve may be a basis for the hypersensitivity in individuals with ASD. Meanwhile, different studies have suggested that individuals with ASD exhibit large diversities about temporal resolution and detection of temporal lags of sensory signals. Thus, we hypothesized that individual's diversities of stimulus temporal processing as well as detection sensitivity is a basis of hypersensitivity. In this study, we investigated the relationships between severities of hypersensitivity and tactile temporal resolution in individuals with ASD. We recruited nine participants with ASD and ten TD participants. Vibrotactile stimuli either 40 Hz and 200 Hz were delivered to left and right index fingers with various stimulus onset asynchronies (SOAs: ±15, 30, 60, 120, 240 ms). The degrees of subjective feeling of hypersensitivity in daily life were measured by using the Adolescent/Adult sensory profile. We found that the temporal resolutions were not different between individuals with ASD (40 Hz: 52.1 ms, 200 Hz: 49.2 ms) and TD individuals (40 Hz: 64.8 ms, 200 Hz: 69.1 ms). In ASD group, temporal resolution was correlated with the degree of

hypersensitivity in 40 Hz stimulus conditions ($r = -0.7$, $p < 0.05$), and the similar trends appeared in 200 Hz ($r = -0.7$, $p = 0.09$). In TD group, such the relationship was found neither 40 Hz nor 200 Hz conditions. These results indicate that the individuals with ASD who have high temporal resolution tend to exhibit strong hypersensitivity. These results indicate that the hypersensitivity might be associated with neural activities in cortical and sub-cortical areas where are known to be dealing with temporal processing.

Title: Impact of virtual stimulation on the ability of autistic children for playing real-sports

Authors: *C. CRESPO-CORTES, G. CORIA, L. GARCIA, R. TOLEDO, M. HERNANDEZ, J. MANZO;
Ctr. de Investigaciones Cerebrales, Univ. Veracruzana, Veracruz, Mexico

Abstract: Autism is a neurodevelopmental disorder manifested and diagnosed by a wide range of particular behaviors, specially poor or abnormal language and limited movements or stereotypes. Decreased social interaction in autism prevents a child to engage on activities such as those that require eye contact, like sports. However, in previous studies we showed how autistic children can respond well to virtual sports whose instructions came from a screen. Through the Nintendo Wii console (Nintendo, Co) and Wii sports videogame, we improved motor, social and cognitive skills in a group of 10 autistic children from CRIVER (3 girls and 7 boys). Due to these results, we proposed for this trial that those acquired skills through virtual stimulation could facilitate playing real sports. We set the same protocol, 2 sessions per week, 20 minutes each one until reach 30 sessions. Children were exposed to the same real sports games they used to play on virtual games (bowling and golf), although they continue to have access to Wii. On the fifth session 71% of children showed interest in real game and were capable to execute it properly, respecting his turn and socially interacting with peers. On session twenty, 100% of subjects were capable to run real sport properly and over 70% shown preference for real sports over virtual games. At the end of the trial all children were capable to switch from virtual to real game and vice versa based on their own will. These results show how a controlled

experimental paradigm of sports on videogame can stimulate autistic children to face the same challenge on real life.

Engin. and Sci., [8]Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA; [9]Dept. of Gastroenterology and Nutr., Lurie Ctr. for Autism, Boston, MA

Abstract: Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by deficits in social interaction and restricted, repetitive patterns of behavior, interests, and activities. Dysfunction of GABAergic circuits has been frequently implicated in the pathophysiology of ASD. Our laboratory has previously characterized the age-dependent frontal electroencephalogram (EEG) oscillations induced by the GABAergic drug propofol (Purdon et al. 2013, 2015). We hypothesized that propofol-induced EEG oscillations in ASD patients would show a structure and age-dependence that was different from neurotypical (NT) patients. In this study, we recorded continuous 4-channel frontal EEG during the routine care of ASD patients and NT patients receiving propofol. To characterize changes in EEG power and coherence, we analyzed data from ASD patients aged 2-23 yr during propofol maintenance with stable EEG dynamics (n=42) and compared them to a 1:1 matched cohort of NT patients. We also compared

the incidence of burst suppression in a larger cohort of ASD (n=56) and NT (n=123) patients aged 2 to 30 yr, including patients in burst suppression for the full case duration. We found that ASD patients had an age-dependent decline in total EEG power relative to NT patients under propofol**,** with significantly reduced alpha power (8-13Hz) after 17 years of age ($p<0.05$). We observed no significant difference in coherence at any frequency. We also found that ASD patients entered burst suppression over twice as often as NT patients (25% vs. 12.2%, $p<0.05$), despite no significant differences in age or medication administration between ASD and NT patients who experienced burst suppression. Together, these results suggest that ASD patients respond differently to the GABAergic drug propofol compared to NT patients. These differences and their age-dependence may reflect underlying differences in GABAergic circuit function and development in ASD. The observed pattern of decreased alpha power and increased sensitivity to burst suppression develops progressively in NT adults through middle age and old age (Purdon et al. 2015). Our results may therefore, in addition, signify a form of accelerated neuronal aging during the late teenage years in ASD patients.

Title: Global and regional brain enlargement in autism spectrum disorder persists through adolescence in a large sample

Authors: L. D. YANKOWITZ[1,2], *J. D. HERRINGTON[3], J. A. PEREIRA[2], B. E. YERYS[2], J. PANDEY[3], R. T. SCHULTZ[2];
[1]Psychology, Univ. of Pennsylvania, Philadelphia, PA; [2]The Ctr. for Autism Res., [3]Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Although converging evidence indicates that toddlers with Autism Spectrum Disorders (ASD) have enlarged brains relative to Typically Developing Controls (TDC), for decades it has remained unclear whether this enlargement persists beyond early development. Some evidence indicates that early brain overgrowth is followed by a period of arrested brain growth in ASD, leading to null group differences in adulthood. However, other studies provide conflicting evidence, showing increased brain size in adults in ASD. These two alternatives point to very different trajectories of brain development in ASD. Unfortunately, a majority of studies on this topic have been limited by small sample sizes, and samples that are confounded by individual differences related to brain volume (namely age, sex-ratio, and IQ). The current study is perhaps the largest structural MRI study of ASD ever conducted on a single MRI scanner and sequence, examining 473 individuals with (N = 253) and without ASD (N = 220) aged 6-25, including a large number of females (N=102) and spanning a wide IQ range (57-158). High-resolution T1-weighted anatomical MRI images were examined for group differences in global total brain, grey, and white matter volume, as well as ventricular volume. Additionally, region-

specific structural differences were investigated with voxel-based morphometry analyzing tissue density maps (specifically, RAVENS maps). Results support enduring enlargement of brain volume in adolescents and adults with ASD, with no interactions with age or sex. However, there were important interactions with IQ, such that normative positive correlations of IQ and brain volume are absent in ASD. Voxel-wise analyses reveal widespread increases in ASD, with large clusters of effects in the temporal lobe, frontal lobe, and cerebellum. The patterns of differences are consistent with reward, default mode, and social information processing networks. These results clarify our understanding of the progression of brain development in ASD, suggesting that brain overgrowth persists across the lifespan. Localization of these volumetric differences suggests overlap with neural networks that relate directly to the clinical features of ASD, including impaired social cognition and reward processing. Importantly, these results would not have emerged without a control group including individuals in the lower end of the IQ range. A critical agenda for future research in this area is to identify mechanisms mediating brain overgrowth in ASD.

Title: Cortical activation for reading semantic words in children with Autism Spectrum Disorder: A MEG study

Authors: *R. OGAWA;
Child of Develop., Osaka Univ., Suita-Shi/Osaka, Japan

Abstract: Aim: Autism spectrum disorder (ASD) is a developmental disorder and characterized by language impairment. A lack of left lateralization in structure and function of brain regions involved in a language cognition such as Broca's and Wernicke areas was reported in ASD. Nevertheless, it is unclear about the differences for language cognition for semantic words in children with ASD. The purpose of this study was to compare the brain activation patterns between ASD and typically developing (TD) for further understanding the differences for visual language processing in ASD. **Methods:** Fourteen boys with ASD (mean age 13.2 years) and 17 age-matched TD boys were included. All participants were right-handed and had a normal intelligence with full scale IQ above 80. Cortical activity was measured by

magnetoencephalography (MEG) during 100 visual stimuli consisted with 3-character Japanese hiragana semantic words. To determine the activities of each brain regions, brainstorm (http: // neuroimage. usc.edu / brainstorm) was used. Written informed consent was obtained from the parents of all the participants. This study was approved by the Institutional Review Board of Osaka University Hospital of the Osaka University. **Results:** In ASD, brain activity showed less intensity in bilateral temporoparietal junction (TPJ), left posterior middle temporal gyrus, posterior insula, angular, anterior insula, central sulcus (CS), frontal inferior opercularis, right middle occipital gyrus, superior temporal gyrus compared with TD. Although both groups were lateralized to the left in TPJ, the left dominancy of the brain activities in CS were shown only in TD, but not in ASD. The peak latency of lateralized activity in TPJ were delayed in ASD (455ms) than that in TD (370ms). **Discussion:** The brain activity during word recognition was not lateralized to the left in primary visual cortex in both groups. In TD, brain activities were lateralized to the left in the brain region associated with high-level word recognition, such as TPJ for word recall and CS for repetition. However, In ASD, the dominancy to the left was less and appeared later than TD. These findings suggest that the characterized brain activity might be associated with cognitive aspects of language impairment in ASD.

Title: Effect of age and autism diagnosis on oxytocin and vasopressin 1a receptors in the basal forebrain and superior colliculus of the human brain

Authors: *S. M. FREEMAN[1], M. C. PALUMBO[1], A. L. SMITH[2], M. M. GOODMAN[2], K. L. BALES[1];
[1]California Primate Ctr., UC-Davis, Davis, CA; [2]Emory Univ., Atlanta, GA

Abstract: Due to the ability of the neuropeptide oxytocin (OT) to enhance social behavior, it is now one of the most promising therapeutics for the treatment of autism spectrum disorder (ASD), a condition characterized by deficits in social function. Indeed, OT treatment can ameliorate some of the social symptoms of ASD, and genetic studies have implicated the OT system in the etiology of ASD. However, it is unknown whether there are differences in OT

receptor (OXTR) expression in the brains of individuals with ASD compared to typically developing individuals. This study used a previously validated method for competitive binding receptor autoradiography to quantify the density of OXTR and the structurally related vasopressin 1a receptor (AVPR1a) in postmortem brain tissue from individuals with ASD (n=17) and matched neurotypical controls (n=24). Patients with ASD have atypical visual attention to social images and disrupted patterns of eye movement; therefore, our analysis focused on the nucleus basalis of Meynert (NBM), which mediates visual attention, and the superior colliculus, which controls gaze direction. Analyses of the superior colliculus are still underway. In specimens of the human NBM, we also found an adjacent region of receptor binding, which we determined to be the ventral pallidum (VP). We found no association between the postmortem interval of the tissue and the density of radioligand binding in either of these two regions, nor did we find any sex differences. We found that receptor binding is greater in the NBM in ASD compared to controls ($p<0.05$) but is reduced in the VP in ASD compared to controls ($p<0.05$). We found no effect of age on receptor binding in the NBM, but we found a significant negative correlation between age and receptor binding in the VP ($r = -0.4066$; $p=0.01$). This association in the VP was driven entirely by the neurotypical controls ($r = -0.6299$; $p<0.01$) and not by our ASD specimens ($r = -0.0902$; $p=0.73$). Further analysis revealed that neurotypical cases have higher levels of receptor binding in the VP from birth to 7 years of age, and these levels drop between ages 8-10 to match the unchanging levels of receptor binding in ASD cases. From ages 8 to 25, there is no difference in receptor density between ASD and controls in the VP. This pattern suggests a possible critical period in childhood, which is lacking in ASD, where OXTR expression is heightened and the VP is maximally sensitive to neuropeptide binding. Further studies are needed to establish a functional role of OXTR in the etiology of ASD. Human tissue was obtained from the University of Maryland Brain and Tissue Bank, which is a Brain and Tissue Repository of the NIH NeuroBioBank. Funding: NIH R21MH110014.

Title: Increased internal noise in autism spectrum disorder is associated with higher response variability in a predictive motion task and overall symptom severity

Authors: *K. B. SCHAUDER[1], W. PARK[2], D. TADIN[2], L. BENNETTO[3];
[1]Clin. and Social Sci. in Psychology, [2]Brain and Cognitive Sci., Univ. of Rochester, Rochester, NY; [3]Clin. and Social Sci. in Psychology, Univ. of Rochester, ROCHESTER, NY

Abstract: Background: Autism spectrum disorder (ASD) is associated with a range of sensory, cognitive, and social deficits that impair everyday functioning. An emerging theory suggests atypically noisy neural processing may underlie global impairments in ASD (Dinstein et al., 2015). Specifically, trial-by-trial variability in neural response has been shown to be increased in ASD across different sensory areas, which may reflect a broad increase in internal noise in sensory processing. In this study, we investigate whether psychophysically characterized internal noise is related to response variability in a predictive motion task and to overall ASD symptom severity. Methods: 20 children and adolescents with ASD and 18 age- and IQ- matched typically developing (TD) controls completed a diagnostic assessment (Autism Diagnostic Observation Schedule; ADOS) and two visual tasks. In an orientation discrimination task, participants judged the orientation direction (right or left from vertical) of titled gratings embedded in external noise. Contrast thresholds were measured at each of eight external noise levels (0-21%), and the amount of internal noise was estimated using the perceptual template model (Lu & Dosher, 2008). In a predictive motion task, participants estimated when a moving object (10-20 deg/sec) would arrive at a visual target at the end of an occluder (0.5-20 deg). Linear regression was used to calculate the relationship between actual time of occlusion and participants' estimates, with R^2 values representing response variability in this task. General ASD symptom severity was assessed using calibrated ADOS severity scores (Gotham et al., 2010). Group differences were tested for both internal noise and response variability. Correlation analyses were performed in the ASD group between internal noise, response variability, and symptom severity. Results: Individuals with ASD showed increased internal noise and increased response variability (i.e., lower R^2) compared to TD controls. Within the ASD group, higher internal noise was significantly related to both higher response variability, $r(20)=-.52$, $p=.02$, and higher ASD symptom severity, $r(20)=.60$, $p=.005$. Higher response variability was not related to higher ASD symptom severity, $r(20)=-.22$, $p=.35$. Conclusions: Our results suggest that increased internal noise in ASD is associated with both response variability in a motion-based time estimation task and with overall symptom presentation. Additionally, these findings provide preliminary evidence that increased internal noise may have perceptual and cognitive consequences, and lead to more overall ASD symptoms.

Title: Visual and auditory responses elicited by movie task in autism spectrum disorder: a magnetoencephalographic study

Authors: *J. MATSUZAKI[1], K. KAGITANI-SHIMONO[1,2], S. AOKI[1], Y. KATO[1], R. HANAIE[1], M. NAKANISHI[1,2], A. TATSUMI[1], T. YAMAMOTO[1], K. TOMINAGA[1,2], Y. NAGAI[3], I. MOHRI[1,2], M. TANIIKE[1,2];
[1]United Grad. Sch. of Child Development, Osaka Univ., Osaka, Japan; [2]Dept. of Pediatrics, Osaka Univ., Osaka, Japan; [3]Grad. Sch. of Engineering, Osaka Univ., Osaka, Japan

Abstract: Aim: Autism spectrum disorder (ASD) is a neurodevelopmental disorder and their sensory abnormality was taken notice recently. We reported that abnormal auditory sensitivity in ASD was correlated with delayed and prolonged responses in the auditory cortex (Matsuzaki, Shimono-Kagitani et al., 2012, 2014). Furthermore, visual sensitivity is also common sensory abnormalities in ASD, its neurophysiological mechanism has not been known. Qin and Nagai (2014) reported differential patterns of perceptual world and developed a virtual reality system for experience abnormal sensation to understand the difficulty of ASD. The aim of this study is to investigate the patterns of regional brain activity associated with visual/auditory perception in ASD elicited by movies from the virtual reality system using magnetoencephalography (MEG). **Methods:** Six boys with high functioning ASD and six age-matched typically developing (TD) boys were participated in this study. All subjects were assessed by the sensory profile (SP) and social communication questionnaire (SCQ). We recorded MEG while participants watched daily life movies (DLM), contrast enhanced movies (CEM) and CEM with sound (CEMS). To determine the activities of each brain regions, brainstorm (http: // neuroimage. usc.edu / brainstorm) was used. Written informed consent was obtained from the parents of all the participants. This study was approved by the Institutional Review Board of Osaka University Hospital. **Results:** Regarding behavioral assessment, there were significantly positive correlation between SP and SCQ. In the occipital area, there were no group differences in three conditions. Both TD and ASD group showed increased responses in DLM compared to in CEM and CEMS. In the temporal, insula and orbitofrontal areas, ASD group showed significantly decreased responses than TD group in CEM and CEMS. **Discussion:** According to the results of the occipital area, ASD might have similar pattern of early visual processing with TD. However, in the temporal area, which is engaged in multisensory system showed decreased responses in

ASD. Also, the decreased responses were observed in the insula and orbitofrontal area, which is related with emotional perception. Thus, we speculated the atypical multisensory integration and emotional perception might be related to abnormal visual/auditory sensitivity in ASD. Our finding suggested that the neurophysiological mechanism underlying sensory abnormalities might be associated with atypical neural networks for hierarchical sensory processing possibly resulting from neurological immaturity, dysfunction of sensory gating system or inhibitory interneurons.

Title: Cortical thickness abnormalities in autism spectrum disorders throughout development: a large scale mri study

Authors: *B. S. KHUNDRAKPAM, J. LEWIS, P. KOSTOPOULOS, A. EVANS; McConnell Brain Imaging Ctr., Montreal Neurolog. Inst., Montreal, QC, Canada

Abstract: Neuroimaging studies in autism spectrum disorders (ASD) have provided inconsistent evidence of cortical abnormality. This is probably due to the small sample sizes used in most studies, and important differences in the sample characteristics, particularly age, as well as to the heterogeneity of the disorder. To address these issues, we assessed abnormalities in ASD within the Autism Brain Imaging Data Exchange dataset, which comprises data from approximately 1100 individuals (~ 6 to 55 years). A subset of these data that met stringent quality control and inclusion criteria (N = 560, 266 ASD; age = 6 to 35 years) were used to compute age-specific abnormalities in cortical thickness in ASD and the relationship of any such differences to symptom severity of ASD. Our results show widespread increased cortical thickness in ASD, primarily left lateralized, from 6 years onwards, with differences diminishing throughout adulthood. The severity of symptoms related to social affect and communication correlated with these abnormalities. These results highlight the dynamic nature of morphological abnormalities

in ASD. Further, the pattern of abnormalities over development suggests delayed cortical maturation in ASD.

JST CREST

Title: Task-dependent modulation of face gaze in high-functioning autism

Authors: *A. GHARIB, R. ADOLPHS, S. SHIMOJO;
Caltech, Pasadena, CA

Abstract: Autism Spectrum Disorder (ASD) is a pervasive developmental disorder in which face processing has been reported to be atypical. A key element of face processing impairments in ASD may be abnormal gaze to facial features, though findings from eyetracking studies are mixed: some studies find abnormal gaze to all features, others only to the eyes or mouth, and yet others find no significant differences. In addition to differences in task and stimulus characteristics between studies that likely contribute to the discrepant findings, there is evidence to suggest that people with ASD, particularly those who are high-functioning, compensate for deficits by using atypical cognitive and visual strategies. These strategies may produce apparently normal task performances that could, however, be unmasked when challenged by a different context or task set.
To test this hypothesis our study asked 2 specific questions: Is there evidence for: 1) active avoidance of the eyes or eye region in ASD? 2) differential bottom-up or top-down effects, driven by facial features or by cognitive strategies such as explicit instruction?
Participants (22-58 yrs; ASD n = 12 TD n = 13) viewed face images showing open eyes and closed eyes under 3 different conditions: free viewing, explicit instruction to avoid the eyes, and explicit instruction to avoid the mouth. In the “Avoid the Eyes” condition we predicted both

groups would increase gaze to the mouth, i.e. the next most salient feature, while continuing to scan the face. In the "Avoid the Mouth" condition we predicted the TD group would look more at the eyes while the ASD group would not.
The broad pattern of proportional dwell time to face features was comparable between groups but there were key differences particularly in gaze to the eye region: of time spent in the eye region in the Free-Viewing (FV) and "Avoid the Mouth" (AM) conditions, ASD spent a smaller proportion of time on the right eye (FV: ASD 18% TD 34% $p < .001$; AM: ASD 22% TD 34% $p = .011$) and a greater proportion between the eyes (FV: ASD 63% TD 47% $p = .005$; AM: ASD 57% TD 47% $p = .013$) compared to TD, regardless of stimulus type. Additionally, in the "Avoid the Eyes" condition a subset of the ASD group showed significantly greater mouth gaze than both the TDs and rest of the ASD group. In sum, while people with ASD did not differ in their general pattern of gaze to face features, we find evidence of atypical distribution of gaze, particularly to the eye region, as a function of
specific task instructions. Overall, the findings suggest a complex interaction between bottom-up and top-down control of gaze that results in avoidance of the eye region in ASD under some conditions and also argue for the heterogeneity of ASD.

Title: Electrophysiological markers of atypical auditory temporal processing associated with symptom severity in autism spectrum disorder

Authors: *J. H. FOSS-FEIG[1,2], K. K. M. STAVROPOULOS[3], E. ISENSTEIN[2], J. C. MCPARTLAND[1], M. T. WALLACE[4], W. L. STONE[5], A. KEY[4];
[1]Child Study Ctr., Yale Univ., New Haven, CT; [2]Seaver Autism Ctr., Mount Sinai Hosp. Icahn Sch. of Med., New York, NY; [3]Univ. of California - Riverside, Riverside, CA; [4]Vanderbilt Univ., Nashville, TN; [5]Univ. of Washington, Seattle, WA

Abstract: Introduction: Sensory processing abnormalities are among the most commonly reported symptoms in autism spectrum disorder (ASD). Previously, we have used behavioral methods to reveal impaired auditory temporal processing in children with ASD. Abnormalities in processing of timing information have been posited to underlie core ASD symptoms, and difficulties with auditory temporal processing could relate to language processing deficits.
Objectives: To explore the brain basis of auditory temporal processing deficits in ASD using electrophysiology and to examine relations among neural markers of auditory temporal processing and clinical features of ASD.
Method: EEG data was recorded from 10-13 year old children (15 ASD; 17 typically developing [TD]) using a 128-channel net. Participants heard: 1) 1000ms continuous white noise, and 2) the same stimuli interrupted by silent gaps. Groups were matched for age, gender, and IQ. Participants indicated via button-press whether each stimulus contained a gap. Amplitude and latency of N1 and P2 event-related potentials were evaluated for near-threshold (3ms) gaps. Repeated measures ANOVAs were conducted (WSF: Detection Accuracy, Site; BSF: Group). Children with ASD received the Autism Diagnostic Interview-Revised (ADI-R) and Autism Diagnostic Observation Schedule (ADOS). Social Responsiveness Scale (SRS) and Clinical Evaluation of Language Fundamentals (CELF) were administered to all children. Correlations were computed between ERP variables and clinical symptoms.
Results: For N1 amplitude, there was a trend for a Group X Site X Accuracy interaction ($p=.07$); central N1 was larger for TD than ASD for undetected gaps ($p<.05$). For P2 amplitude, a significant Group X Site interaction was observed ($p<.05$); central P2 was larger for ASD than TD regardless of detection accuracy. Across groups, attenuated P2 to detected gaps related to worse social (SRS: $r=-.408$, $p=.038$) and receptive language (CELF: $r=.402$, $p=.052$) skills. In ASD, attenuated P2 related to greater ASD language/communication symptomatology (ADI-R: $r=-.547$, $p=.035$; ADOS: $r=-.533$, $p=.034$).
Discussion: Atypical neural responses to rapid temporal changes in auditory events were found for children with ASD. Moreover, reduced neural classification of near-threshold silent gaps in auditory stimuli was associated with weaker social and language skills across ASD and TD, as well as greater communication-related symptomatology in ASD. This research suggests that aberrant neural response to low-level auditory information could play an important role in higher-level ASD symptomatology.

Title: A slower speed in early coding phase of happy facial processing in children with autism spectrum disorder

Authors: *Q. LIN, Y. JIN;
Dept. of Maternal and Child Hlth., Sch. of Publ. Health, Sun Yat-Sen Univ., Guangdong, China

Abstract: Individuals with autism spectrum disorder (ASD) are impaired in emotional face recognition, which has been postulated to underlie most of their social behavioral impairments. Accumulated studies have investigated this impaired social skill in autistic adults. The present study aimed to the analyze the characteristic in early processing phrase during emotional facial expression recognition on children with ASD using two event-related potentials(ERP) components, N170 and P1 which have proved to be sensitive to early face processing. Thirteen high functional autistic children and thirteen typical development children with matched age (from 6 to 13) and IQ were recruited in this study. Photos of Chinese static face with basic expressions (including happy, sad, fearful and angry) were used as stimulation material. ERP data were recorded and compared between two groups. No significantly differences were found in accuracy and reaction time among different negative expressions in ASD group (P>0.05) by t-test. We used the one-way ANOVA to compare the differences between faces in each group, and we found the accuracy of in angry face task had no significantly difference with other three faces (P>0.05) in ASD children . However, these differences were found in typical development children group. Multiple-factor repetitive measurement ANOVA results showed that the latency of P1 component in ASD children were longer than typical development children (142.38±7.65ms vs 134.92±10.08ms, P<0.05), which suggested the processing speeds in early coding phrase of basic facial expression processing in ASD children were slower than typical development children, especially derived from happy expression (145.58±8.92ms vs 135.92±10.68ms,P<0.05). For N170 component, difference between ASD and typical development children showed a trend of right lateralized weakness for negative facial expression in ASD children (-1.64±9.02uV vs -7.21±5.15uV, P=0.07). Therefore we concluded that children with ASD showed slower speed in early coding phase of happy expression processing and weaker trend to recognize the angry face from other negative face, which may impair their facial processing and social ability. **Key words:** expression processing; Autism Spectrum Disorder; Event-related potential

Title: Atypical eye gaze as a biomarker in autism spectrum children: an eye tracking study

Authors: *J. HAN[1], Y. LI[2], X. LI[3];
[1]Beijing Normal Univ., State Key Lab. of Cognitive Neurosci. and, BEIJING, China; [2]Instituteof Electrical Engin., qinhuangdao, China; [3]State Key Lab. of Cognitive Neurosci. and Learning, Beijing, China

Abstract: Objective: Eye gaze is a key channel of social communication in humans. Atypical eye gaze is a hallmark characteristic of autism spectrum disorder (ASD). Eye contact is crucial for social learning and adult-infant communication and the ability to follow gaze is important for joint attention. Deficits in eye contact and following gaze of autism have been widely researched.The primary aim of the the study was to create an objective biomarker from multiple dimensional eye tracking-based index.
Method: A sample of 88 toddlers (72 toddles with ASD and 26 typical-developing toddles) was studied. Face scanning and gaze following were assessed using eye tracking.An eye-mouth index (EMI) and fixation duration of each area of interest were computed.
Results: (1) Toddlers with ASD have strongly decreased eye-mouth index.Lower EMI reflects a lower bias to look toward eye. (2)Toddlers with ASD have fewer saccades when following gaze and point to the importance of separating information.
Conclusion: To find an early objective biomarker from multiple dimensional indexs will allow for earlier diagnosis of ASD in infants.

Title: Atypical lateralization of face processing in autism spectrum disorder

Authors: *L. M. SOLOMON-HARRIS[1], N. KHAN[1], V. REPLETE[1], C. S. PENG[2], W. D. STEVENS[1], A. MARTIN[2];

Abstract: Autism spectrum disorder (ASD) is characterized by a combination of social deficits, language deficits, and repetitive behaviours. Social impairment is a critical feature of ASD that has been investigated through many studies of face processing. Individuals with ASD demonstrate behavioural deficits in face processing, and event-related potentials suggest a lack of typical hemispheric asymmetry. However, neuroimaging findings are inconsistent, with some studies reporting abnormal brain activation patterns, such as hypoactivation for faces and facial expressions, and reduced connectivity among face processing regions, while other studies find no reduced connectivity, or no differences in activation patterns. Mixed results in the literature may be due to methodological differences in identifying regions of interest (ROIs) for functional magnetic resonance imaging (fMRI) analysis. Here, we individually localized face-preferential brain regions in a matched group of high functioning males with ASD and typically developing (TD) participants to investigate differences in activation patterns using a methodologically rigorous approach. This study employed a blocked multi-category functional localizer with a one-back repetition detection task. We found no differences in the number, location, or size of face-preferential ROIs between groups. However, we found a lack of right hemisphere lateralization of face activation in the posterior superior temporal sulcus (pSTS) in the ASD group. Whereas the TD participants showed substantially increased activation for faces in the right pSTS relative to the left, participants with ASD showed no difference in pSTS activation across the hemispheres. The pSTS is critical for processing dynamic faces, facial expressions, multisensory integration, and theory of mind, which are all cognitive functions that may be impacted in ASD. Hemispheric lateralization is a critical component of human brain specialization, such as for face processing and language skill. Reduced hemispheric specialization of the pSTS could play a critical role in ASD.

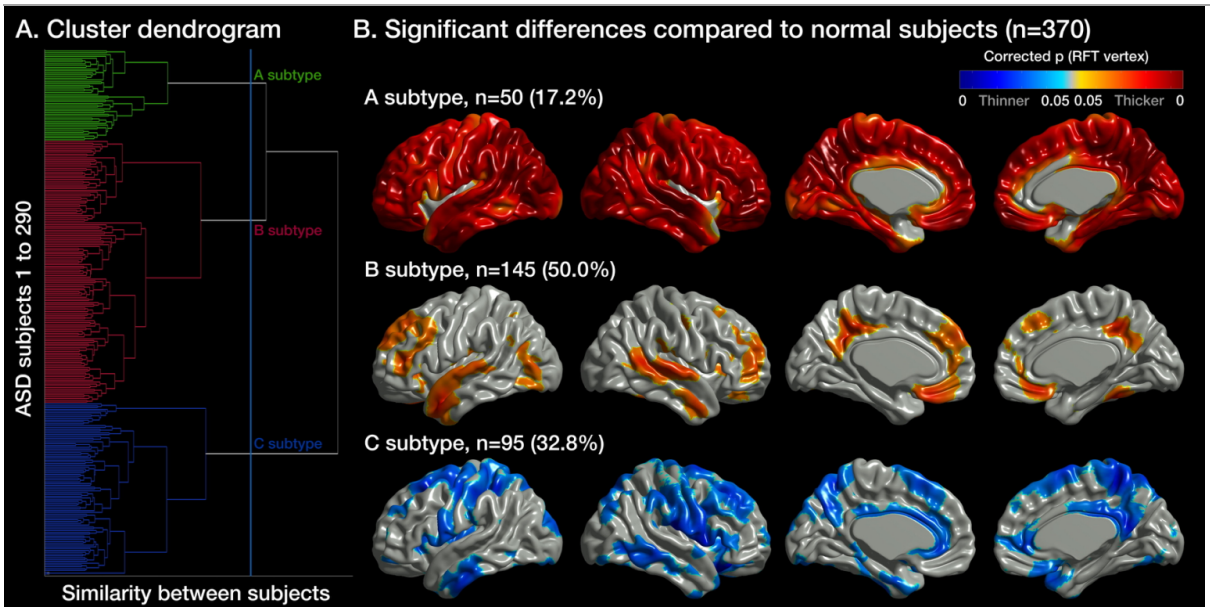
Title: Anatomical heterogeneity of autism spectrum disorder based on cortical thickness



Authors: *S. JEON, B. KHUNDRAKPAM, A. EVANS;
McGill Ctr. for Integrative Neurosci., Montreal Neurolog. Inst. & Hospital, McGill, Montreal, QC, Canada

Abstract: Autism spectrum disorders (ASD) is a highly heterogeneous disorder characterized by deficits in social interaction and communication. We examined patterns of cortical thickness (CTh) in ASD patients and these patterns were categorized into different subtypes that correspond to anatomical distinction. These subtypes displayed distinct behaviors. We measured CTh using the data collected from Autism Brain Imaging Data Exchange project. 290 patients and 370 controls (age- and sex-matched, 6 to 35 years) were selected after strict quality control. In patient group, Ward's hierarchical clustering was performed (Figure 1A). The identified clusters of patients were compared to controls adjusting for age, sex and scanner effect. Multiple comparisons were corrected using random field theory (RFT vertex $p<0.05$). At the 3-cluster level, the patients were divided into following: A subtype (n=50, 17.2%) has most of the cortex thicker than controls; B subtype (n=145, 50.0%) has area thicker than controls; and C subtype (n=95, 32.8%) has area thinner than controls (Figure 1B). The demographics and Autism Diagnostic Observation Schedule (ADOS) scores of the 3 subtypes were compared (Table 1). Among these subtypes, age was not significantly different. However, communication, social and calibrated symptom severity score in ADOS were significantly different. In conclusion, ASD can be categorized into various anatomical subtypes with distinct clinical features. Subtyping ASD is especially important because it may have different responses to the treatment. Consideration of the heterogeneity may be important when planning future preventative and treatment strategies.

Demographics and ADOS scores of the 3 ASD subtypes

Subtype	A (n=50)	B (n=145)	C (n=95)	p-value (ANOVA)
AGE at MRI, y	18.6 (±11.7)	17.4 (±6.6)	17.2 (±7.6)	0.603
Sex, female, n (%)[d]	9 (18.0%)	9 (6.2%)	17 (17.9%)	0.01[c]
Mean thickness	3.76 (±0.21)	3.56 (±0.14)	3.38 (±0.16)	<0.001[a,b,c]

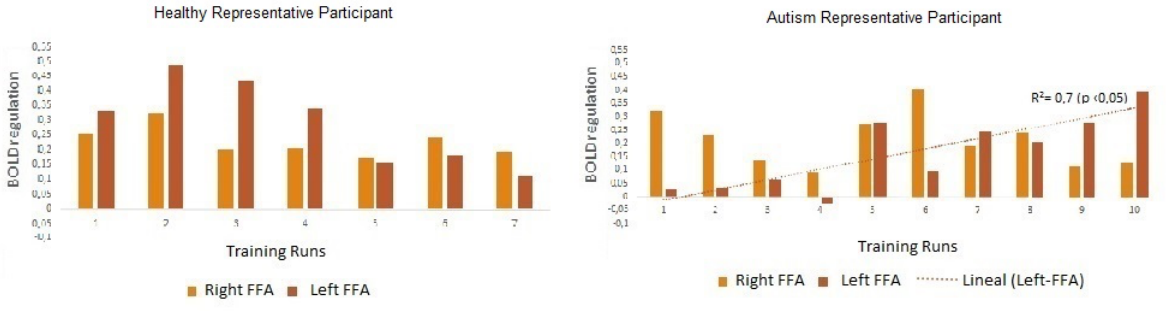
Title: fMRI brain-computer interfaces for self-regulation of fusiform face area in autism spectrum disorders

Authors: J. A. PEREIRA[1], R. SITARAM[1], P. SEPULVEDA[1], M. RANA[1], C. MONTALBA[2], R. TORRES[1], C. TEJOS[3], *S. RUIZ[4];

Católica de Chile, Santiago, Chile; [4]Dept. of Psychiatry and Interdisciplinary Ctr. for Neurosci., Escuela de Medicina, Pontificia Univ. Catol, Santiago, Chile

Abstract: BrainComputer Interfaces based on real-time fMRI (fMRI-BCI) is a technique that have allowed psychiatry patients to achieve self-regulation of circumscribed brain regions, leading to behavioral changes[1]. This methodology has not yet been used in Autism (ASD). One of the most important impairments in ASD is the abnormal processing of human faces. This deficit is associated with an abnormal activity of fusiform face area (FFA)[2]. Therefore, the modulation of this area could lead to positive behavioral modifications in this disorder. The aim of this preliminary work is to determine if young patients with ASD can achieve selfregulation of the activity of FFA with Fmri-BCI.



Two healthy subjects (males, age= 25 and 33) and two ASD patients (males, age= 17 and 18) participated in a 2-4 day experiment (8-13 rt-fMRI training runs in total; 3 upregulation (UP), 4 baseline blocks (REST)/run). During UP, subjects received real-time contingent visual feedback of the BOLD signal coming from bilateral FFA.

Healthy individuals could self-regulate FFA from day 1. ASD patients achieved self-regulation of FFA after 2 days of training. Importantly, ASD subjects showed a positive learning through the days of training. Patient 1 showed a positive learning slope for bilateral FFA (R2 LFFA: .464 ($p<.05$); R2 RFFA: .431 ($p<.05$)). Patient 2 showed a positive learning slope for left FFA throughout sessions (R2:.7 ($p<.05$)) (Fig 1).

Albeit preliminary, our results indicate that selfregulation of FFA with fMRI-BCI is possible in patients with ASD. These results open important possibilities for the correction of abnormally activated brain areas in ASD. New subjects are being currently tested, along with behavioral analyses to explore the effect of FFA self-regulation as a potential tool for clinical researches.

Abstract: Autism spectrum disorder (ASD) is a major neurodevelopmental disorder characterized by deficits in reciprocal social interactions and communication, and by repetitive and restricted behaviors. Despite the significance of this disorder, its underlying neural mechanism remains unclear. Recently, using resting-state functional-connectivity magnetic resonance imaging (rs-fcMRI) techniques, attempts have been made to develop classifiers of ASD and typically developed (TD) individuals, and thereby to identify the abnormality of functional connections (FCs) in ASD. However, none of the previous classifiers has ever been successfully validated for an independent cohort because of over-fitting and the interferential effects of nuisance variables (NVs) such as measurement conditions and demographic distributions. Here, using a multiple-site data set from Japan, we developed an ASD classifier by focusing on abnormal FCs in ASD as revealed by rs-fcMRI. To overcome the difficulties associated with over-fitting and the effects of NVs, we developed a novel machine-learning algorithm that automatically and objectively identified a small number of abnormal FCs in ASD (0.2% of all FCs considered). The resultant classifier attained high accuracy for a Japanese discovery cohort [85%, area under the curve (AUC) = 0.93], and furthermore, demonstrated a remarkable degree of site generalization for two independent validation cohorts in the US ABIDE Project (75%, AUC = 0.76) and in Japan (70%, AUC = 0.77). The identified FCs predicted socio-communicative scores of ASD individuals and constituted the neural substrates of ASD (ADOS A; $r = 0.44$, $P = 0.001$). We also examined the extent to which the ASD classifier was specific to ASD or extendable to other psychiatric disorders (disorder generalization). We found that the developed classifier did not distinguish individuals with major depressive disorder ($P = 0.83$, AUC = 0.48) and attention-deficit hyperactivity disorder ($P = 0.65$, AUC = 0.57) from their controls but moderately distinguished patients with schizophrenia from their controls ($P = 0.012$, AUC = 0.65). Therefore, the results leave open the viable possibility of exploring neuroimaging-based dimensions that quantify the multiple-disorder spectrum.

Abstract: Autism is a developmental disorder characterized by severe and sustained impairment in social interaction and communication, and restricted or stereotyped patterns of behavior and interest. Recently, it has been reported that genetic heritability is lower than that previously estimated, and environmental factors also have a greater influence on the development of autism. Epigenetic processes such as DNA methylation and histone modification are considered to be an interface of genetic and environmental factors. Additionally, two well-characterized epigenetic processes, parental imprinting and X chromosome inactivation, are known to be involved in several conditions that mimic autism spectrum disorders, such as Angelman and Rett syndromes. This clinical evidence suggests that epigenetic processes may play a role in the pathophysiology of autism. On the other hand, many studies suggested involvement of serotonergic system in pathophysiological mechanisms of autism. Therefore, we investigated genome-wide DNA methylation profiles in post-mortem brain tissue from individuals with autism. We measured methylation levels of CpG sites in the dorsal raphe from 6 male subjects with autism and 7 age- and 5 sex-matched healthy control subjects using Infinium HumanMethylation450 BeadsChip. We found differentially methylated regions (DMRs) not only in promoters, but also in gene bodies, 3′ untranslated regions (UTR) and intergenic regions in autism. In addition, because autism is a highly heterogeneous disorder, we screened for individual-specific DNA methylation (IS-DMRs) and found differentially methylated CpG sites at promoters, gene bodies, 3′ UTRs and intergenic regions in autism. Intriguingly, we found DMRs and IS-DMRs in genes related in serotonergic system. We propose that genes, such as *OR2C3 and KLK5*, are novel potential candidate genes for autism by epigenetic approach.

Title: Social attention is context-dependent in adolescents with autism spectrum disorder

Authors: *K. UNRUH, J. BODFISH;
Vanderbilt Univ., Nashville, TN

Abstract: Background: Our experiences with the world play a critical role in neural and behavioral development. Clinically and anecdotally, children with autism spectrum disorder (ASD) spend a disproportion amount of time seeking out and engaging with aspects of their environment that are largely nonsocial in nature. How might these exaggerated patterns of experience influence opportunities for social experience, and in turn, opportunities for social learning and development? We adapted an established method for eliciting and quantifying aspects of visual choice behavior related to preference to test the hypothesis that the presence of nonsocial sources of stimulation diminishes orientation and attention to social sources of stimulation in children with ASD.
Method: Preferential viewing tasks can serve as objective measures of preference, with a greater proportion of viewing time to one item indicative of increased preference. The current task used gaze-tracking technology to examine patterns of visual orientation and attention to stimulus pairs that varied in social (faces) and nonsocial content (high autism interest, HAI or low autism interest, LAI). Participants included both adolescents diagnosed with ASD (N = 33, mean age = 13.9 years) or typically developing (TYP; N = 31, mean age = 13.75 years); groups were matched on IQ and gender.
Results: Repeated measures ANOVA revealed that individuals with ASD had a significantly greater latency to first fixate on social images when this image was paired with an HAI image ($F = 4.3$, $p = .042$), compared to an LAI image pairing. As expected, participants with ASD showed greater total look time to objects ($F = 7.95$, $p < .01$), while TYP participants preferred to look at faces ($F = 21.14$, $p < .0001$). In the ASD group only, a measure of nonsocial interest was associated with reduced preference for social images, when paired with HAI images.
Conclusions: In ASD, the presence of nonsocial sources of stimulation can significantly increase the latency of look time to social sources of information. These results suggest that atypicalities in social motivation in ASD may be context-dependent, with a greater degree of plasticity than is assumed by existing social motivation accounts of ASD.

Title: Pharmacological characterisation of novel kainate receptor antagonists based on kynurenic acid

Authors: *A. V. EAPEN[1], R. J. THATCHER[1], M. W. IRVINE[1], J. WOOD[1], S. MALLAH[1], G. CULLEY[1], A. VOLIANSKIS[2], E. MOLNAR[1], G. L. COLLINGRIDGE[1,3,4], D. E. JANE[1]; [1]Sch. of Physiology, Pharmacol. and Neurosci., Univ. of Bristol, Bristol, United Kingdom; [2]Ctr. for Neurosci. and Trauma, Queen Mary Univ. of London, London, United Kingdom; [3]Dept. of Physiol., Univ. of Toronto, Toronto, ON, Canada; [4]Lunenfeld-Tanenbaum Res. Inst., Mount Sinai Hosp., Toronto, ON, Canada

Abstract: Kainate receptors (KARs) are ionotropic glutamate receptors (iGluRs) that regulate excitatory and inhibitory synaptic transmission in the CNS. The extent to which different types of KAR subunits (GluK1-5) contribute to synaptic physiology is unknown mainly due to a lack of subunit-specific antagonists. In this study, we used kynurenic acid, a non-specific, competitive iGluR antagonist as a lead to develop competitive antagonists that target GluK2 containing KARs. An iterative approach of molecular modelling combined with structure-activity relationship studies, using data from functional assays on KARs, provided the rationale for the design of novel compounds. Two functional assays were employed to study the activity of novel kynurenic acid derivatives. Firstly, a calcium fluorescence assay using HEK293 cells expressing human homomeric GluA1, GluK1, or GluK2 receptors was used to estimate the affinity of compounds for each KAR subtype. Secondly, extracellular field recordings of Schaffer collateral-CA1 synapses in rat hippocampal slices were used to characterise the compound activity on AMPARs and NMDARs in native tissue. These studies revealed that it was possible to develop KAR antagonists without activity on NMDARs but although some compounds were found to show some selectivity for GluK2 versus GluK1, they retained some AMPAR antagonist

activity. Molecular modelling studies have been used to rationalise the receptor selectivity pattern associated with our lead compounds and future studies will utilise these findings to design antagonists with greater GluK2 selectivity.

Title: Design, Synthesis and SAR study of novel kainate receptor antagonists based on kynurenic acid

Authors: *R. J. THATCHER[1], A. V. EAPEN[1], M. IRVINE[1], J. WOOD[1], S. MALLAH[1], G. CULLEY[1], A. VOLIANSKIS[2], G. L. COLLINGRIDGE[1,3,4], E. MOLNAR[1], D. E. JANE[1]; [1]Physiology, Pharmacol. and Neurosci., Univ. of Bristol, Bristol, United Kingdom; [2]Ctr. for Neurosci. and Trauma, Queen Mary Univ. of London, London, United Kingdom; [3]Dept. of Physiol., Univ. of Toronto, Toronto, ON, Canada; [4]Lunenfeld-Tanenbaum Res. Inst., Toronto, ON, Canada

Abstract: Kainate receptors (KARs) are ionotropic glutamate receptors that are involved in synaptic plasticity in the CNS and a range of neurological disorders such as chronic pain and epilepsy. Research into the roles of different types of KAR subunits (GluK1-5) in synaptic physiology and neurological diseases requires the development of subunit-specific antagonists. In this study, we used kynurenic acid, an antagonist of KARs, AMPARs and NMDARs, as a lead to develop competitive antagonists that target GluK2 containing KARs. A range of kynurenic acid derivatives bearing various substituents at the 5-, 6- and/or 7- position were synthesised and evaluated using a calcium fluorescence assay using HEK293 cells expressing human homomeric GluA1, GluK1, or GluK2 receptors.
The data from the pharmacological assays revealed that it was possible to develop KAR

antagonists without activity on NMDARs and reduced activity at AMPARs, with some examples exhibiting some selectivity for GluK2 versus GluK1 containing receptors. Structure-activity relationship (SAR) studies and molecular modelling studies using X-ray crystal structures of GluK1 (PDB code 2QS1) and GluA2 (PDB code: 3B7D) and an homology model of GluK2 (based on GluK1: PDB code 2QS1) have been used to rationalise the receptor selectivity pattern associated with our lead compounds. Future studies will utilise these findings to design antagonists with greater GluK2 selectivity.

Title: GluK2-containing kainate receptors mediate the effects of hypoxia in area CA3 of the neonatal mouse

Authors: *D. K. GROSENBAUGH, B. M. ROSS, S. A. ZANELLI;
Univ. of Virginia, Charlottesville, VA

Abstract: Background: Kainate receptors (KARs) are tetrameric ionotropic glutamate receptors composed of GluK1-5 subunits with peak subunit expression occurring during the late embryonic/early postnatal period. Homomeric GluK2 and heteromeric GluK2/5-containing KARs are robustly expressed throughout area CA3 of the hippocampus where they contribute to excitatory neurotransmission and have been implicated in the hyperexcitable network associated with temporal lobe epilepsy. The potential role of KARs in mediating hypoxia-induced seizures in the neonatal period is not known. **Objective:** To examine the impact of hypoxia on synaptic transmission in area CA3 of the neonatal mouse and to determine if these effects are mediated by GluK2-containing KARs. **Methods:** All experiments were conducted postnatal day 7 - 9 wild type and $GluK2^{-/-}$ mice. Miniature excitatory postsynaptic currents (mEPSCs) were recorded from area CA3 using an *in vitro* hypoxia model (oxygen glucose deprivation, OGD). Additionally, mEPSCs were recorded from area CA3 in naive mice 1 hour following *in vivo* hypoxia (4min 30 sec at 4% FiO_2) a model shown to lead to consistent hypoxic and post-hypoxic seizures. A subset of mice received subcutaneous injections of the KAR antagonist UBP310 (75mg/kg) 30 min prior to hypoxia. Western blots analysis of GuK2/3 subunits was performed on microdissected CA3 region in naïve mice and mice 1h following *in vivo* hypoxia. **Results:** mEPSC frequency increased significantly (1.5 fold) during OGD. UBP310 prevented the observed increase in mEPSC frequency during OGD, suggesting a potential role of KARs. To confirm this finding we studied the effects of OGD in a $GluK2^{-/-}$ mouse and found, in agreement with our pharmacological studies, that OGD failed to increase mEPSC frequency, strongly suggesting a role of GluK2-containing KARs. In a separate set of preliminary experiments we found that GluK2/3 subunit expression trended towards an increase in area CA3 of the neonatal mouse 1h following *in vivo* hypoxia. In support of these results mEPSC frequency increased significantly (1.8 fold) in mice 1h post-hypoxia. This increase was blocked by administration of UBP310 prior to *in vivo* hypoxia. **Conclusions:** These findings, from 2 different models of hypoxia, suggest that GluK2-containing KARs mediate, at least in part, the observed increase in excitatory synaptic transmission following hypoxia. Activation of GluK2-containing KARs during hypoxia may be an important mechanism of increased excitability in the neonatal brain and may represent a potential novel pathway for the development of mechanisms-based and developmentally appropriate therapies for neonates with hypoxic seizures.

Title: Neto regulation of somatodendritic and presynaptic kainate receptors expressed by hippocampal interneurons

Authors: *K. A. PELKEY[1], M. WYETH[2], G. VARGISH[1], C. FANG[1], A. JOHNSTON[3], X. YUAN[1], S. HUNT[1], R. MCINNES[4], M. W. SALTER[5], C. J. MCBAIN[1];

Abstract: Neuropilin- and tolloid-like proteins (Neto1/Neto2) have emerged as auxiliary kainate receptor (KAR) subunits capable of regulating almost every parameter of receptor function. Indeed, overexpression studies in heterologous cells or neurons have demonstrated that Netos regulate KAR desensitization and deactivation kinetics, channel open probability, ligand affinity, and subcellular localization. Consistent with these findings, studies at hippocampal mossy fiber to CA3 pyramidal cell (MF-CA3) synapses indicate that Neto1 regulates binding affinity, kinetics, and synaptic targeting of native GluK2 containing postsynaptic KARs. However, direct evidence for Neto2 mediated regulation of endogenous KAR function remains lacking despite association with native KAR complexes. Similarly, despite a wealth of overexpression data supporting Neto1/2 regulation of GluK1 expressing KARs, direct evidence for endogenous Neto1/2 association with and regulation of native GluK1 containing KARs is lacking. Importantly, Neto-mediated regulation of fully assembled recombinant KARs exhibits GluK subunit and Neto isoform specificity. Thus, as Neto1/2 and GluK1-5 display discrete expression profiles throughout the CNS it is critical to consider network and cell subtype specificity in Neto regulation of native KARs. Here using combined in situ hybridization, immunohistochemical, and genetic reporting strategies we localize Neto1/2 in combination with GluK1/2/5 in somatostatin (SOM), cholecystokinin/cannabinoid receptor 1 (CCK/CB1), and parvalbumin (PV) expressing subsets of hippocampal interneurons. Moreover, we demonstrate that Neto1, but not Neto2, regulates KAR currents in SOM, CCK/CB1, and PV interneurons as well as recruitment of inhibitory drive onto pyramidal cells. Finally, we demonstrate that presynaptic GluK1 containing KARs on CCK/CB1 interneurons are regulated by both Neto1 and Neto2, with Neto1 being required for presynaptic KAR function and Neto2 modulating KAR affinity.

Title: Low-affinity kainate receptor subunit, gluk1, gluk2 and gluk3, are responsible for mouse anxiety-like behavior

Authors: *I. WATANABE;
Dept. of Cell. Neurobio. Basic Neurosci, Niigata, Japan

Abstract: A kainate receptor (KAR) is a member of the ionotropic glutamate receptor family, which plays various roles in the central nervous system. KARs are tetramers composed of the combinations of low-affinity GluK1-GluK3 (GluR5-GluR7) and high-affinity GluK4-GluK5 (KA1-KA2) subunits. GluK1-3 subunits can form functional homomeric receptors on their own, while GluK4 and GluK5 require GluK1-3 to form functional receptors. We previously showed relative amounts of low affinity subunits, GluK2 and GluK3, were three and seven times larger than those of high affinity, GluK4 and GluK5, in mouse hippocampus and cerebellum.
Until now, we have generated all kinds of KAR subunit knockout mouse and analyzed their behavior. Because of a large amount of literature on psychiatric diseases, we focused on the emotional behaviors in these mice. GluK3-KO mice exhibited a significant increase in time spent in open area in the elevated plus maze test (EPM). GluK2-KO mice also spent more time in open area in the EPM, even though they had abnormal locomotor and motor coordination problems, which were found by the open field test and the balance beam test. In contrast, GluK1-KO mice spent significantly a shorter time in open area than wild type mice in the EPM. These results suggest that low-affinity KAR subunits, GluK1-3, are associated with anxiety-like behavior. In addition, immunoprecipitated analysis of GluK2 antibody revealed that GluK3 was co-immunoprecipitated with GluK2 in hippocampus, and vice versa, showing the formation of heteromers. And the expression patterns of GluK1 and GluK4 shown by in situ hybridization were similar to those of cortex and cerebellum. These data indicated GluK2/GluK3 and GluK1/GluK4 heteromeric KARs were locally co-expressed in the brain regions. Thus, we examined anxiety-like behavior of GluK2/3 double KO and GluK1/4 double KO mice to find whether each KAR subunit is involved in anxiety-like behavior (or not). The GluK2/3-KO mice

stayed twice longer in open area in the EPM, in agreement with the results of GluK2 and GluK3 single KO mice. The GluK1/4-KO mice also showed 14.4% decrease in time spent in open area in the EPM, similar to the result (13.5 % decrease) of GluK1 single KO mice. Together, these results demonstrate that GluK2/3 and GluK1/4 heteromeric KARs contribute to anxiety-like behavior rather than GluK2 and GluK3 homomeric KARs.

Title: Kainate receptors and metabotropic glutamate receptors mobilize 2-AG in striatal direct pathway SPNs

Authors: *J. MARSHALL[1], J. XU[1], A. CONTRACTOR[2];
[1]Physiol., Northwestern Univ. Dept. of Physiol., Chicago, IL; [2]Northwestern Univ., Chicago, IL

Abstract: The striatum is the main input structure of the basal ganglia, integrating information from the thalamus and cortex to control planning and modulation of movement. Endocannabinoid (eCB) dependent plasticity at afferent cortical synapses formed on the two major types of striatal neurons, direct and indirect pathway spiny projection neurons (SPNs), is crucial for balancing striatal output. In indirect pathway SPNs, mGluRs can generate two distinct eCB species (anadamide, 2-AG) by activating separate pathways with distinct patterns of presynaptic stimulation. However, whether or not direct pathway SPNs are able to synthesize the same eCB species by linkage of the same glutamate receptor types to the same pathways is less clear.
Here we found that in striatal direct pathway SPNs, activation of group I mGluRs transiently depressed corticostriatal synaptic transmission (DHPG 50μM: 68.1 ± 6.9%, n=4) through the generation of the eCB 2-arachidonoylglycerol (2-AG) (2-AG synthesis inhibitor THL: 105 ± 5.4%, n = 3 $p < 0.05$). Additionally kainate receptors, members of a distinct glutamate receptor family, were also able to transiently depress corticostriatal synaptic transmission by mobilizing

2-AG via a similar pathway (Kainic acid 100nM: 71.4 ± 9.1%, n = 6; 2-AG synthesis inhibitor RHC: 101 ± 7.4%, n = 11 $p < 0.05$). This effect of kainic acid is dependent upon postsynaptic kainate receptors as corticostriatal synaptic depression was not observed when kainate receptors were ablated in direct pathway SPNs (WT: 63.1 ± 7.03 %, n = 5; GluK2 D1 SPN KO 101 ± 11.0 %, n = 5 $p < 0.05$). Furthermore, short-term eCB dependent depression could be achieved by activating synaptic kainate receptors with short trains of high frequency stimulation (WT: 68.9 ± 6.16 %, n =12; GluK2 D1 SPN KO 89.38 ± 6.93%, n = 8 $p < 0.05$), a form of short-term plasticity that is independent of group I mGluR activity.
In summary, these results demonstrate that in direct pathway SPNs, members of two distinct glutamate receptor families, group 1 mGluRs and kainate receptors can couple to 2-AG mobilization to cause short term depression of corticostriatal synapses.

Title: Enhanced fear memory as a result of neuronal TDP-43 depletion

Authors: *P. KOZA[1], A. SUSKA[1], A. KONOPKA[2], T. GÓRKIEWICZ[1], E. KNAPSKA[1], W. KONOPKA[1], L. KACZMAREK[1];
[1]Nencki Inst. of Exptl. Biol., Warszawa, Poland; [2]Experts' Ctr. for Anatlytical Chem. Biol. and Chem. Res. Centre, Univ. of Warsaw, Warsaw, Poland

Abstract: TDP-43 is a predominantly nuclear RNA binding protein that has been identified as a hallmark of a range of neurodegenerative disorders. Despite the wide scale research, neither the mechanism underlying TDP-43-mediated degeneration of neurons nor its physiological role is fully defined.
In order to explore TDP-43 physiological functions, we have developed transgenic rat model characterized by substantially depleted TDP-43 protein level in neurons. Behavioral analysis of those rats revealed improved cognitive functions, demonstrated by enhanced memory of acquired fear. Those alterations were subsequently confirmed by more stable LTP in the CA1 area of hippocampus, one of the regions required for expression of fear related behaviors. At the same time, the basic electrophysiological properties of CA1 pyramidal neurons were unchanged. However, when pentylenetetrazole (PTZ) massive neuronal stimulation was introduced, control animals presented significantly reduced excitability of CA1 neurons, as a result of short-term

plasticity. Surprisingly, TDP-43 transgenic rats maintained cell excitability at the same level. Behavioral and electrophysiological consequences of TDP-43 depletion applied to altered morphology of dendritic spines, characterized by wider heads diameters. However, both control and transgenic animals presented analogous mode of structural changes of spines in response to PTZ induced seizures, what suggested dominance of molecular over morphological differences. In fact, using label-free UHPLC-ESI MS/MS for quantitative proteomic analysis, we verified that TDP-43 depletion led to changed subunit composition of glutamatergic AMPA receptors, regarding FLOP and FLIP splice variants. Alterations of FLOP variant of GluR1 and GluR2 subunits observed under control conditions were further outlined by neuronal stimulation. Proteomic results were subsequently confirmed by electrophysiological whole-cell patch clamp recordings in CA1, in the presence of cyclothiazide, AMPAR allosteric modulator, influencing different receptor kinetics depending on a balance between FLOP and FLIP subunit variant. We consider that the modifications we observe may underlie more general mechanisms possibly leading through disturbed TDP-43 to alterations of RNA metabolism and in a longer run to degeneration of neurons. Undeniably, here we show the involvement of TDP-43 in mechanisms of neuronal plasticity, as its depletion led to enhanced fear memory, more stable LTP and alterations in dendritic spines morphology, expressed as altered assembling of AMPARs.

Title: Acute methylmercury exposure leads to alterations in AMPA and NMDA receptor expression in the motor neuron NSC34 cell line

Authors: *A. COLON-RODRIGUEZ[1,2,3], W. D. ATCHISON[1,2,3];
[1]Pharmacol. and Toxicology, [2]Comparative Med. and Integrative Biol., [3]Inst. for Integrative Toxicology, Michigan State Univ., East Lansing, MI

Abstract: Methylmercury (MeHg) leads to cell death of motor neurons (MNs) through Ca^{2+} mediated pathways *in vitro* and *in vivo*. Ca^{2+} permeable glutamate receptors α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPAR) and N-methyl-D-aspartate (NMDA) receptors are thought to contribute to these alterations. Although AMPAR are not normally permeable to Ca^{2+}, changes in the expression of the receptor GluA2 subunit or its RNA editing enzyme, adenosine deaminase acting on RNA2 (ADAR2), lead to Ca^{2+} permeability. To examine the effects of *in vitro* MeHg exposure on mRNA levels of the AMPAR, the ADAR2 enzyme, and NMDAR, a MN cell line (NSC34) was exposed to 0, 0.5, 1, and 1.5μM MeHg starting on DIV 2 for 24hr. MeHg effects on cell viability were examined by Trypan blue exclusion assay. QPCR was performed on reverse transcript (cDNA) of RNA isolated from NSC34 cells. AMPAR GluR1, 2, 3, and 4 subunits, ADAR2 enzyme and the NR1, NR2A, NR2B and NR2C subunit expression was measured from treated and untreated NSC34 cells. We hypothesized that MeHg would differentially affect the receptor subunits studied, decreasing expression of GluA2 and ADAR2 and increasing expression of the other subunits studied, compensating for MeHg effects and thus contributing to the observed $[Ca^{2+}]_i$ alterations. Time and concentration-dependent cell death of NSC34 cells occur after 24hr MeHg exposure. AMPAR subunits and ADAR2 levels increased after 24h exposure to 0.5μM MeHg. However, after 1 or 1.5μM MeHg exposure GluA2-4 and ADAR2 were downregulated. The mRNA levels of all the NMDAR NR1 and NR2C were significantly downregulated after 24hr exposure to 0.5 and 1μM MeHg. These results support the idea that MeHg effects in MNs are in part mediated by increased expression of the Ca^{2+} permeable AMPAR. This was mainly due to the decrease observed in the RNA editing enzyme ADAR2 and the GluA2 subunit.

Title: AMPA and Kainate Receptors are required for navigation in taxis behaviors in *C. elegans*

Authors: *P. J. MALDONADO-CATALA[1], P. J. BROCKIE[2], J. MELLEM[2], D. MADSEN[2], A. V. MARICQ[2];
[2]Dept. of Biol., [1]Univ. of Utah, Salt Lake City, UT

Abstract: The nematode *C. elegans* is capable of detecting environmental cues and modifying its behavior accordingly. For example, worms can navigate towards attractive odors and favorable temperatures. The neuronal circuits underlying these behaviors have been identified via cell-ablation studies; however, how the neurons in these circuits modulate navigation towards an attractant is not well understood. The RIA interneurons integrate information from sensory neurons in these circuits and send information to a variety of interneurons and motor neurons. Interestingly, the GLR-3 and GLR-6 kainate subtype of ionotropic glutamate receptors (iGluRs) are exclusively expressed in RIA, which also express the GLR-1 AMPA-type iGluR. Electrophysiological analysis revealed that GLR-3 and GLR-6 form a heteromeric iGluR that is gated by both glutamate and kainate. In addition, the kinetics and amplitude of the glutamate-gated current mediated by GLR-3 and GLR-6 are distinctly different from that of the AMPAR-mediated current. *glr-1* single and *glr-3; glr-6* double knockout animals show deficits in chemotaxis to attractive odorants, similar to those observed in worms lacking the RIA interneurons. Behavioral analysis shows that kainate and AMPA receptor mutants spend more time navigating in trajectories that do not lead to the odorant. In addition, the rate of reversals during chemotaxis is increased in these mutants. Taken together, our results suggest that the AMPA and kainate iGluRs are required for error correction during taxis behaviors.

Title: Deletion of Neurexin 1 binding glutamate delta-1 subunit produces cortico-striatal dysfunction: relevance to autism

Authors: J. LIU, *S. DRAVID;
Creighton Univ., Omaha, NE

Abstract: The delta family of ionotropic glutamate receptors, that includes glutamate delta-1 (GluD1) and delta-2 have been recently discovered to interact presynaptically with adhesion

molecule neurexin 1 leading to synapse formation. There is an enriched expression of GluD1 in striatum. We have previously shown that mice with GluD1 deletion exhibit hyperactivity, repetitive behaviors, social interaction deficits, depression and hyperaggression, which are behaviors associated with striatal function. Here we addressed the potential role of GluD1 in regulating striatal synapses. We performed whole-cell voltage-clamp recordings from medium spiny neurons (MSNs) in dorsal striatum. Deletion of GluD1 produced a reduction in frequency of mEPSCs with no change in amplitude. A reduction in the number of functional synapses in GluD1 KO potentially underlies this result, since no change in paired-pulse ratio was observed indicating lack of presynaptic effect. The mIPSCs characteristics were unchanged in GluD1 KO MSNs. Additionally, we did not detect any significant deficit in either AMPA/NMDA receptor-mediated current ratio or coefficient of variation ratio in GluD1 KO mice, suggesting no alteration of silent synapses by the deletion of GluD1. Furthermore, we analyzed long term depression (LTD) at cortico-striatal synapses. Bath application of a group 1 mGluR agonist, DHPG, caused a robust depression of evoked EPSC amplitude with no change in the paired-pulse ratio. Interestingly, a significant reduction in DHPG-induced LTD was observed in GluD1 KO mice. Together, these results reveal a critical role of GluD1 in the regulation of glutamatergic neurotransmission and cortico-striatal synaptic plasticity in DS MSNs.

Title: Functional characterisation of glutamate receptors of the delta subfamily

Authors: *T. STRASDEIT, M. HOLLMANN;
Biochem. I, Building NC, Level 6, Room 131, Ruhr Univ. Bochum, Bochum, Germany

Abstract: Glutamate-gated receptors are the main excitatory receptors in the brain. The glutamate receptor family comprises metabotropic and ionotropic receptors, with the latter including AMPA, kainate, NMDA and the orphan receptors, also called delta receptors. The two members of the delta receptor subfamily (GluD1, GluD2) so far failed to show any ligand-gated currents, although they have been shown to possess functional channels. It is known that the delta receptors play important roles in cerebellar functions and high-frequency hearing. Besides, it was shown that they are also involved in the structural stabilization of synapses. Recent studies from Ady et al. (2014) now have shown that GluD2 is able to gate ions in HEK-293 cells, if the

metabotropic receptor mGlu1a is coexpressed. After activation of mGlu1a an as of yet unknown intracellular mechanism leads to opening of the GluD2 channel, which then leads to ionic influx. This was also shown at parallel fiber synapses in the cerebellum of mice. This gating mechanism provides unexpected new perspectives regarding synaptic transmission. The present project was designed to pursue further electrophysiological characterization of this mechanism by coexpressing the delta and the metabotropic receptors in different cell systems. On the one hand the receptor combination was tested in HEK-293 cells via patch clamp recordings under several conditions, including different agonists, expression times, and variations of the patch clamp method itself. On the other hand, voltage clamp recordings in *Xenopus* oocytes were performed to clarify if this activation of delta receptors can be reproduced in other cell systems. A further goal was to check if this activation mechanism also works with other members of the metabotropic receptor family and with GluD1.

Abstract: The ATP-gated ion channel P2X7 has emerged as a potential central nervous system (CNS) drug target based on the hypotheses that pro-inflammatory cytokines such as IL-1β that are released by microglia and may contribute to the etiology of various disorders of the CNS including mood disorders. Emerging science has strengthened the role of P2X7-IL-1β signaling in animal models of depression. To that end, we disclose a CNS penetrant, high-affinity and selective P2X7 antagonist, that is now a clinical candidate for mood disorders. This compound

exhibits high potency for both rodent and human P2X7. The IC50 of the P2X7 antagonist in the human blood IL-1β release assay is approximately 10 nM. In human and rat brain slices, the compound demonstrated concentration dependent binding to P2X7; in-vivo the compound dosed orally produced excellent bioavailability, good pharmacokinetic properties in rodents, dogs and non-human primates. Finally, P2X7 receptor occupancy was demonstrated in rat brain by ex-vivo autoradiography. In summary, we present the pharmacology of a novel, CNS penetrant clinical candidate that is a functional antagonist of the P2X7 ion channel.

Title: Antidepressant escitalopram blocks 5-hydroxytryptamine$_3$ (5-ht$_3$) receptor-mediated currents in ncb-20 neuroblastoma cells

Authors: *K.-W. SUNG[1], S. JEUN[1], Y. JOO[1], S. HAHN[2];
[1]Pharmacol., [2]Physiol., The Catholic Univ. of Korea, Med. Col., Seoul, Korea, Republic of

Abstract: The effect of escitalopram on 5-hydroxytryptamine$_3$ receptors (5-HT$_3$R) expressed in NCB-20 neuroblastoma cells was examined using whole-cell voltage clamp technique combined with a fast drug application method. Co-application of escitalopram (1-100 μM) produced a concentration-dependent reduction in the peak amplitude and the rise slope of 5-HT$_3$R-mediated currents induced by 3 μM of 5-HT. The IC$_{50}$ of escitalopram was 5.34 μM. Co-application of 10 μM of escitalopram increased EC$_{50}$ of 5-HT$_3$R-mediated currents amplitude from 3.16 μM to 6.33 μM, but decreased E$_{max}$ to 89.35% without altering the Hill coefficient (2.61). No voltage dependence and reversal potential shift were evident in the inhibitory effect of escitalopram on 5-HT$_3$R-mediated currents over the entire voltage range tested. The decay time constant for receptor desensitization and deactivation of 5-HT$_3$R-mediated currents were also significantly attenuated by escitalopram. However, the time constant for recovery from desensitization was not changed by escitalopram. These results suggest that the escitalopram directly inhibits 5-HT$_3$R function expressed in NCN-20 neuroblastoma cells in a noncompetitive manner by

delaying channel opening, and that this inhibitory effect of escitalopram probably contribute to the pharmacological effects.

Title: Activation and modulation of recombinant glycine and $GABA_A$ receptors by 4-halogenated analogues of propofol

Authors: *G. AKK[1], A. GERMANN[1], D. SHIN[1], B. MANION[1], C. J. EDGE[2], E. H. SMITH[2], N. P. FRANKS[2], A. S. EVERS[1];

Abstract: Glycine receptors can be modulated by the intravenous anesthetic propofol (2,6-diisopropylphenol); however, the drug is more potent, by at least one order of magnitude, on the $GABA_A$ receptor. It has been proposed that halogenation of the propofol molecule may generate compounds with selective enhancement of glycinergic modulatory properties. We have compared the effects of propofol and its halogenated analogues, 4-bromo-, 4-chloro-, and 4-fluoropropofol, on glycine and $GABA_A$ receptors expressed in oocytes. The data indicate that the four compounds are essentially equally potent modulators of the $\alpha1\beta3\gamma2L$ $GABA_A$ receptor with EC_{50}s between 4 and 7 μM. The EC_{50}s for loss of righting in *Xenopus* tadpoles, a proxy for loss of consciousness and considered to be mediated by actions on $GABA_A$ receptors, ranged from 0.5-1 μM. In homomeric α1, α2, and α3 glycine receptors, the concentration-response curves for potentiation were shifted to lower drug concentrations by 2-10-fold for the halogenated compounds. Direct activation by all compounds was minimal with all subtypes of the glycine receptor. Overall, our findings confirm that halogenation of propofol more strongly affects modulation of glycine receptors. However, the effective concentrations of all tested halogenated

compounds were lower for $GABA_A$ receptors, and we infer that 4-bromo-, 4-chloro, or 4-fluoropropofol cannot be used as selective glycine receptor modulators.

Title: The deactivation of acid sensing ion channel 1a is strikingly pH-dependent

Authors: *D. M. MACLEAN, V. JAYARAMAN;
Biochem. and Mol. Biol., UTHealth, Houston, TX

Abstract: Acid sensing ion channels (ASICs) are trimeric cation-selective ion channels activated by protons in the physiological range. Recent reports have revealed that postsynaptically-localized ASICs contribute to excitatory postsynaptic currents (EPSCs) by responding to the transient acidification of the synaptic cleft which accompanies neurotransmission. We have recently examined how recombinant and native ASICs respond to such rapid (~ 1 ms) acidic stimuli which they are likely to encounter at a synapse. We found that ASIC deactivation in response to a pH 5 to pH 8 jump is extremely rapid, a property which enables them to follow high frequency stimulus trains. However, investigation at pH's nearer to physiological was hampered by steady-state inactivation. Here we have circumvented this problem using a triple jump approach. By rapidly jumping outside-out patches from pH 8 through pH 5 for approximately 1 ms to a third pH ranging from pH 8 to 6.6, the deactivation kinetics of ASICs at a many pH's can be investigated. Strikingly, rat ASIC1a deactivation kinetics range across nearly three orders of magnitude, from very fast (~ 0.6 ms) at pH 8 to rather slow (~ 400 ms) at pH 7. This strong pH dependence of rat ASIC1a was conserved in chicken and human subunits but was absent in rat ASIC1b, ASIC3 or heteromeric ASIC1a/2a. Given that synaptic pH levels correlate with activity, this enormously dynamic deactivation range provides ASIC1a with the capacity to encode the recent activity history of the synapse at the level of the EPSC.

Title: The role of prolines in ELIC

Authors: *S. C. LUMMIS[1], F. LOVE[1], M. RIENZO[2], D. A. DOUGHERTY[2];
[1]Univ. of Cambridge, Cambridge, United Kingdom; [2]Caltech, Pasadena, CA

Abstract: *Erwinia* ligand-gated ion channel (ELIC) is a bacterial homologue of vertebrate pentameric ligand-gated ion channels (pLGIC), and has proved a valuable model for understanding the structure and function of this important protein family. There is nevertheless still a question as to whether molecular details can be accurately extrapolated from this protein to those found in eukaryotes. To probe this we here explore the role of Pro residues in ELIC, as we have shown that the unusual properties of Pro result in a range of specific functions of these residues in the pLGIC family. All the Pro residues in ELIC were substituted with Ala. Receptors were expressed heterologously in *Xenopus laevis* oocytes, and whole-cell voltage-clamp electrophysiology was used to monitor channel activity. Non-functional receptors were further probed with non-canonical amino acids using *in vivo* nonsense suppression. There was a range of effects with the different mutant receptors, with both increases and decreases in EC_{50} values; only one substitution, however, the Pro in the 'Cys-loop', resulted in loss of function. These data are not equivalent to those obtained from vertebrate pLGIC, where many (up to 20%) Pro to Ala substitutions ablate receptor function. Thus while our data clarify the role of Pro residues in ELIC, they suggest caution must be applied in using data from this prokaryotic receptor to understand molecular details of eukaryotic pLGIC receptor function.

Title: Cannabinoid receptor ligands differently modulate acetylcholine-induced Ca^{2+} signals in pancreatic acinar cells

Authors: *K. XIA[1,2], Z. HUANG[1], D. CHEN[1], M. GAO[1], S. ZHANG[2], J. WU[1,2];
[1]St.joseph's Hosp. and Med. Ctr., Phoenix, AZ; [2]The First Affiliated Hosp. of Zhengzhou Univ., Zhengzhou, China

Abstract: Acute pancreatitis occurs when pancreatic pro-enzymes (especially trypsin), secreted from pancreatic acinar cells, are activated in the pancreas instead of the small intestine, causing autodigestion. In clinical practice, there are still no efficient drugs that specifically treat acute pancreatitis. Evidence demonstrates that the primary event initiating the process of acute pancreatitis is the excessive release of Ca^{2+} from intracellular Ca^{2+} pools. This provides a promising therapeutic strategy, as the blockade of intracellular Ca^{2+} signals in pancreatic acinar cells may provide protection against Ca^{2+} overload, intracellular protease activation and necrosis, which are major triggers of acute pancreatitis. Synthetic and endogenous cannabinoid (CB) compounds exert their pharmacological roles through cannabinoid receptor type 1 (CB_1R), type 2 (CB_2R) or non-CBRs. Emerging evidence suggests that CB_1 and CB_2 receptors are expressed in the pancreatic gland and modulate pancreatic cell function, alter insulin release, and play important roles in the regulation of body metabolism. In addition, activation of CB_2Rs in pancreatic acinar prevents acinar cell pathogenesis in acute pancreatitis animal models. However, whether or not CB ligands modulate intracellular Ca^{2+} signals in pancreatic acinar cells is largely unknown. We address this question by examining the effects of CB ligands on ACh-induced Ca^{2+} oscillations in acutely-dissociated pancreatic acinar cells using patch-clamp whole-cell recordings in wild type (WT), CB_1 knockout (KO) and CB_2 KO mice. We found that bath application of CB_2R agonists at 10 μM concentration, GW, GP1a and JWH133 significantly reduced ACh (10-30 nM)-induced Ca^{2+} oscillations, while other agonists tested such as SER601, CB65, JWH015, Hu308, L759656 showed little inhibitory effect. CB_1R agonist (10 μM ACEA) played a similar inhibition on Ca^{2+} oscillations. Non-selective CB receptor agonist WIN55,212-2, rather than 2-AG inhibited Ca^{2+} oscillations. In CB_2 KO mice, the inhibitory effect by GW, GP1a and JWH133 were significantly eliminated, but ACEA and WIN55,212-2 still exhibited inhibition, while in CB_1R KO mice, GW, ACEA and WIN55,212-2 are still shown inhibition. Collectively, our study provides novel information that CB receptor ligands differently modulate intracellular Ca^{2+} signals in mouse pancreatic acinar cells. The targets that mediate this modulation may involve CB_2R and non-CB receptors. This complexity of modulations by

different CB receptor ligands acting on different targets gives rise to a caution to choose appropriate CB receptor ligands for therapeutic strategy of acute pancreatitis.

Pasteur, Paris, France; [6]Inst. of Pharmaceut. Sci., Swiss Federal Inst. of Technol. (ETH), Zurich, Switzerland

Abstract: Diminished inhibitory neurotransmission in the superficial dorsal horn contributes to chronic pain. In inflammatory pain, this reduction occurs at least partially through a prostaglandin E_2 (PGE_2) and protein kinase A (PKA)-dependent phosphorylation of a specific subtype of glycine receptors (GlyRs) containing α3 subunits (GlyRα3). Restoring the activity of spinal GlyRα3 through positive allosteric modulators may thus constitute a rational approach against inflammatory pain. Here, we investigated the modulation of GlyRs by the non-anesthetic propofol derivative 2,6-di-tert-butylphenol (2,6-DTBP). We found that 2,6-DTBP reverses

inflammation-mediated dis-inhibition through a specific interaction with heteromeric αβGlyRs containing phosphorylated α3 subunits. Electrophysiological analyses of recombinant mutated receptors show that 2,6-DTBP interacts with a conserved phenylalanine residue in the membrane-associated stretch between transmembrane regions 3 and 4 of the GlyR α3 subunit. In native mouse spinal cord tissue, 2,6-DTBP modulated synaptic GlyR currents only after priming with PGE_2, consistent with molecular modeling data that suggest that in heteromeric α3βGlyRs this site is accessible to 2,6-DTBP only after PKA-dependent phosphorylation. In mouse models of inflammatory pain, 2,6-DTBP reduced inflammatory hyperalgesia in an α3GlyR-dependent manner. Our data thus demonstrate that pharmacological modulation of GlyRs can be restricted to disease-primed receptors and that this specific modulation reduces hyperalgesia in mouse models of inflammatory pain.

Title: Acid-sensing ion channels in ventrolateral medulla contribute to central chemoreception

Authors: Q. JIANG[1], N. SONG[2], R. GUAN[2], C. J. HASSANZADEH[1], Y. CHU[1], X. WANG[2], L. SHEN[2], *X. CHU[1,2];

Abstract: Among several potential regions involved in the central chemoreceptors, the ventrolateral medulla (VLM) is one of the critical area and sensitive to the changes of extracellular pH. Acid-sensing ion channels (ASICs) are activated by acidic microenvironment and expressed in medulla, however, the roles of ASICs in VLM remain uncertain. Here, we found that ASIC currents were triggered by pH drop in medulla including VLM with pH value for half-maximal activation of 6.6. ASIC currents in medulla were dose-dependent blocked by

amiloride, a non-selective ASIC blocker. Homomeric ASIC1a and heteromeric ASIC1a/2 channels were likely responsible for the acid-mediated currents in medulla based on their sensitivity to psalmotoxin 1 and zinc. ASIC currents by pH drops from 7.4 to 6.5 were disappeared in VLM neurons from ASIC1, but not ASIC2 knock-out mice. Activation of ASICs in medulla also triggered membrane excitability. Moreover, microinjection of pH 6.5 of artificial cerebrospinal fluid into VLM increased integrated phrenic discharge, inspiratory time and respiratory drive. ASIC antagonist amiloride inhibited the acid-induced stimulating effect on respiration. Collectively, our data suggest that ASIC1a and ASIC1a/2 channels are main components for acid-induced currents in medulla and activation of ASICs in VLM contributes to central chemoreception.

Title: A missense mutation A384P associated with human hyperekplexia reveals a desensitization site of glycine receptors

Authors: *D. WU[1], C.-H. WANG[1], M.-L. SHEN[2], N. ZHOU[3];
[1]China Med. University, Grad. Inst. of Clin. Med. Science,, Taichung, Taiwan; [2]Grad. Inst. of Chinese Med., Taichung, Taiwan; [3]Grad. Inst. of Clin. Med. Sci., China Med. Univ., Taichung, Taiwan

Abstract: Hyperekplexia, which is an inherited neuronal disorder characterized by exaggerated startle responses with unexpected sensory stimuli, is caused by the dysfunction of glycinergic inhibitory transmission. From analysis of newly identified human hyperekplexia mutations in glycine receptor (GlyR) α1 subunit, we found that a missense mutation $\alpha1^{A384P}$ showed

substantially enhanced desensitization but no or mild changes in agonist sensitivities, agonists-induced maximum responses, or voltage-dependence when expressed in HEK cells. In comparison, another human hyperekplexia mutation $\alpha1^{P250T}$, which was previously reported to relate to desensitization, caused strong reduction of maximum currents in addition to altered desensitization. The mutation-caused desensitization was partially reversed by co-expression of the β subunit in $\alpha1^{P250T}$-containing GlyRs, whereas the reduced maximum currents in $\alpha1^{P250T}$ were even aggravated by β co-expression. $\alpha1^{A384P}$ β showed no significant difference on desensitization state compared with $\alpha1^{A384P.}$ Moreover, co-expression of the R392H and A384P mutants, which mimic the expression of compound heterozygote in the patient, resulted in similar channel properties to that of A384P expression alone. These results were further confirmed by overexpression of $\alpha1^{P250T}$ or $\alpha1^{A384P}$ in cultured neurons. Together, our findings revealed that, while the P250T mutant affected both channel conductance and desensitization, enhanced desensitization was the major functional deficit in $\alpha1^{A384P}$ and was highly associated with pathogenesis of human hyperekplexia.

Title: Glycine-activated outward currents in neurons of the hippocampus

Authors: *S. SATO[1], N. EGUCHI[2], M. MORI[2];
[1]Kobe Univ., Kobe-Shi, Japan; [2]Kobe Univ., Kobe, Japan

Abstract: Glycine receptor-channels permeate anions such as chloride, and hyperpolarize adult neurons. Their molecular identities of glycine receptors such as amino acid sequences and subunit compositions are well clarified. Glycine receptors are widely expressed throughout the central nervous system including spinal cord, brain stem, hippocampus and neocortex. In the spinal cord, the endogenous ligand of glycine receptors is glycine that is released as a neurotransmitter together with GABA. In the brain endogenous ligands of glycine receptors have not been identified as neurotransmitters in spite of the broad expression of glycine receptors. ß-alanine or taurine released from glial cells are proposed as endogenous ligands in the mature hippocampus. Althogh much information on glycine receptors and their ligands are provided, the their roles in the brain have not been clarified yet. Here we sought for the roles of glycine receptors in the hippocampus, using organotypic rat hippocampal slice culture, prepared from P6

rats. Pressure application of glycine (0.3 mM in an application pipette; 50 μm away from the soma of the neurons studied) activated an outward current in the neurons but not in the glial cells identified by their failure to generate action potentials at a holding potential of -70 mV. The glycine-activated currents were blocked by the bath-perfusion of a glycine receptor antagonist, strychnine. Peak amplitudes of glycine-activated current density in interneurons were larger than those in pyramidal cells (CA3 pyramidal cell, 17.5 ± 3.24 pA/pF, n=5; interneurons, 36.0 ± 13.2 pA/pF, n=5). We found that the variance of the glycine-activated currents density in interneurons was much more than that in CA3 pyramidal cells, suggesting that this significant variation of the glycine-activated currents in interneurons could be derived from diversity of the type of interneurons.

Title: Potentiation of glycinergic IPSCs in the dorsal horn by Ca^{2+}, NMDA, and cAMP

Authors: *M. KLOC, A. CHIRILA, R. STEVENSON, J. A. KAUER;
MPPB, Brown Univ., Providence, RI

Abstract: Glycine is a fast inhibitory neurotransmitter that plays a vital role in signaling in the brain and spinal cord. However, little is known about how glycinergic synapses are modulated in the CNS. Here we tested the modulation of glycinergic (GlyR) IPSCs on GABAergic neurons in acute slices of dorsal horn (DH) lamina II. Many forms of LTP are dependent on postsynaptic calcium, which can enter a neuron in a variety of ways: release from intracellular stores, or influx through VGCCs or NMDA receptors. We found that repetitive depolarization (DP) of lamina II GABAergic neurons (200ms DP to -10 mV, 1 Hz, 6 minutes) potentiated GlyR IPSCs (IPSC amplitude: 162±19% of pre-DP amplitude, n=12, $p< 0.001$). This effect was blocked when 15 mM intracellular EGTA was included in the recording pipette (IPSC amplitude: 100±14% of pre-DP amplitude, n=5, n.s.). These results suggest that a rise in intracellular calcium is sufficient to potentiate GlyR. NMDA receptor activation has been shown to increase GlyR numbers in the postsynaptic membrane and mIPSC amplitudes in cultured neurons (Levi et al, 2008; Neuron 31:261). We investigated whether NMDA could also induce LTP of GlyRs in

GABAergic dorsal horn neurons. Bath application of NMDA (50 μM) rapidly potentiated GlyR IPSCs on GABAergic neurons (IPSC amplitudes: 125±10% of pre-NMDA values, n=12, $p<0.001$). This potentiation was not reversed by later addition of the competitive NMDA antagonist AP5 (50 μM, n=3). Bath-applied strychnine (1 μM) completely blocked the potentiated GlyR IPSCs (n=2). NMDA potentiation was only observed in slices from animals older than p25, while in those from younger animals, NMDA did not potentiate GlyR IPSCs (IPSC amplitude: 80±10% of pre-NMDA values, n=5, $p<0.001$). Activation of adenylyl cyclase leads to cAMP production and PKA activation, which can modulate synaptic strength in many CNS synapses. Bath application of forskolin, an adenylyl cyclase activator, significantly potentiated GlyR IPSCs on GABAergic DH neurons (IPSC amplitudes: 120±13% of pre-forskolin amplitude, n=7, $p<0.01$). Both presynaptic and postsynaptic potentiation of GlyR IPSCs by cAMP have been reported previously, and we will explore both possibilities. Together our findings indicate that glycinergic IPSCs can be rapidly potentiated in the same cell type by a variety of signaling mechanisms. Our previous work demonstrated that after acute peripheral inflammation, GlyR synapses on these neurons are potentiated; the modulatory pathways described here may therefore have relevance to nociceptive processing.

Title: Extracellular glycine receptors of lateral habenula and alcohol related behaviors

Authors: *W. LI[1,2], W. WU[1,3], W. ZUO[1], J. LI[1], R. FU[1], A. BEKKER[1], J.-H. YE[1]; [1]anesthesiology, Anesthesiol., Newark, NJ; [2]Dept. of Anatomy, Histology and Embryology, Inst. of Basic Med. Sciences,Chinese Acad. of Med. Sci., Beijing, China; [3]Dept. of Anesthesiol., Gen. Hosp. of Chengdu Military Area Command, Sichuan, China

Abstract: There is much interest in brain regions that drive alcohol intake in alcoholics. Interestingly, both the rewarding and aversive effects of alcohol are probably critical for sustained alcohol addiction. The lateral habenular (LHb) plays important roles in processing aversion, and recent work has focused on the critical involvement of the LHb in encoding and responding to aversive stimuli, including pain. Several neurotransmitter systems are implicated in alcohol's actions, with certain receptors and ion channels emerging as putative targets. The glycine receptors (GlyRs) that mediate classical inhibitory neurotransmission in the spinal cord and lower brain stem, have been linked to the pathogenesis and/or treatment of alcohol dependence and pain. Previous rat study from our laboratory has shown functional GlyRs exist in the LHb. However, the role of LHb excitability and in ethanol-related behaviors is unknown. In the current study, we trained male Sprague Dawley rats to drink ethanol in an intermittent access two-bottle free choice paradigm for three months. *Ex vivo* studies in brain slices indicated that bath application of glycine caused a robust inhibition of firing in LHb neurons in both ethanol-naïve rats and rats at 24h withdrawal from chronic ethanol, and the inhibition was blocked by GlyR antagonist strychnine. In addition, strychnine alone produced a large tonic conductance mediated by extrasynaptic GlyRs. In agreement, strychnine induced membrane depolarization, and increased the excitability of LHb neurons. These findings identify extrasynaptic GlyRs as a critical regulator of LHb excitability. Importantly, intra-LHb infusion of glycine substantially mitigated mechanical allodynia and thermal hyperalgesia observed in rats at 24 h withdrawal from ethanol. In parallel, LHb glycine infusion reduced ethanol intake and preference. Furthermore, these effects of glycine were blocked by LHb infusion of strychnine, indicating that they are mediated by strychnine-sensitive GlyRs. Thus, GlyRs in the LHb represent a cellular substrate for aversive experience induced by ethanol withdrawal. Furthermore, its reversal by glycine may provide a novel therapeutic approach to alleviate symptoms of ethanol withdrawal.

Abstract: The transient receptor potential vanilloid 1 (TRPV1) channel is sensitive to noxious heat, acidic pH, and irritant vanilloids and is highly expressed in a specific subset of sensory neurons in dorsal root ganglia (DRG) and trigeminal ganglia contributing to pain sensation. Some TRPV1-positive neurons coexpress transient receptor potential ankyrin 1 (TRPA1) channels responsive to noxious cold and irritant stimuli. In this study, we examined the kinetics of current induced by TRPV1 channel activation in both TRPA1-positive and -negative mouse DRG neurons using whole-cell recording to understand the interactions between TRPV1 and TRPA1 channels. TRPV1 and TRPA1 channels were activated using 1 μM capsaicin (a TRPV1 agonist) and 500 μM allyl isothiocyanate (a TRPA1 agonist), respectively. Perfusion of capsaicin for 15 s caused a large inward current without desensitization at a membrane potential of −70 mV. Compared with TRPA1-negative neurons, capsaicin-induced currents in TRPA1-positive neurons demonstrated a smaller current density and larger time constant of decay. These differences were eliminated using intracellular 10 mM ethylene glycol-bis(2-aminoethylether)-N,N,N',N'-tetraacetic acid (EGTA, a Ca^{2+} chelator) or 3 μM HC030031 (a TRPA1 blocker), while the latter alone had no effect on the basal current. Protracted perfusion of capsaicin for 90 s desensitized inward currents after a transient peak response. The desensitization of inward currents during capsaicin perfusion was notably slower in TRPA1-positive neurons than in TRPA1-negative neurons. Furthermore, the capsaicin-induced current measured during desensitization was attenuated by HC030031 in TRPA1-positive neurons but not in TRPA1-negative neurons. These results suggest that the TRPV1 channel activates the TRPA1 channel via intracellular calcium elevation, thereby suppressing TRPV1 channel activity in DRG neurons and by coexpressing TRPA1 channels.

Title: TRPV1 receptor activation triggers intracellular calcium responses in hippocampal Cajal-Retzius cells

Authors: *G. MACCAFERRI, M. ANSTOETZ, S. K. LEE;
Dept Physiol, Northwestern Univ. Dept. of Physiol., Chicago, IL

Abstract: Although transient receptor potential vanilloid 1 (TRPV1) receptors are known to play important roles in the peripheral nervous system, their pattern of expression and functions in the central nervous system are much less understood. In the hippocampus, TRPV1 expression has been suggested to be limited to specific neuronal populations, including Cajal-Retzius cells (Cavanaugh et al., 2011). In order to study their functional activation, we took advantage of Cre-loxP technology to target a genetically-encoded calcium indicator (GCaMP6s) to hem-derived hippocampal Cajal-Retzius cells. Capsaicin application (at 100 nm, 1 uM or 10uM) triggered intracellular calcium responses both in the soma and in the dendrites of the monitored neurons. Calcium responses to capsaicin (1-10 uM) were prevented by the TRPV1 antagonists capsazepine (10 uM) and ruthenium red (20 uM). Additionally, they did not depend either on synaptic transmission or action potentials or voltage-dependent calcium channel activation. In fact, they persisted in the presence of a cocktail of antagonists of glutamate and $GABA_A$ receptors (D-AP5 50 uM, NBQX 20 uM and picrotoxinin 50 uM), TTX (500 nM) and cadmium (150 uM), respectively. In order to define the cellular location of the functional TRPV1 channels we applied capsaicin (10 uM) on slices bathed in a modified ACFS (0 calcium plus EGTA 150 uM). Under these conditions, we failed to observe responses, which, however, could be restored in the same cells after the reintroduction of external calcium and the wash out of EGTA. I Lastly, we directly recorded capsaicin-induced (10 uM) currents in voltage-clamp conditions (Vh=-60 mV), which could not be observed in the presence of capsazepine (100 uM). Taken together, these results indicate that hippocampal Cajal-Retzius express functional TRPV1 receptors on their plasma membrane.

Abstract: Osthole, an active coumarin isolated from *Cnidium monnieri* (L.) Cusson, has long been used in China as an antipruritic herbal medicine; however, the antipruitic mechanism of osthole is unknown. We studied the molecular mechanism of osthole in histamine-dependent itch by behavioral test, Ca^{2+} imaging, and electrophysiological experiments. First, osthole clearly remitted the scratching behaviors of histamine, HTMT, and VUF8430 induced in mice. Second, in cultured dorsal root ganglion (DRG) neurons, osthole showed an inhibitory and dose-dependent effect to histamine. On the same neurons, osthole also decreased the response to capsaicin and histamine. In further tests, the capsaicin-induced inward currents were inhibited by osthole. These results revealed that osthole inhibited histamine-dependent itch by modulating TRPV1 activity. This study will be helpful in understanding how osthole exerts anti-pruritus effects and suggests that osthole may be a useful treatment medicine for histamine-dependent itch.

Title: SK channels regulate resting and firing properties of MNTB neurons

Authors: Y. ZHANG, *H. HUANG;
Dept. of Cell and Mol. Biol., Tulane Univ., New Orleans, LA

Abstract: The Medial nucleus of trapezoid body (MNTB) of the superior olivary complex plays important roles in sound source localization. Fast transfer of signals from globular bushy cells of the ventral cochlear nucleus to MNTB principal cells are facilitated by the calyx of Held, a giant glutamatergic nerve terminal. In general, it is believed that the MNTB is a relay nucleus that preserves the temporal pattern of firing at a frequency up to 1 kHz. In this study, we investigated the postsynaptic K^+ channels that shape the fidelity and reliability of signal transfer across the calyx-MNTB synapse. Using whole-cell patch-clamp recordings, we observed a potassium current mediated by small-conductance calcium-activated potassium (SK) channels in rat MNTB neurons. SK channels are activated at resting membrane potentials. Blocking SK channels with apamin depolarized the resting membrane potential and reduced resting conductance of MNTB neurons while SK channel opener EBIO showed the opposite effects. In addition, SK channel mediated spontaneous transient outward currents, which are activated by calcium influx through voltage-gated calcium channels and calcium induced calcium release from intracellular Ca^{2+} stores. SK channels shaped the EPSP to presynaptic glutamate release. Blocking of SK channels disrupts the one-to-one spike transmission from presynaptic calyces to postsynaptic MNTB neurons and induced extra action potentials in response to 100 Hz presynaptic firing. These data revealed that SK channels play important roles in controlling the reliability and fidelity of action potential transmission.

Title: Allosteric modulation of SK channels

Authors: B. WHITMORE[1], Y. NAM[1], *M. ZHANG[2];
[2]Dept. of Biomed. and Pharmaceut. Sci., [1]Chapman Univ. Sch. of Pharm., Irvine, CA

Abstract: Small conductance Ca^{2+}-activated potassium (SK) channels play a vital role in regulating excitable cells in both the central nervous and cardiovascular system. In animal models SK channels have been linked to the pathophysiology of neurological disorders such as ataxia and alcohol use disorders. Genome studies have also associated single nucleotide polymorphisms in the SK coding region, with cardiovascular conditions such as arrhythmias and hypertension. The sensitivity of the SK channel to Ca^{2+} binding results from interaction with calmodulin (CaM), a Ca^{2+} binding protein. Previous work has identified positive allosteric modulators (PAMs) of the SK channel and structural studies revealed these modulator's binding pocket as located between the CaM binding domain and CaM. This observation motivated us to introduce mutations in the PAM binding pocket which also result in changes in the Ca^{2+} sensitivity of SK channels.

Title: Development of stable recombinant cell lines expressing human small-conductance (SK) calcium-activated potassium channels

Authors: *D. PAU, P. MADAU, L. HUTCHISON, P. CONWAY, N. BRYSON, D. DALRYMPLE, I. MCPHEE;
SB Drug Discovery, Glasgow, United Kingdom

Abstract: Small-conductance Ca^{2+}-activated K^+ channels (SK channels) are widely expressed throughout the central nervous system, but also in the human atria, lymphocytes, fibroblasts, vascular smooth muscle cells and endothelium. They are part of a subfamily of the calcium-activated potassium channels (K_{Ca}), of which highly conserved subfamilies exist in mammals (1.1, 2.1, 2.2, 2.3, 3.1, 4.1, 4.2 and 5.1). The human SK channels play an important role in neuronal firing activity by regulating the afterhyperpolarising (AHP) currents, affecting synaptic plasticity and long term potentiation (LTP). There is considerable evidence that modulation of these channels could have numerous clinical uses, including neuroprotection against neurological disorders such us schizophrenia, Parkinson's disease, epilepsy, depression and improving processes related to learning and memory. SK channels have also been shown to be involved in cardiac repolarisation of the human atria and could be an important anti-arrhythmic target. Screening for inhibitors and modulators is typically achieved using in-vivo neuronal preparations or using mammalian cells transiently expressing recombinant SK channels. We have developed a range of constitutive HEK-293 cell lines expressing the four recombinant SK channels (SK1, SK2, SK3 and SK4) in order to overcome common limitations experienced when using neurons or transiently expressed channels, such as limited numbers of cells, compatibility for HTS platforms and long-term expression of the channel. We show high-throughput fluorescent assay data and confirmatory electrophysiological data to validate our alternative approaches. The mean (±SEM) current amplitudes of the human SK1, SK2, SK3 and SK4 channels, activated by internal calcium, were found to be approximately 4.1±1.1 nA (n=14), 2.8±0.3 nA (n=24), 4.3±0.8 nA (n=14) and 5.2±0.9 nA (n=22), respectively. In a cross-study, the IC_{50} values for TEA (broad SK blocker), Apamin (selective SK1, SK2 and SK3 blocker) and TRAM-34 (selective SK4 blocker) were found to be in line with literature values. Furthermore, the EC_{50} values for NS-304 (a broad SK activator) were also found to be in line with literature values. In conclusion, we confirmed the presence of functional recombinant SK channels in stably transfected HEK-293 cell lines. High-throughput screening of this SK panel will help identify novel compounds which modulate SK channel behavior and potentially allow for new and more effective treatments for a variety of disorders in humans.

Title: A unique human N-terminal point mutation in the Slack potassium channel causes early onset epilepsy and exhibits gain of function

Authors: *J. KRONENGOLD[1], R. NABBOUT[2], L. K. KACZMAREK[1];
[1]Pharmacol., Yale Univ. Sch. of Med., New Haven, CT; [2]Ctr. de Reference Epilepsies Rares, Paris, France

Abstract: The Slack potassium channel subunit ($K_{Na}1.1$, Slo2.2, KCNT1) is one of two subunits that contribute to Na^+-activated K^+ channels in the nervous system. It is a large conductance channel that is widely expressed in the brain, where its opening regulates firing frequency and neuronal excitability. The transmembrane domain (TMD) topology of Slack closely resembles that of voltage-gated K^+ channels. These channels are activated by elevations of intracellular Na^+, which binds a large 900 amino acid gating ring formed by the cytoplasmic C-terminal domain of the protein. This C-terminal region also interacts with protein kinase C and with the Fragile X Mental Retardation protein, both of which regulate current amplitude. Human mutations in the RCK1 and RCK2 domains of this extended C-terminus and in the TMD produce several early onset epileptic encephalopathies including EIMFS (epilepsy of infancy with migrating focal seizures), ADNFLE (autosomal dominant nocturnal frontal lobe epilepsy) and Ohtahara Syndrome, all of which are associated with intellectual disability. Electrophysiological studies have demonstrated gain of function increases in macroscopic current in these human point mutations with no change in levels of channel expression. At the single channel level, we have found that positive cooperative gating is substantially increased compared to that in wild type channels and can account for the increases in macroscopic current. We have also examined the allosteric mechanism for cooperativity and have found that a Slack C-terminal RCK2 truncation mutant eliminates coupled gating channel interactions. We have now characterized a human mutation in a different domain of the channel. The P39L hSlack EIFMS mutation has been documented in two patients and is the first report of an N-terminal mutation in any of the early onset epileptic encephalopathies. We therefore expressed wild type hSlack and P39L hSlack in *Xenopus* oocytes and found a six-fold increase in macroscopic currents for the P39L mutant compared to the wild type channel. Our studies suggest that the intracellular N-terminal domain of Slack may be coupled functionally to the TMD and the C-terminal gating ring to

influence channel properties and potentially, the ability of Slack to interact with neighboring Slack channels. Ongoing single channel studies are testing this hypothesis.

Title: Slack ($K_{Na}1.1$) potassium channels can regulate their own rate of protein synthesis.

Authors: *T. J. MALONE[1], G. E. KIM[2], M. R. FLEMING[2], L. K. KACZMAREK[3]; [1]Cell. and Mol. Physiol., [2]Pharmacol., [3]Cell. and Mol. Physiology, Pharmacol., Yale Univ., New Haven, CT

Abstract: The Slack sodium-activated potassium channel ($K_{Na}1.1$) is encoded by the *KCNT1* gene and is expressed throughout the brain where it regulates neuronal excitability and patterns of firing. There exist multiple N-terminal splice isoforms of Slack, of which Slack-B is the largest characterized. Numerous putative phosphorylation sites are found in Slack-B, but their physiological relevance and role remain largely untested. Using liquid-chromatography tandem mass spectrometry, we determined that two serine residues (S34 and S44) close to the N-terminus of Slack-B are phosphorylated under basal conditions. To test the biological role of these sites we generated 8 different combinations of S34 and S44 mutations that mimic either phosphorylation or dephosphorylation at each site. We found that protein levels for the "dephosphorylated" mutant channel (AA-Slack) are increased by 15-20 fold in cRNA-injected *Xenopus* oocytes and transiently transfected HEK293 cells compared to wild type Slack. This is correlated with an increase in currents measured in two-electrode voltage clamp experiments using oocytes and immunofluorescence staining of the protein in HEK cells. The increase in current was not associated with alterations in channel kinetics or single channel properties. The increase in Slack protein levels can be attributed predominantly to an increase in protein translation, because protein half-lives of AA- and wild type Slack were similar. Moreover, preventing proteasomal degradation did not elevate the wild-type Slack protein expression levels within the time window when AA Slack channel rapidly accumulates in HEK cells. To measure

the rate of translation directly, we assayed the incorporation of puromycin into nascent Slack channels, and found that that incorporation was greatly increased for the "dephosphorylated" AA-Slack relative to wild type Slack. Taken together, the results indicate that dephosphorylation of these two N-terminal residues is a key step during Slack biogenesis. Our findings also suggest that regulation of the phosphorylation state of S34 and S44 during biogenesis may allow neurons to alter channel abundance rapidly in response to stimulation.

Abstract: Mutations in Slack potassium channels, which underlie sodium-activated potassium currents in mammalian neurons, give rise to several forms of genetic epilepsy. In addition to controlling the accuracy and adaptation rate of neuronal action potentials during high frequency firing, these channels undergo interactions with proteins that regulate activity-dependent protein translation in neurons. In this study Slack$^{-/-}$ mice were evaluated for their susceptibility to seizures and were also screened for behavioral abnormalities. Although Slack$^{-/-}$ mice did not have spontaneous seizures, their thresholds for seizures induced by maximum electroshock were lower than those of wild type controls. Strikingly, however, their survival from maximum electroshock-induced seizures was greatly increased compared to wild-type animals, indicating that they tolerate higher levels of stimulus current. In contrast to maximum electroshock,

thresholds for seizure induction via pentylenetetrazole administration were unaffected by deletion of the Slack gene. On behavioral testing, Slack$^{-/-}$ mice demonstrated decreased exploratory behavior and motor skill ability. These findings suggest that Slack channels play a role in the development of procedural learning and of pathways that link cortical seizures to brainstem areas, such as respiratory nuclei, that are required for animal survival.

Title: Insights from molecular modeling, docking and simulation of the Fragile X Mental Retardation protein and the Na^+-dependent K^+ channel Slack

Authors: *D. P. JENKINS, L. K. KACZMAREK;
Pharmacol., Yale Univ., New Haven, CT

Abstract: Fragile X syndrome results from the loss of the Fragile X mental retardation protein (FMRP) and is the most common form of inherited intellectual disability. Experiments have indicated that the amino terminal domain of FMRP binds to the distal cytoplasmic domain of the sodium-activated potassium channel (Slack, KNa1.1) to modulate gating. A detailed description of this binding site is, however, lacking. The amino terminal of FMRP contains tandem Tudor (Agenet) domains that mediate protein-protein interactions by binding to methylated amino acid residues. In a recent comprehensive screening of protein methylation in T-cells, a residue (Arg1106) in the carboxy terminal of Slack was found to be methylated. Using a recent cryo-EM structure of full-length Slack and the X-ray crystal structure of the N-terminal of FMRP, we modelled FMRP docking to Slack with R1106 unmethylated, mono- and di-methylated. Using the HADDOCK 2.2 webserver our simulations predicted that monomethyl and asymmetric dimethyl Arginine-1106 docked preferentially within the aromatic cage residues (Y16, F32 and W36) the Tudor (Agenet) domain 1 of FMRP. In contrast, FMRP had no predominant docking site with Slack unmethylated at R1106. These findings suggest that the interaction of Slack and FMRP could be regulated by methylation of R1106 and provide a focus for molecular biological

and electrophysiological experiments aimed at characterizing the interaction and regulation of these proteins.

Title: Regulation of electric organ discharge frequency by the Slack and Slick sodium activated potassium channels in the weakly electric fish Eigenmannia virescens

Authors: *Y. BAN, R. MALTBY, M. R. MARKHAM;
Biol., Univ. of Oklahoma, Norman, OK

Abstract: The weakly electric fish *Eigenmannia virescens* generates electric organ discharges (EODs) to navigate and communicate. The EODs are brief monophasic voltage pulses with brief inter-pulse intervals, resulting in a sinusoidal waveform. EODs are produced by the simultaneous action potentials (APs) of ~1000 electric organ cells (electrocytes). Electrocytes in *E. virescens* initiate the AP with voltage-gated Na^+ (Na_v) channels and terminate the AP with Na^+ activated K^+ (K_{Na}) channels, rather than voltage-gated K^+ channels, as is the case in all other electric fish where electrophysiological data are available. We have determined that there are at least three different types of K_{Na} channel subunit expressed in *E. virescens* electrocytes. Two of them, tentatively termed *Slack-1* and *Slack-2*, closely resemble K_{Na} channels encoded by the *Slack* (KCNT1) gene in mammalian systems, and the third channel more closely resembles K_{Na} channels encoded by the *Slick* (KCNT2) gene in mammals. The *E. virescens Slack-1*, *Slack-2* and *Slick* channel subunits consist of 1164, 996, and 1169 amino acids respectively. Unlike mammalian Slack isoforms which are created by alternative RNA splicing and only differ in the N-termini, the amino acid sequences of *E. virescens Slack-1* and *Slack-2* only share 67.9% homology, with residue differences between the two channel subunits dispersed along the entire sequence. Though BLAST searches of protein sequences suggest that both *Slack-1* and *Slack-2* are indeed *Slack* channel subunits, they are more likely encoded by analog genes rather than the products of alternative RNA splicing. *Slack-2* also has a much shorter C-terminal region than

Slack-1 and all other mammalian *Slack* isoforms. The kinetics of the K_{Na} channels determine the frequency of the electrocye AP. Because *E. virescens* has considerable animal-to-animal variability in the frequency of the EOD (200-600 Hz), we predict that the relative mRNA levels of *Slack-1*, *Slack-2*, and *Slick* channels in the electric organ will vary across fish with different EOD frequencies.

Title: Scaffolding of the sodium-activated potassium (k_{na}) channels slack and slick by magi-1

Authors: *K. D. PRYCE[1], D. AGWA[2], D. TOMASELLO[2], A. NIP[3], A. BHATTACHARJEE[4]; [1]Pharmacol., State Univ. of New York At Buffalo, Buffalo, NY; [2]Program in Neurosci., [4]Pharmacol. and Toxicology, [3]State Univ. of New York at Buffalo, Buffalo, NY

Abstract: Understanding the various mechanisms of ion channel trafficking and signaling in pain-sensing neurons could lead to new approaches for the treatment of pain. In this study, we probed the molecular determinants of the sodium-activated potassium (K_{Na}) channel Slack channel trafficking by targeting the evolutionary conserved last 10 amino acids sequence of the distal Slack C-terminus. In this region there is a type 1 **P**ost-synaptic density-95/**D**iscs large/**Z**onulaoccludens-1 (PDZ) binding motif that is conserved across species. Previous studies have shown that protein kinase A (PKA) consensus phosphorylation sites reside in close proximity to the PDZ binding motif and PKA-induced internalization of Slack from the membrane contributes to hyperexcitability in dorsal root ganglion (DRG) neurons. To investigate the role of this conserved region we created a myristolated C-terminal peptide (NPETRDETQL) to compete with endogenous modulators of Slack C-terminus. We then incubated cultured DRG neurons with this peptide or a scramble peptide and performed whole cell recordings. We found that incubating neurons with the C-terminal peptide resulted in DRG neuronal hyperexcitability, whereas, a scrambled peptide did not alter neuronal firing. After demonstrating the response of DRG neurons to our peptide, we analyzed the surface expression of Slack using biotinylation assays showing that peptide incubation led to significant reduction of channel expression at the plasma membrane. We next focused on the PDZ containing protein, Membrane-Associated

Guanylate kinase with Inverted organization-1 (Magi-1), as a putative scaffolding protein that stabilizes Slack channels at the membrane. Previous studies have found that Magi-1 and Slack channels are highly expressed in DRG neurons and the dorsal horn in the spinal cord. Using immunoprecipitation and co-immunolocalization assays we found that Magi-1 localizes with and interacts with Slack channels in heterologous expression systems and in DRG neurons. We also demonstrated using whole-cell voltage-clamp recordings that co-expression of Magi-1 with Slack and Slick resulted in increased outward potassium current density. Furthermore we demonstrated that Magi-1 interacts and localizes with other channels that contain PDZ binding motifs in DRG neurons namely Slick K_{Na} channels and the voltage-gated sodium channel NaV1.8. Our findings suggest that membrane Slack/Slick expression is stabilized by the ability of these channels to bind PDZ containing proteins, specifically Magi1 and that Magi-1 is a primary scaffold protein for coupling ion channels in DRG neurons.

Title: Store-operated calcium channels modulate of A-type potassium currents in excitatory dorsal horn neurons

Authors: *Y. DOU, J. XIA, R. GAO, H. HU;
Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Store-operated calcium channels (SOCs) are calcium-selective cation channels that play an important role in autoimmune and inflammatory diseases. We have demonstrated that inhibition of SOCs attenuates chronic pain. However, the mechanisms underlying this analgesic action remain unexplored. In the present study, we sought to explore the potential roles and mechanisms of SOCs in the modulation of A-type currents. In dorsal horn neurons, application of thapsigargin (TG, a potent Ca^{2+}-ATPase inhibitor), which activates SOCs, significantly reduced A-type currents in cultured dorsal horn neurons and increased neuronal excitability in dorsal horn neurons from slices. Inhibition of SOCs by SOC inhibitors (YM-58483 and $GdCl_3$) completely blocked TG-induced modulation of A-type K+ currents and neuronal excitability. We

previously showed that Kv4.2 containing A-type K+ channels modulate pain plasticity. Here we also demonstrated that SOCs are mainly functional in neurons expressing A-type K+ channels. Using a transgenic mouse strain expressing enhanced green fluorescent protein (GFP) under control of the promoter for glutamic acid decarboxylase 67 (GAD67), we found that TG-induced modulation of A-type currents mainly occurred in non-GAD67-GFP neurons. Additionally, activation of SOCs by TG increased A-type currents and phosphorylation of ERK, and both effects were completely blocked by PD98059 (a MEK/ERK inhibitor). Interestingly, Orai1 deficiency abolished TG-induced modulation of A-type currents, neuronal excitability and ERK activation. These results suggest that Orai1-dependent modulation of A-type currents and neuronal excitability is mediated by the ERK signaling pathway in dorsal horn neurons.

Title: Novel photoaffinity derivative of the inhalational anesthetic sevoflurane reveals sites of voltage-gated ion channel modulation

Authors: *K. WOLL[1], W. PENG[2], Q. LIANG[3], J. JACOBS[4], N. V. BHANU[5], B. GARCIA[5], M. COVARRUBIAS[3], P. LOLL[6], W. DAILEY[2], R. ECKENHOFF[4];

Abstract: Sevoflurane is a commonly used inhalational general anesthetic, particularly within pediatric care. Despite this, the molecular mechanisms of the drug remain elusive, chiefly due to complications with volatility and low apparent affinities of the ligand. We report here the synthesis and validation of azisevoflurane, a photoaffinity ligand derivative for the direct identification of sevoflurane binding targets and sites. We demonstrate that azisevoflurane retains major protein binding interactions as well as the pharmacological properties within in vivo models. Azisevoflurane displayed successful photoactivation and photolabeling of known sevoflurane protein binding sites. We applied azisevoflurane within mammalian Shaker Kv1.2 potassium channels due to the unique modulation of the channel by sevoflurane and potential pharmacological relevance. Analogous to the activity displayed by sevoflurane, azisevoflurane potentiated the channel at pharmacologically relevant concentrations. Upon UV exposure, azisevoflurane photolabeled the leucine (L317) residue within the S4-S5 linker, a tether-region between the voltage sensor and the pore forming helixes (S5/S4), as the likely site of sevoflurane allosteric modulation of Kv1.2 channel activity. This phototaffinity derivative of sevoflurane should provides a means for uncovering haloether anesthetic targets and binding sites therein, as well as contribution of these targets within larger neuronal networks.

Title: Neonatal epileptic encephalopathy-associated KCNQ2 channels set layer 2/3 pyramidal neuron excitability

Authors: *Z. NIDAY, V. HAWKINS, H. SOH, D. K. MULKEY, A. V. TZINGOUNIS; Physiol. and Neurobio., Univ. of Connecticut, Storrs, CT

Abstract: KCNQ2 channels have emerged as potassium channels critical for normal brain function, as both loss- and gain-of-function KCNQ2 variants could lead to various forms of neonatal epilepsy. Despite their fundamental importance, little is known about the role of KCNQ2 channels in setting the excitability of neocortical upper layer pyramidal neurons - cells critical for the development of cortical seizures. Here, we report that conditional ablation of *Kcnq2* from mouse neocortex leads to hyperexcitability of L2/3 pyramidal neurons, manifested as increased action potential firing and frequency. Importantly, these changes in excitability are also accompanied by axon initial segment (AIS) plasticity - the site of action potential generation. We found that the AIS in *Kcnq2* null-neurons shortened, accompanied by a mismatch between known AIS markers (Ankyrin-G, KCNQ3) and sodium channels. Additionally, we show that the KCNQ2 loss-of-function variant $KCNQ2^{I205V}$, introduced to L2/3 pyramidal neurons using *in utero* electroporation, leads to similar neurophysiological phenotypes as *Kcnq2* ablation. Lastly, we demonstrate that partial inhibition of Nav1.6 channels, by using the toxin 4,9-anhydro-tetrodotoxin at concentrations specific to Nav1.6 channels, is sufficient to counteract the hyperexcitability of *Kcnq2*-null neurons, while retaining action potential properties. Therefore, our work also identifies Nav1.6 as a new potential molecular target to reduce excitability in patients with KCNQ2 encephalopathy.

Title: Differential regulation of action potentials by potassium channels

Authors: H. E. SMALL[1], C. A. VILLALBA-GALEA[2], *L. M. BOLAND[1];
[1]Biol, Univ. of Richmond, Richmond, VA; [2]Dept. of Physiol. and Biophysics, Virginia Commonwealth Univ., Richmond, VA

Abstract: Potassium channels, found throughout the animal and plant kingdoms, play important roles in maintaining membrane potentials and regulating action potential firing, shape, and

duration, among other functions. Using the *Xenopus laevis* (frog) oocyte as model system, we induced high expression of sodium and potassium voltage-gated channels and recorded action potentials by a modification of the two-electrode voltage-clamp recording technique. The voltage-dependent sodium conductance was due to expression of the skeletal muscle Na_V channel ($Na_V1.4$) and the delayed rectifier voltage-dependent potassium conductance was due to expression of a *Shaker* (K_v1) potassium channel. Upon this background, we mixed different potassium-selective ion channels, such as inwardly rectifying potassium (K_{IR}) channels, tandem pore domain (K_{2P}) potassium channels and voltage-gated (K_V) channels. We analyzed how these potassium channels affected firing thresholds, reliability of action potential generation, action potential duration, after-hyperpolarization potentials, and refractory periods. Phase plots in which the rate of change of the membrane potential with respect to time (dV/dt) is plotted as a function of membrane potential, revealed the impact of specific potassium channel currents on the rising and falling phases of the action potential. The results of the differential regulation of action potentials by potassium channels expressed in oocytes are compared to action potentials reported in native neurons and muscle cells.

Title: GIRK channels modulate Purkinje cell excitability and synaptic response to climbing fiber stimulation in mice cerebellum

Authors: *M. C. MINIACI[1], P. LIPPIELLO[1], E. HOXHA[2], F. TEMPIA[2];
[1]Dept. of Pharm., Univ. of Naples Federico II, Napoli, Italy; [2]Dept. of Neurosci., Univ. of Turin, Torino, Italy

Abstract: G protein-activated inwardly rectifying K^+ (GIRK) channels are members of a family of inward-rectifier K^+ (Kir) channels widely expressed in the brain. GIRK channels are important regulators of neuronal resting potential and excitability, and they are also involved in G protein-coupled receptor (GPCR) signaling including muscarinic, noradrenergic and serotonergic receptors. In situ hybridization and immunohistochemical studies indicate that GIRK channel subunits are abundantly expressed in the cerebellar cortex, with labeling particularly prominent

in granule cells and Purkinje neurons (Aguado et al. 2008; Fernandez-Alacid et al., 2009). Purkinje cells (PCs) express GIRK1, 2 and 3 channel subunits on dendritic spines, at the periphery of postsynaptic densities, where they co-localize to form heteromeric channels. Although GIRK channels show such a precise subcellular compartmentalization, their contribution in information processing within PCs is still unclear. Using patch-clamp recordings in cerebellar slices of mice, we investigated the effects of ML297 (ML), a selective activator of GIRK channels containing the GIRK1 subunit, on the intrinsic membrane properties and synaptic inputs of PCs. We found that application of ML induced a significant reduction of PC firing associated with an alteration of the inward rectifier cationic current (Ih). Activation of GIRK channels contributed to the modulation of the resting potential of PCs, shifting the membrane voltage by approximately -7 mV. Under current clamp mode, ML decreased the complex spike response of PC to climbing fiber stimulation; but it did not affect the parallel fiber (PF)-PC synapses. However, activation of GIRK channels interfered with the expression of long-term depression of the PF-PC synapse, produced by pairing PF stimulation with PC depolarization. Our results indicate that GIRK channels shape the cerebellar neuronal network activity by regulating PC excitability and synaptic plasticity.

Title: Functional roles of kv1 channels in genetically-identified neocortical layer 5 pyramidal cells.

Authors: *R. C. FOEHRING[1], D. GUAN[2];
[1]Anat. & Neurobio., Univ. Tennessee Hlth. Sci. Ctr., Memphis, TN; [2]Anat. and Neurobio., Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: We studied deep layer 5 pyramidal neurons from two transgenic mice lines to examine the differences in electrical properties between genetically-identified cell types and the roles of Kv1 channels in determining functional differences between them. In motor and somatosensory cortex, Thy1-YFP-H mice (thy1: C57BL/6J background) express YFP in a subset of large pyramidal cells in layer 5B. In somatosensory (S1) cortex of Tg(Glt25d2-

EGFP)BN20Gsat/Mmnc mice (glt: Swiss Webster background), EGFP is mostly expressed in a subset of layer 5B pyramidal cells. In acute brain slices from 3-6 week old mice, YFP- or GFP-positive cells were identified under epifluorescence and studied using whole-cell current-clamp recordings or voltage-clamp recordings on outside-out patches pulled from the cell soma (both at 33^{o}C). We found that resting potentials of thy1 cells were similar in both motor and S1 areas, but they were more negative than those of glt cells. Thy1 cells in S1 had lower input resistance and higher rheobase, compared to thy1 cells in motor cortex or glt cells. Both pyramidal cell types had similar action potential thresholds, amplitudes and half-widths. All cells had a sag response to hyperpolarizing current injection, with similar percent sag. All cells studied generated repetitive spikes throughout a 2-s DC current injection. Most thy1 cells in somatosensory cortex exhibited an accelerating firing pattern with time. In contrast, about 40% of thy1 cells in motor cortex exhibited an accelerating firing pattern, and 40% showed regular spiking with spike-frequency adaptation (SFA). The remaining thy1 cells in motor cortex and the majority of glt cells showed regular spiking with modest SFA. Thy1 cells in motor cortex had significantly smaller F-I slopes than glt cells. Applying Kv1 channel blockers [100 nM Dendrotoxin (Dtx) for Kv1.2, Kv1.5 and Kv1.6; 10-30 nM Margatoxin (MTX) for Kv1.3] caused significant changes in cell excitability in these neurons. In particular, MTX significantly reduced AP threshold, rheobase, latency to the first spike, and significantly increased firing rate in all cell types tested. For voltage-clamp experiments, TTX and $CdCl_2$ were used to block Na^+ and Ca^{2+} currents, and 5-mM EGTA was in the internal to suppress Ca^{2+}-dependent currents. All cell types expressed rapidly activating currents sensitive to MTX and to DTX. We also tested the fractional contributions of Kv1 channel types to the whole outward current and examined the biophysical properties of these currents.

Title: Zn^{2+}-induced Ca^{2+} release via ryanodine receptors triggers calcineurin-dependent redistribution of cortical neuronal Kv2.1 K^+ channels

Authors: *A. J. SCHULIEN[1], J. A. JUSTICE[1], R. DI MAIO[2], Z. P. WILLS[3], N. H. SHAH[3], E. AIZENMAN[1];
[1]Dept. of Neurobiology, Pittsburgh Inst. for Neurodegenerative Dis., [2]Dept. of Neurology, Pittsburgh Inst. for Neurodegenerative Dis., [3]Dept. of Neurobio., Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

Abstract: Sub-lethal injurious stimuli in neurons induce transient increases in free intracellular Zn^{2+} that are associated with regulating adaptive responses to subsequent lethal injury, including alterations in the function and localization of the delayed-rectifier potassium channel, Kv2.1. However, the link between intracellular Zn^{2+} signaling and observed changes in Kv2.1 has remained undefined. Here, utilizing exogenous Zn^{2+} treatment, along with a selective Zn^{2+} ionophore, we show that transient elevations in intracellular Zn^{2+} concentrations are sufficient to induce calcineurin-dependent Kv2.1 channel dispersal in rat cortical neurons *in vitro*, which is accompanied by a relatively small but significant hyperpolarizing shift in the voltage-gated activation kinetics of the channel. Critically, using a molecularly encoded calcium sensor, we found that the calcineurin-dependent changes in Kv2.1 likely occur as a result of Zn^{2+}-induced cytosolic Ca^{2+} release via activation of neuronal ryanodine receptors. Finally, we couple this mechanism with an established model for *in vitro* ischemic preconditioning and show that Kv2.1 channel modulation in this process is also ryanodine receptor-sensitive. Our results strongly suggest that intracellular Zn^{2+}-initiated signaling may represent an early and possibly widespread component of Ca^{2+}-dependent processes in neurons.

Title: Distinct association of the Kv2 family of voltage-gated potassium channels with ER:PM junctions

Authors: *M. KIRMIZ, J. S. TRIMMER;
NPB, UC Davis, Davis, CA

Abstract: Voltage-gated potassium (Kv) channels are important and diverse regulators of neuronal excitability. Among these, Kv2.1 and Kv2.2 are robustly expressed in micron-sized plasma membrane (PM) clusters on the soma, proximal dendrites, and axon initial segment of most brain neurons. These Kv2 paralogs are distinct in their cellular expression patterns in brain neurons, extent of multisite phosphorylation, and responses to stimuli that trigger phosphorylation-dependent changes in the voltage-dependent gating and clustered localization of Kv2.1, but not Kv2.2. The PM clusters of Kv2.1 and Kv2.2 overlay endoplasmic reticulum (ER):PM junctions. Kv2.1 clustering induces and/or stabilizes formation of ER:PM junctions in HEK293 cells and cultured neurons that colocalize with calcium signaling machinery including the STIM1:Orai complex and the L-type calcium channel Cav1.2 (J Cell Sci 128:2096). Here, we used total internal reflection fluorescence (TIRF) microscopy of live cells to further investigate the relationship of Kv2 channels with ER:PM junctions. We find that Kv2.2 also mediates enhanced formation of ER:PM junctions, and that similar to Kv2.1, a single point mutation in the C-terminus of Kv2.2 is sufficient to disrupt Kv2.2 clustering and enhancement of ER:PM junctions. We find that both Kv2.1 and Kv2.2 cocluster with multiple components of ER:PM junctions including Cav1.2, and all members of the STIM and extended synaptotagmin families of junctional proteins. While the association of Kv2.1 with these known components of ER:PM junctions, and the Kv2.1-mediated induction and/or stabilization of ER:PM junctions are disrupted by stimuli that lead to dephosphorylation of Kv2.1 and dispersion of Kv2.1 clustering, Kv2.2 clustering and the subsequent effects on ER:PM junctions are refractory to these stimuli. Finally, we find that near membrane calcium signals are distinct at sites of Kv2.1- and Kv2.2-associated ER:PM junctions. Our findings suggest that these abundant Kv channels can influence neuronal calcium signaling through their canonical ion conducting function, and through physical (i.e., nonconducting) effects on the structure and function of ER:PM junctions, important sites of intracellular calcium release and uptake. Moreover, the role of these individual Kv2 paralogs at ER:PM junctions is distinct in that the role of Kv2.1, but not Kv2.2, is conditional and phosphorylation-dependent. This suggests that the distinct cellular expression patterns of Kv2.1 and Kv2.2 in brain neurons could have a cell-type specific impact on the dynamics of ER:PM junction structure and calcium signaling in these cells.

Title: Low pH_o boosts burst firing and enhances catecholamine release by blocking TASK1-3 and BK channels while preserving Cav1 channels in mouse chromaffin cells

Authors: L. GUARINA[1], D. H. F. VANDAEL[2], V. CARABELLI[1], *E. CARBONE[1];
[1]Univ. of Turin, Turin, Italy; [2]Inst. of Sci. and Technol. Austria, Klosterneuburg, Austria

Abstract: We have recently found that slow inactivation of Nav1.3/Nav1.7 channels during sustained depolarizations causes a sudden switch from "tonic" to "burst" firing mostly sustained by Cav1 channels in mouse chromaffin cells (MCCs) (Vandael et al, 2015). This indicates that MCCs are capable of undergoing "neuron-like" firing modes that allow drastic enhancements of catecholamine release by simply switching their spontaneous firing mode. With the idea of finding physiological stimuli that induce cell depolarization, burst firing and increased catecholamine release in MCCs we tested the effects of lowering the extracellular pH (pH_o) from 7.4 to 6.8, which are reported to induce sustained depolarization and massive release of catecholamines during acidosis. Here we show that lowering pH_o from 7.4 to 6.6 causes resting depolarizations (from -48 to -41 mV), increased firing frequency and clear shifts of the firing from tonic to burst. Burst firing increased proportionally with lowering the pH_o. At pH_o 6.6, spontaneous bursts lasted ~300 ms, sustained 3-5 action potentials and were separated by 350 ms. Burst firing caused also massive increase of catecholamine release (> 300% cumulative charges) as determined by the simultaneous recordings of action potentials and amperometric spikes. Given this, we tested whether burst firing at low pH_o was due to the block of TASK1-3 K^+ channels that are responsible for the cell depolarization at low pH_o (Inoue et al., 2008). We found that the TASK1 selective blocker A1899 (IC_{50} = 35 nM) at 300 nM produced nearly the same resting depolarization of pH_o 7.0 (-43 mV) but failed to mimic the sustained burst firing of lower pH_o. We next checked whether also the block (or gating changes) of the ionic conductances responsible for MCCs firing (Nav, Cav, Kv, SK and BK) were involved in the low pH_o effects. We found that Nav, Cav, Kv and SK channels were little or not affected by low pH_o, while BK currents were drastically reduced (60% at pH 7.0). Block of BK channels was evident on both the V-dependence of BK conductance and Ca^{2+}-dependence of BK channel opening. Following this, we could nicely mimic cell depolarization and burst firing by applying mixtures of TASK1-3 and BK channel blockers (300 nM A1899 + 300 nM paxilline). Burst firing either induced by A1899 and paxilline mixtures or low pH_o were reverted to tonic firing and then blocked by adding 3 μM nifedipine. This suggests that regardless of the origin of cell depolarization and burst firing (block or slow inactivation of Nav1 channels, block of TASK1-3 and BK channels) the inward L-type Cav1 current is a critical component for sustaining burst firing in MCCs.

Title: The potassium channel Kv1.3 as a target for inhibiting detrimental M1 microglia functions in ischemic stroke

Authors: *H. WULFF[1], H. M. NGUYEN[1], I. MAEZAWA[2], L.-W. JIN[2], Y.-J. CHEN[1]; [1]Pharmacol., Univ. of California Davis, Davis, CA; [2]Pathology and Lab. Med., Univ. of California, Davis, Sacramento, CA

Abstract: Kv1.3 was first discovered in human T cells in 1984 and has since then been pursued as a potential target for immunosuppression. It was later shown to be overexpressed in effector memory T cells, suggesting that Kv1.3 blockers would be particularly useful for the treatment of T cell mediated autoimmune diseases such as multiple sclerosis, psoriasis and rheumatoid arthritis. In fact, the Kv1.3 blocking peptide ShK-186 has recently been found to be effective in Phase-1b studies for plaque psoriasis. In order to test the hypothesis that Kv1.3 blockers might also be useful for reducing microglia activation in ischemic stroke and other neurological diseases accompanied by neuroinflammation we generated both in vitro and in vivo proof-of-concept data: 1) Starting with cultured neonatal mouse microglia, we observed an increase in Kv1.3 expression following stimulation with LPS or LPS plus IFN-gamma using qPCR, whole-cell patch-clamp and immunohistochemistry. IL-4 stimulation in contrast increased expression of the inward-rectifier Kir2.1. 2) We found that Kv1.3 blockers reduce the production of IL-1beta and TNF-alpha and the expression of iNOS and COX2. 2) In organotypic hippocampal slices exposed to hypoxia/aglycemia Kv1.3 blockers significantly reduced microglia activation and increased neuronal survival as effectively as minocycline. 3) Acutely isolated microglia from the infarcted hemisphere of mice subjected to middle cerebral artery occlusion (MCAO) exhibited higher Kv1.3 current densities than microglia isolated from the contralateral hemisphere or microglia isolated from controls. 4) Using immunohistochemistry we observed strong Kv1.3 expression on microglia/macrophages in human stroke biopsies validating Kv1.3 as a potential therapeutic target. 5) In both mouse and rat models of ischemic stroke the small molecule Kv1.3 blocker PAP-1 significantly reduced infarct area and improved neurological deficit on day-7 when administered 12 hours after reperfusion at doses of 10 and 40 mg/kg. In the mouse model,

PAP-1 selectively reduced brain levels of the inflammatory cytokines IL-1beta and IFN-gamma without affecting IL-10 and BDNF. Based on these findings we propose Kv1.3 inhibitors as potential therapeutic agents for preferentially inhibiting pro-inflammatory M1 microglia functions in ischemic stroke and other neurological diseases such as Alzheimer's and Parkinson's disease.

Title: Kv3.3 channels regulate the activation of tank binding kinase 1, tbk1

Authors: ***Y. ZHANG**, L. VARELA, T. L. HORVATH, L. K. KACZMAREK;
Yale Univ. Sch. Med., New Haven, CT

Abstract: Spinocerebellar ataxia type 13 (SCA13) is a human autosomal dominant disease that results in degeneration of the cerebellum. It is caused by mutations in the *KCNC3* gene, which encodes the Kv3.3 voltage-dependent potassium channel. One disease-causing mutation, G592R Kv3.3, is located in the cytoplasmic C terminus of Kv3.3 within a proline-rich domain conserved in proteins that activate nucleation through the Arp2/3 complex. In contrast to wild type Kv3.3 channels, G592R mutant channels fail to trigger the formation of a Arp2/3- dependent actin cytoskeleton under the plasma membrane, but significantly increase the rate of cell death in transfected CHO cells. To determine which transduction pathways are selectively activated by G592R Kv3.3 channels we carried out an *in situ* kinase profiling screen (ActivX) to compare levels of activity of protein kinases in the cerebella of G592R-knock-in mice with those of wild type animals. The activity of Tank-binding kinase 1, TBK1 was found to be significantly elevated in the cerebellum but not the cerebral cortex of G592R Kv3.3 mice. This result was confirmed by western blotting for pTBK1, the phosphorylated active form of TBK1, which showed that TBK1 activity was increased approximately four-fold in cerebella of mutant animals. We next transfected wild type and G592R Kv3.3 into CHO cells. Under resting

conditions, there was no significant difference in pTBK1 levels in the two types of cells. Depolarization of the cells with a high K^+ external solution produced an increase in pTBK1 levels. The magnitude of this increase was, however, much greater in cells expressing the G592R mutant channel. We also tested the effects of TBK1 activity on the gating of Kv3.3 channels. Pharmacological inhibition of TBK1 inhibitor dose-dependently greatly increased the rate of inactivation of wild type Kv3.3 currents, but G592R Kv3.3 currents were less sensitive to actions of the inhibitor. Our results indicate that activation of TBK1 is activity-dependent increasing when Kv3.3 channels are depolarized, and further suggest that TBK1 activity may regulate neuronal excitability.

Title: Therapeutic dose of Li^+ dually modulates the function of G protein-activated inwardly rectifying K^+ channels in CA1 pyramidal neurons.

Authors: *M. RUBINSTEIN, N. DASCAL;
Sackler Sch. of Med., Tel Aviv Univ., Tel Aviv, Israel

Abstract: Lithium (Li^+) is widely used for treating bipolar disorder (BPD). However, the molecular basis for BPD, as well as the mechanisms of Li^+ actions are poorly understood. Cellular and biochemical studies identified multiple cellular targets for Li^+, including G proteins, and genetic studies indicated association with G-protein-coupled receptors (GPCRs) and ion channels. G protein-activated inwardly rectifying K^+ (GIRK) channels regulate neuronal excitability by contributing to the resting K^+ conductance, and mediating the inhibitory effects of neurotransmitters. GIRKs are opened by direct binding of Gβγ subunit released from $G\alpha_{i/o}$ subunits following GPCRs activation. *KCNJ3*, the gene encoding the ubiquitous GIRK1 subunit, has been genetically linked to schizophrenia and BPD in *Asian populations. W*e recently discovered a dual regulation of GIRK channels by therapeutic doses of Li^+. In cultured hippocampal neurons, therapeutic doses of Li^+ (1 mM) increased GIRK basal current but attenuated GPCRs -evoked GIRK currents. Molecular studies indicated that these effects are mediated by the action of Li^+ on G proteins by 1) promoting the GPCR-independent dissociation

of $G\alpha_i^{GDP}$ from $G\beta\gamma$ (this increases the basal current), and 2) inhibiting the GPCR-activation of G proteins (this attenuates GPCRs -evoked GIRK currents). These results linked between ion channels, G proteins and anti- BPD drugs. Here, we continued this work in hippocampal slices and tested the effect of therapeutic doses of Li^+ on neuronal excitability of CA1 pyramidal neurons. Incubation in 1 mM Li^+ had no effect action potential (AP) threshold or rheobase, however it hyperpolarized the resting membrane potential, and prolonged the latency to reach AP threshold. Both of these effects were abolished in the presence of tertiapin (TPNq), a specific GIRK channels blockers, indicating that Li^+ can enhance basal GIRK currents. Moreover, Li^+ shortened the duration of APs, also in the presence TPNq, suggesting modulation of additional ion channels. Additionally, neuronal responses to $GABA_BR$ activation were smaller after Li^+ incubation, with reduced hyperpolarization of membrane potential, attenuated reduction of input resistance, and smaller decrease of neuronal firing. Together, therapeutic doses of Li^+ modify neuronal function of CA1 pyramidal neurons via dual modulation of GIRK channels providing an important link between Li^+ action, neuronal excitability, cellular and genetic targets of BPD.

Title: Functional role of kir4.1 channel-expressing ng2 cells in a mouse model of stroke

Authors: *G. MA[1], F. SONG[1], Y. PENG[2], N. SHENG[2], Y. LI[2], X. TONG[1];

Abstract: The inwardly rectifying K^+ channel subtype Kir4.1 is expressed in the central nervous system (CNS) and plays prominent roles in the maintenance of resting membrane potentials, extracellular K^+ uptake, cell volume regulation and facilitation of glutamate uptake. All these

functions have been mainly observed in astrocytes and Müller glia in the brain. More recently, another type of glial cell, known as NG2 cells, was found to express high levels of Kir4.1 (Kcnj10) channels as evidenced by RNA-Seq transcriptome analysis. However, the functional role of NG2 cells expressing Kir4.1 channels and their pathological relevance are largely unexplored. NG2 cells, also called OPCs, give rise to oligodendrocytes to allow myelination of axons during neuronal development and remyelination following injury and in disease. Interestingly, these cells also have direct synaptic contacts with both glutamatergic and GABAergic neurons in adult mammals, suggesting they have as yet undefined physiological functions by their membrane-expressing ion channels and receptors. In the present study, we combined genetic mouse tools, with electrophysiological methods in an ischemic mouse disease model (tMCAO) to explore the functional role of NG2 cells expressing Kir4.1 channels and their pathological relevance in stroke. We found that in the tMCAO stroke model, there is a remarkable loss of NG2 cells in the infarct and peri-infarct areas. In addition, electrophysiological recordings from the remaining NG2 cells show a significant reduction of Kir4.1 mediated currents in tMCAO mice, indicating the loss of Kir4.1 proteins and / or dysfunction of this channel. This work demonstrates that Kir4.1 impairment/dysfunction may lead to glia and neuronal cell death in ischemia and identifies a new potential therapeutic target based on NG2 cells expressing Kir4.1 channels.

Title: Unique cellular distribution of voltage gated potassium channel expression in the CA2 region of the mouse hippocampus

Authors: *S. PALACIO[1], J. D. LEWIS[3], D. H. BRANN[4], K. D. MURRAY[2], J. S. TRIMMER[1]; [1]Neurobiology, Physiology, and Behavior, [2]Ctr. for Neurosci., Univ. of California Davis, Davis, CA; [3]Dept. of Biol., Brigham Young Univ. Idaho, Rexburg, ID; [4]Dept of Neurosci., Columbia Univ., New York, NY

Abstract: The CA2 region of the hippocampus has a distinct morphology, connectivity and function relative to the flanking CA1 and CA3 regions. Recent studies have shed light on the unique circuitry associated with CA2 pyramidal neurons (PNs), and its involvement in the formation of specific types of memory. Nonetheless, the properties of PNs in CA2 are relatively understudied compared to the CA1 and CA3 PNs that are components of the classic trisynaptic circuit. In particular, little is known of the expression levels of voltage-gated ion channels, which are the determinants of intrinsic excitability and neurotransmission. In the present study, we used fluorescent multiplex immunolabeling experiments to determine the relative expression of numerous ion channel subunits in the CA2 region of mouse hippocampus. To distinguish CA2 PNs we used immunolabeling against the CA2 marker RGS14, and genetically encoded AMIGO2-Cre mice expressing GFP in CA2 PNs. Relative expression levels (measured as a function of immunolabeling intensity) across CA1, CA2 and CA3 were measured using linescan analysis. Our results show that in stratum pyramidale (s.p.), the somatodendritic delayed rectifier voltage-gated potassium (Kv) channel subunits Kv2.1, Kv2.2 and their auxiliary subunit AMIGO-1 have the highest expression levels in CA1, and these levels substantially decrease in CA2. However, at the transition from CA2 to CA3 s.p. there is a gradual increase in the expression of Kv2.2 and AMIGO-1, without a corresponding increase in the levels of Kv2.1, which remain low. These distribution patterns are similar between male and female mice. In stratum radiatum (s.r.), the highest expression levels of the dendritic A-type Kv channel subunit Kv4.2 are in CA1, with lower levels in CA2. In contrast, Kv4.3 was highest in s.r. of CA2 and CA3, with lower levels in CA1, where Kv4.3 is mainly expressed in interneurons and not PNs. Immunolabeling for the KChIP auxiliary subunits of these Kv4 channels also differs in CA2 versus the CA1 or CA3 regions. Immunolabeling for PSD-93 and mGluR1/5 also changed noticeably at the CA2 boundary. However, immunolabeling for Nav1.2 voltage-gated sodium channels showed no discernible changes between CA1, CA2 and CA3, indicating that not all ion channels are differentially distributed between the CA regions of the hippocampus. Our results indicate that the boundaries of the CA2 region demark pivotal areas for changes in the expression of ion channels in the hippocampus, which could confer to CA2 PNs distinct patterns of intrinsic excitability and output relative to synaptic input.

Title: Generation of a transgenic mouse expressing BK channels tagged with a fluorogen-activating peptide

Authors: *C. PRATT[1], D. KULJIS[1], G. HOMANICS[2], S. DUDEM[3], M. A. HOLLYWOOD[3], A. L. BARTH[1], M. P. BRUCHEZ[1];

Abstract: BK channels are critical regulators of neuronal activity, involved in neuronal homeostasis, neurotransmitter release, cerebellar function, circadian rhythms, and seizure disorders. Modulation of BK channel gating is well-characterized, regulated by accessory subunit interactions, intracellular signaling pathways, and membrane potential. In contrast, the role of intracellular trafficking mechanisms in controlling BK channel function, especially in live cells, has been poorly studied. Fluorogen activating peptides (FAPs) are well-suited for trafficking and physiological studies due to the binding of malachite green (MG) based dyes with sub-nanomolar affinity to the FAP, resulting in bright, photostable, far-red fluorescence. The generation of cell excluded MG dyes enables the selective tagging of surface protein and tracking through endocytic pathways. N-terminal FAP-BKα constructs expressed in *Xenopus* oocytes show a voltage and calcium response similar to the untagged channel. In order to investigate the properties of BK channels expressed at endogenous levels, with the appropriate stoichiometry for assembly with beta and gamma subunits, we generated transgenic mice using CRISPR to insert the FAP, along with an HA tag, into the N-terminus of the BK channel in its native locus.
Southern blot analysis was used to confirm insertion into the *Kcnma1* locus. Western blots of membrane fractions showed the presence of FAP-tagged BK in brain and bladder membrane fractions. Immunofluorescence against either BKα or the HA tag showed tagged BK expression in appropriate brain regions, including cerebellum, substantia nigra, hippocampus, and cortex. Homozygous FAP-BK transgenic mice showed normal cerebellar dependent behaviors, including gait analysis and rotorod performance. Cerebellar Purkinje cells from mutant mice showed normal spontaneous firing rates that were suppressed by the BK channel antagonist paxilline, similar to controls. Live- and fixed cell imaging revealed FAP-BK channels on the plasma membrane of Purkinje cells; FAP signal showed showed a clustering phenotype similar to previous reports using freeze-fracture and electron microscopy. FAP-BK transgenic mice can be a useful tool for analysis of BK channel trafficking under normal and pathological conditions.

Abstract: The dysfunction of the small-conductance calcium-activated K^+ channel SK3 has been described as one of the factors responsible for the progress of psychoneurological diseases but the molecular basis of this is largely unknown. This report is revealing a notable bilateral hippocampal reduction (more than 50%) as indicated by immunohistochemistry and computational tomography induced by the long-term increased SK3 small-conductance calcium-activated potassium channel (SK3-T/T) expression in mice. Histological analysis showed that SK3-T/T mice have cellular disarrangements and neuron discontinuities in the hippocampal

formation CA1 and CA3 neuronal layer. SK3 overexpression induced cognitive loss as determined by object recognition test. Electrophysiological examination of hippocampal slices revealed that SK3 channel overexpression induced deficiency of long-term potentiation in hippocampal microcircuits. In association with these results there were changes in the mRNA levels of some genes involved in Alzheimer's disease as well as linked to schizophrenia. Taken together, these features suggest that increasing the function of SK3 ion-channel may therefore be a unique opportunity to investigate the neural basis of central nervous system dysfunctions such as in schizophrenia or Alzheimer's disease. Since the progress concerning SK3 channel in brain disorders is limited by the lack of specific SK3 antagonists and agonists the results observed in this study are of marked interest representing a new approach for the development of neuroprotective strategies in neuropsychiatric/neurodegenerative diseases.

Title: Comparisons of GABAergic synapses between a reduced synaptic preparation and a slice preparation of the basal forebrain in vGAT ChR2-eYFP BAC mice using minimal optogenetic stimulation

Authors: *K. S. MONTGOMERY[1], D. W. DUBOIS[2], D. MURCHISON[1], A. S. FINCHER[1], E. A. BANCROFT[1], W. H. GRIFFITH[1];

Abstract: Our lab is actively investigating the rodent basal forebrain (BF), an area of the brain known to be compromised in age-related dementia and important in age-sensitive processes such as attention and some forms of memory. We have identified what we believe are two critical physiological changes that are associated with cognitive impairment in aged rats, namely a deficit in inhibitory synaptic transmission onto cholinergic BF neurons and an enhanced intracellular calcium buffering. We have shown that the frequency, but not amplitude, of spontaneous GABAergic inhibitory postsynaptic currents (IPSCs) are reduced in BF cholinergic cells of aged cognitively impaired rats (Griffith et al., J. Neurophysiol. 111:27-286, 2014). The present study extends these earlier results by considering potential presynaptic mechanisms that may be responsible for these age- and cognition-associated decreases in IPSC frequency. As a first step, we are measuring GABAergic synaptic properties in BF neurons using vGAT ChR2-eYFP BAC transgenic mice (Jackson labs) and minimal optogenetic (470 nm) stimulation. Optogenetic stimulation has the great advantage of specifically exciting GABAergic synaptic terminals where electrical stimulation is impractical or impossible. We utilized conventional whole-cell patch clamp in chloride$^-$loaded cells and two different BF synaptic preparations: *ex vivo* brain slices and an *ex vivo* reduced synaptic preparation that consists of dissociated neurons with synaptic terminals attached. Brief light stimulation (2-5 ms) evoked single IPSCs that could be used for estimates of quantal properties, such as quantal content (*m*), using the failure method.

When the probability of release was reduced using a low calcium (0.5 mM) solution, *m* was estimated from the relationship (*m*=ln(stimuli/failures). No assumptions were made about probability of release (p) or synaptic number. In the reduced synaptic preparation *m*= 0.64±0.2 (±SE, n=3) while in the slices, *m*=1.30±0.3 (±SE, n=3). The mean evoked IPSC was smaller in the reduced synaptic preparation (23.1± 31.7 pA (±SD, n=144 events) compared to 59.7±38.8 pA (±SD, n=107 events) in the slice. These data suggest that the reduced synaptic preparation may be more a reliable tool to estimate quantal properties. Experiments are in progress to extend these results to include additional methods for quantal analysis and to determine the reliability of different methods. Eventually, we intend to apply these methods to examine changes in synaptic function in behaviorally characterized mice during aging.

Title: Optogenetic channelrhodopsin (chr2) function is maintained through middle age (10-14 mo) in neurons from chr2-eyfp (vglut2 and vgat) bac mice

Authors: *D. W. DUBOIS, K. S. MONTGOMERY, A. S. FINCHER, E. A. BANCROFT, V. E. PROVASEK, W. H. GRIFFITH;
Dept. of Neurosci. and Exptl. Therapeut., Texas A&M Univ. Hlth. Sci. Ctr., Bryan, TX

Abstract: Understanding the relationship between altered synaptic physiology and age-related cognitive impairment in the basal forebrain (BF) is critical to defining new therapeutic targets to treat cognitive decline. Our long term goal is to reverse this decline by maintaining youthful synapses across aging. Currently, we are profiling the optogenetic properties and network connectivity of glutamatergic (expressing vesicular glutamate transporter 2, vGlut2) and GABAergic (expressing vesicular GABA transporter, vGAT) synaptic transmission in the BF using light-evoked synaptic currents in immunohistochemically identified neurons from vGlut2- and vGAT-ChR2 (H134R)-eYFP BAC optogenetic mice. We used patch-clamp electrophysiology and 470 nm light stimulation in brain slices to demonstrate functional expression of ChR2 in glutamatergic thalamic neurons from young (3-6 mo) vGlut2 mice and in

GABAergic BF neurons from young vGAT mice by generating input/output curves for ChR2 inward currents with synaptic currents blocked. Peak ChR2 current density for vGlut2 neurons was 4.6 ± 1.1 pA/pF (n = 6), and for vGAT neurons it was 4.6 ± 1.4 pA/pF (n = 9). In vGAT mouse BF, inhibitory postsynaptic currents (IPSCs) were evoked using brief light pulses (2-5 ms) in the majority of GABAergic neurons (8/10) and in 12 of 17 non-GABAergic neurons. Paired-pulse (PP) stimulation in BF neurons from vGAT mice resulted in PP depression (PPR_{200} = 0.77 ± 0.06, n = 23). Interestingly, no excitatory postsynaptic currents (EPSCs) could be evoked in BF neurons from the medial septum/diagonal band (0/46) from vGlut2 mice. As our optogenetic mouse colonies have now produced middle aged (10-14 mo) individuals, we have extended our functional studies to these animals. Glutamatergic thalamic neurons and GABAergic BF neurons from middle aged optogenetic mice show light-evoked ChR2 currents similar to young (peak current density = 4.7 ± 0.6 pA/pF, n = 7 for vGlut2; 3.8 ± 1.1 pA/pF for vGAT). Light-evoked IPSCs were observed also in middle-aged BF neurons (11 of 11) from vGAT mice. Additionally, middle aged BF neurons displayed similar PP ratios to young mice (PPR_{200} = 0.78 ± 0.01, n = 3). Results of this study demonstrate that optogenetic and synaptic profiles are maintained through middle age in these mice. These results support the idea that these BAC optogenetic mice provide a useful model for examining the effects of synaptic aging. Future studies will focus on examining ChR2 expression, synaptic function, and behavioral characterization into late aging.

Title: Functional characterization of VIP-expressing interneurons in the hippocampal dentate gyrus

Authors: *Y.-T. WEI[1], C.-C. LIEN[1,2,3];
[1]Inst. Of Neurosci., Natl. Yang-Ming Univ., Taipei, Taiwan; [2]Inst. Of Brain Science, Natl. Yang-Ming Univ., Taipei, Taiwan; [3]Inst. Of Brain Res. Center, Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract: The hippocampus is a key brain structure for learning and memory. The dentate gyrus (DG) serves as the primary gate of the hippocampus and controls information flow from the cortex. To maintain normal functions, granule cells (GCs), the principal neurons in the DG, receive fine-tuned inhibition from local-circuit GABAergic interneurons (INs). There are various classes of GABAergic inhibitory INs with different physiological, anatomical and molecular features. Among them, vasoactive intestinal peptide-expressing (VIP^+) INs mainly target somatostatin-expressing INs in both the hippocampal CA1 area and cortex. As a result, VIP^+ INs are thought as IN-specific cells. However, the functional and anatomical properties of VIP^+ INs in the DG remain largely unknown. Here, we combined electrophysiology and single-cell biocytin staining to investigate the intrinsic properties and anatomical structures of DG VIP^+ INs using *VIP-ires-cre*::*Ai14* mice. Our preliminary results revealed that VIP^+ INs in the DG showed diverse electrophysiological properties, but relatively specific axonal projection patterns. VIP^+ INs show various input resistances, ranging from 200 MΩ to 2 GΩ and different firing patterns, including fast-spiking, accommodating, and stuttering. In addition, we observed approximately 80% of VIP^+ INs with axonal distribution in the hilus. By combining optogenetics and electrophysiology, we will further identify their potential target neurons in the DG.

Title: Excitatory GABAB receptors

Authors: *J. ZHANG[1,2], L. TAN[1], Y. REN[1], J. LIANG[1], R. LIN[1], Q. FENG[1], J. ZHOU[1], B. BETTLER[3], F. WANG[1], M. LUO[1,2];
[1]Natl. Inst. of Biol. Sciences, Beijing, Beijing, China; [2]Sch. of Life Sciences, Tsinghua Univ., Beijing, China; [3]Dept. of Biomedicine, Inst. of Physiol., Basel, Switzerland

Abstract: GABA is the major inhibitory neurotransmitter of mammalian central nervous system. It inhibits neuron activity through two classes of receptors, $GABA_A$ and $GABA_B$ receptors. $GABA_B$ receptors are widely distributed throughout the whole nervous system, and commonly considered to mediate only inhibitory response in both pre-synaptic site and post-synaptic site. In this study, we investigated the physiological and behavioral function of pre-synaptic $GABA_B$ receptors in the neural pathway from the medial habenula to the interpeduncular nucleus. We found that both GABA and $GABA_B$ selective agonist baclofen drastically potentiate the co-release of glutamate, acetylcholine and gate the release of neurokinin B. These $GABA_B$ receptors mediate excitation by amplifying presynaptic calcium entry through R-type caliucm channels. Inactivating these $GABA_B$ receptors enhances fear memory expression, whereas activating these receptors reduces conditioned fear of animals. In conclusion, $GABA_B$ receptors can also mediate excitatory response, which challenges and expands the traditional concept of neurotransmitter based neural circuit. These excitatory $GABA_B$ receptors regulate the expression and extinction of fear memory, providing a potential target for treating phobias and post-traumatic stress disorder.

Title: Characterization of transmission at synapse of inhibitory interneuron onto noradrenergic neuron in locus coeruleus

Authors: *C.-C. KUO[1], M.-Y. MIN[1], H.-W. YANG[2];
[1]Lifescience, Natl. Taiwan Univ., Taipei, Taiwan; [2]Dept. Biomed. Sci., Chung-Shan Med. Univ., Taichung, Taiwan

Abstract: locus coeruleus (LC) consists of noradrenergic (NAergic) neurons that provide major epinephrine supply to the brain and spinal cord. Recent studies reported that local inhibitory interneurons play important role in integrating synaptic inputs onto NAergic LC neurons. Nevertheless, the physiological properties of LC interneurons and of transmission at synapse of these interneurons onto NAergic neurons synapses remain to be determined. Here, we addressed these issues by using optogenetic method. We injected a cre-dependent adenosine-associated virus carrying eYFP and channelrhodopsin2 sequences into LC in transgenic mouse in which the promoter of vesicular-GABA-transporter controls expression of *cre* recombinase. The animals were killed 2-3 weeks after AAV injection for brainstem slice preparation and whole-cell patch recording was made from NAergic LC neurons. Delivery a single blue-light pulse (470 nm) evoked inhibitory postsynaptic currents (IPSCs) that were mediated by both $GABA_A$ and glycine receptors, with roughly an equal contribution of the both receptor types to the total IPSCs. Similar results were obtained with the presence of 1 μM TTX and 50 mM 4-AP in the bath medium, suggesting the activity was monosynaptic. In current-clamp recording, application of a train of blue-light pulse at variant frequency could effectively decrease the spiking activity of NAergic LC neurons with the optimal frequency being at 10Hz. *Post-hoc* histochemical investigation revealed that the optimal AAV injection site for producing most effectively inhibitory effect on NAergic neurons was in area ventrolateral to LC proper. Together, the above results show interneuron pool located ventrolateral to LC proper were GAGA/glycinergic and played important role in integrating synaptic input onto LC.

Title: Targeting vesicular gaba transporter (vgat)-expressing cells with a polyclonal antibody to the lumenal domain of vgat: results with a saporin conjugate

Authors: C. A. FRIEDMAN, B. J. RUSSELL, M. D. KOHLS, L. R. ANCHETA, P. A. SHRAMM, *D. A. LAPPI;
Advanced Targeting Systems, San Diego, CA

Abstract: The vesicular GABA transporter (vGAT) mediates the accumulation of GABA into synaptic vesicles and the release from these vesicles. vGAT is expressed in nerve endings of GABAergic neurons throughout the CNS. The GABAergic system is crucial for the development

and functional maturation of the nervous system, as well as the maintenance of balance between excitation and inhibition required for normal neural circuit function. A panel of research tools has been created that target the lumenal domain of vGAT. Antiserum was raised against a peptide from the C-terminus of rat vGAT and resulted in an affinity-purified antibody and an immunotoxin specific for vGAT-expressing cells. The antigen sequence is identical among human, rat, mouse, pig and guinea pig. A stably-transfected clone of HEK293 cells (2E11HEK) that expresses vGAT on the cell surface shows excellent results for western blot, ICC and flow cytometry using both the antiserum and affinity-purified antibody. The affinity-purified antibody was used to create an immunotoxin by conjugating it to the ribosome-inactivating protein, saporin. Saporin irreversibly inactivates ribosomes, blocking protein synthesis, when it is escorted into a cell. Saporin cannot enter a cell on its own, but when escorted by something that binds to a cell surface marker it is internalized along with the binding moiety and causes cell death. The immunotoxin (Anti-vGAT-SAP) is 1000-fold more cytotoxic to 2E11HEK cells than non-conjugated saporin, based on the EC_{50} in a cytotoxicity assay. The affinity-purified vGAT antibody binds specifically to cells that express vGAT, and delivers a payload to the interior of these cells. Anti-vGAT-SAP could be an important tool in studying diseases involving dysfunction of GABAergic neurons. GABAergic neuron dysfunction is thought to be an underlying factor in Epilepsy, Down Syndrome, Fragile X Syndrome, Schizophrenia and Autism. *In vivo*, elimination of vGAT-expressing cells in a particular area (rather than knocking out vGAT systemically) makes it possible to study the functions of those regional cells. Animals can then be tested behaviorally before and after injections of Anti-vGAT-SAP to demonstrate the effects of loss of cells in a particular region of interest.

Title: Depletion of synaptic vesicles inhibits the nitric oxide-dependent release of internal chloride

Authors: *V. K. DUNN, JR, E. GLEASON;
Louisiana State Univ., Baton Rouge, LA

Abstract: Amacrine cells (ACs) are interneurons that form inhibitory synapses with bipolar, ganglion, and other ACs in the inner retina. Our lab has previously shown that NO can alter the synaptic response properties of ACs by releasing Cl^- from internal stores. This alteration in the Cl^- gradient brings about a positive shift in the reversal potential (E_{GABA}) of the GABA-gated (or glycine-gated) current, which can convert inhibitory synapses into excitatory synapses (Hoffpauir, et al. 2006). We have recently demonstrated that this release of Cl^- originates from acidic organelles in ACs (Krishnan & Gleason, 2015). Here, we test the hypothesis that (acidic) synaptic vesicles (SVs) are a source of NO-releasable Cl^-. If SVs are a source of Cl^-, then depleting SVs should decrease the NO-dependent shift in E_{GABA}. The efficacy of two inhibitors of endocytosis were assessed using the fluorescent endocytosis marker FM1-43, where Dynasore and MiTMAB both decreased labelling in SV populations after stimulation with the V-step protocol (Dynasore -3.3±14.4%, n=6 vs control 98.3±15.7%, n=8, p=0.0006: MitMAB 15.5±14.1%, n=11, vs. control 99.5±18.8%, n=6, p=0.0030). To investigate whether SVs could be a source of NO-releasable Cl^-, we made whole cell voltage (V) clamp recordings from cultured chick retinal ACs. In order to deplete SVs, V-steps (-70 to -10 mV, 100 msec, n=15) were used to activate V-gated Ca^{2+} channels and stimulate the SV cycle either under control conditions or after treatment with the inhibitors. Voltage-ramps were used to measure the NO-dependent shift in E_{GABA} under both conditions . Our results reveal that activating the SV cycle in the presence of Dynasore completely blocked the NO-dependent shift in E_{GABA} (28.2 ±8.9 mV control shift, n = 5; 0 mV, n = 5 $p<0.001$). However, when MiTMAB was used under the same conditions, the shift was not blocked (control 30±8.5 mV, MiTMAB 22±4.3 mV, n=5, p=0.49) It has been reported that MiTMAB can block V-gated Ca^{2+} channels required for exocytosis (Quan et al., 2009). To investigate this, ACs loaded with the Ca^{2+} indicator Oregon Green Bapta (OGB) were stimulated with a 50mM K^+ external solution to activate V-gated Ca^{2+} channels. When MiTMAB was included in the high K^+ external solution, the increase in OGB fluorescence was inhibited (control 22.5±3.35 control, MiTMAB 3.44 ±1.595, n = 22, $p<0.0001$) suggesting that MiTMAB blocks V-dependent Ca^{2+} increases required for SV exo- and endocytosis, and therefore disrupts our attempt to deplete SVs. These data provide evidence that SVs may be a source of NO-releasable Cl^-. This result implies that in the retina, local NO signals could change the sign of postsynaptic responses at AC reciprocal synapses.

Title: Changes in the striatal neuronal inhibition in the MMP-1 transgenic mouse

Authors: *N. AL-MUHTASIB[1], M. ALLEN[2], K. CONANT[3], S. VICINI[1];
[1]Dept. of Pharm, [2]Interdisciplinary Program in Neurosci., [3]Dept. of Neurosci., Georgetown Univ., Washington, DC

Abstract: Matrix metalloproteinases (MMPs) have been studied in the context of their effect on neuronal excitation in the hippocampus and several other brain regions. Similarly, activation of protease activated receptor-1 (PAR-1), a known MMP-1 target, induced a change in both miniature and spontaneous inhibitory post synaptic currents (mIPSCs and sIPSCs) in a subset of hippocampal neurons. The effect of MMP-1 mediated PAR-1 signaling on neuronal inhibition has yet to be studied in the ventral striatum. Traditionally, the dorsal striatum has been associated with the coordination of motor movement. However, recent evidence suggests that changes in neuronal inhibition and excitation in the ventral striatum play a role in the motor movement changes seen in fragile X syndrome-like animal models. The neuronal makeup of the ventral striatum includes two subtypes of GABAergic spiny projection neurons (SPNs), cholinergic interneurons, and GABAergic interneurons. The SPNs consist of dopamine D1 receptor containing SPNs (D1 SPNs) part of the direct pathway and dopamine D2 receptor containing SPNs (D2 SPNs) part of the indirect pathway. We currently have mice in which the D1 SPNs express tdTomato and the D2 SPNs express green fluorescent protein, allowing for the differentiation between the two subsets of SPNs through red and green fluorescence, respectively. We currently have a transgenic mouse that overexpresses MMP-1 and has been crossed with our D1/D2 double reporter mice. These transgenic mice display improved rotarod performance, which have been described with altered striatal function. Using the whole-cell patch clamp method, we recorded mIPSCs, sIPSCs, and tonic currents in D1 and D2 SPNs in the transgenic mice and their wild-type littermates. We recorded using a potassium chloride based internal solution, and to detect synaptic input from more distal locations, a cesium chloride based internal solution was used. Additionally, we investigated the effect of MMP-1 on dendritic tree complexity and segment length using Golgi stained sections of brains from transgenic mice and their wild-type littermates. We confirmed PAR-1 protein expression and localization in the striatum of transgenic and WT littermate controls with immunohistochemistry and western blotting. We also performed immunotstaining using parvalbumin antibodies to quantify the extent of innervation of SPNs by fast-spiking interneurons, a subset of GABAergic interneurons. Our results suggest that MMP-1 overexpression alters the occurrence of sIPSCs and mIPSCs and

ongoing experiments will determine whether this occurs in relationship to changes in the number of primary and secondary dendrites.

Title: Inhibitory GABAergic signaling is strengthened by NMDAR derived reactive oxygen species

Authors: *E. A. LARSON, M. V. ACCARDI, D. BOWIE;
McGill Univ., Montreal, QC, Canada

Abstract: In recent years there have been new advances towards understanding the nature of inhibitory signaling in the brain. Previous work has shown a novel mechanism for strengthening of inhibitory GABAergic signaling by cytosolic reactive oxygen species (ROS) elevated by insulin signalling (Accardi et al (2015)). Whether GABAergic synapses can also be potentiated by ROS generated by excitatory neurotransmission has yet to be examined. To investigate this question, we performed whole-cell electrophysiological recordings from molecular layer interneurons of the mouse cerebellum. Additionally, we placed an extracellular stimulating electrode in the molecular layer of the cerebellum to activate a network of excitatory parallel fibers (PFs) from granule cells and neighbouring inhibitory interneurons. As anticipated, high frequency activation stimulation of PFs activated extrasynaptic NMDARs which led to elevated cytosolic ROS. This in turn caused a time-dependent increase in the strength of GABAergic synapses. The use of pharmacological blockers suggest that the origin of ROS generated by NMDAR activation is due to the combined activities of neuronal nitric oxide synthase and neuronal NADPH oxidase. Taken together, our data reveal a novel mechanism for the strengthening of GABAergic transmission through a NMDAR-ROS mediated pathway.

Title: Effects of oxytocin on gabaergic circuits in the lateral septum

Authors: *S. M. SINGHAL[1], S. W. HARDEN[2,3], C. J. FRAZIER[1,3];
[1]Dept. of Pharmacodynamics, Col. of Pharm., [2]Col. of Dent., [3]Dept. of Neuroscience, Col. of Med., Univ. of Florida, Gainesville, FL

Abstract: The lateral septum (LS), present in the subcortical forebrain, is believed to play a prominent role in modulation of limbic function, and is also a site with robust expression of oxytocin receptors (OTRs). Recent work has indicated that central infusion of oxytocin reduces activation of LS neurons as caused by restraint stress, and yet activation of OTRs in LS also enhances fear responding as observed after social defeat. It would be of interest to further understand the cellular and synaptic effects of OTR activation that underlie these phenomena. We report here that acute bath application of the specific oxytocin receptor agonist TGOT (100 nM), increases the frequency of spontaneous inhibitory postsynaptic currents (sIPSCs) as observed in a subset of neurons in the lateral septum (n= 18/32). TGOT induced release of GABA in the LS is activity dependent and likely OTR specific, as indicated by sensitivity to the voltage gated sodium channel blocker, tetrodotoxin, and the selective oxytocin receptor antagonist L-368, respectively (both bath applied at 1 μM). Consistent with this interpretation, we successfully identified a subset of neurons present in the LS (n=12/51) that are directly depolarized beyond threshold for action potentials by bath application of 100 nM TGOT. TGOT responsive neurons filled with biocytin were uniformly found to have significant axonal arborizations within the LS (n=9). No significant difference was found in passive or active electrical properties (resting membrane potential, hyperpolarization induced cation current (sag), input resistance, capacitance, or accommodation ratio in response to a depolarizing current step) between TGOT responsive and TGOT unresponsive LS neurons. Further studies using biochemical markers could potentially help differentiate between the two groups. Collectively, our results indicated that TGOT directly depolarizes a sub-population of putative GABA neurons in the LS, and causes a clear increase in sIPSC frequency observable in LS neurons. Collectively these results suggest that oxytocin activates local inhibitory circuits within the LS, possibly reducing the output of projection neurons.

Title: Mu and delta opioidergic modulation of inhibitory synaptic transmission in the rat insular corte

Authors: E. YOKOTA[1], *Y. OI[1], M. KOBAYASHI[2];
[2]Pharmacol., [1]Nihon Univ. Sch. of Dentisitry, Tokyo, Japan

Abstract: The insular cortex (IC) plays a key role in modulation of nociception, and the major analgesics such as morphine are thought to produce analgesic effects through opioid receptors. IC neurons express opioid receptors, including the mu (MOR), kappa (KOR), and delta (DOR) subtypes. Although the suppressive effect of opioidergic agonists on cortical excitatory synaptic transmission has been addressed, little is known about opioidergic roles in inhibitory synaptic transmission, which critically regulates excitatory propagation in the cerebral cortex. The present study aimed to examine the effects of opioid receptor agonists on unitary inhibitory postsynaptic currents (uIPSCs) and on cortical excitatory propagation in the IC and the neighboring cortices, the primary (S1) and secondary somatosensory (S2) areas, using an in vivo optical imaging technique. We performed multiple whole-cell patch-clamp recordings from rat IC pyramidal and GABAergic neurons. The application of 1 μM DAMGO, an MOR agonist, suppressed uIPSC amplitude in fast-spiking GABAergic interneuron (FS)-FS connections without a significant effect on FS-pyramidal cell (Pyr) connections. Moreover, 1 μM of DPDPE, a DOR agonist, suppressed uIPSC amplitude in both FS-FS and FS-Pyr connections. U50488 (1 μM), a KOR agonist, had little effect on uIPSC in FS-FS/Pyr connections. To assess the opioidergic effects on the cortical circuits, we applied electrical stimulation to the maxillary 1st molar pulp, which induced excitation in the ventral part of S1 and the S2/insular oral region (IOR) around the middle cerebral artery. The initial excitatory response was observed 10-14 ms after stimulation, and excitation propagated concentrically. DAMGO (10-100 μM) suppressed the amplitude of cortical excitation and shrank the maximum excitation areas in S1 and S2/IOR. In contrast, 10-100 μM DPDPE increased the amplitude of excitation and expanded the area of maximum excitation. These results suggest that MOR-induced suppression of excitatory propagation in the IC is an underlying mechanism of the powerful analgesic effects of MOR but not DOR agonists.

Title: Intermittent alcohol exposure alters gabaergic function in the central nuclei of amygdala in mice lacking BK channel β1 or β4 subunits

Authors: *Q. LI[1], C. CONTET[2], S. N. TREISTMAN[3], S. D. MOORE[1];
[1]Psychiatry, Duke Univ. Med. Ctr., Durham, NC; [2]Committee On The Neurobio. Of Addictive Disorders, The Scripps Res. Inst., La Jolla, CA; [3]Inst. of Neurobio., Univ. of Puerto Rico, Puerto Rico, PR

Abstract: BK channel accessory *β*1 and *β*4 subunits are essential for maintaining BK channel function and regulate excitatory and inhibitory synaptic transmission in the central amygdala nucleus (CeA) neurons. These BK subunits are also sensitive to acute actions of ethanol. Therefore, the alterations in expression of these subunits may also influence the function of CeA neurons following long term intermittent exposure to ethanol. We have assessed GABAergic sIPSCs and eIPSCs in CeA neurons from male BK *β1* or *β4* knockout (KO) mice that were subjected to chronic intermittent exposure (CIE) to ethanol or air via a vapor inhalation chamber. Utilizing whole cell voltage clamp techniques, spontaneous or evoked inhibitory postsynaptic currents (sIPSCs, mIPSCs and eIPSCs) were isolated from CeA neurons in acute slice preparations. In BK *β1* mice exposed to air only, the mean frequency of sIPSCs of CeA neurons in BK *β1* KO mice was slightly higher than that of wildtype (WT) mice. In contrast, KO CeA neurons exhibited a significant increase in the mean frequency of sIPSCs compared to WT neurons in CIE mice. Similarly, there was a significant increase in the mean frequency of sIPSCs of CeA neurons in BK *β4* KO CIE mice than in WT CIE mice. The mean amplitude of sIPSCs of CeA neurons was unaffected by either genetic background or the treatment received. The effects of chronic ethanol exposure on eIPSCs of mice were further examined by constructing input/output curves of eIPSCs in CeA neurons. eIPSCs of CeA were recorded by delivering a single electrical stimulus from 10 to 100μA in increments of 10μA. In BK β1 KO mice, CeA neurons showed an increase in the mean amplitude of eIPSCs compared to WT mice regardless of the treatment received. In BK β4 mice exposed to air only, there was a significant difference in the input/output curve between KO and WT CeA neurons. CIE treatment enhanced the amplitude of eIPSCs in KO more than that of WT CeA neurons. Paired pulse facilitation (PPF) was observed in all groups when two consecutive eIPSCs were evoked by stimuli with an inter-

pulse interval that was less than 50ms. However, a progressive paired pulse depression (PPD) was evident in all neurons tested but with a distinctive pattern when the inter-pulse intervals were between 100 and 3200ms: in both BK β1 and β4 mice, KO CeA neurons showed a larger PPD than that of WT neurons in air-exposed mice. However, KO CeA neurons from CIE mice exhibited a PPD larger than that of WT neurons from CIE mice. Finally, the mean frequency of mIPSCs appears to be higher in KO CIE mice than that of WT Mice. These results suggest that the effect of long-term exposure to alcohol on inhibitory synaptic transmission in CeA neurons is regulated by BK channel β subunits.

Title: Comparison of distribution of parvalbumin immunoreactive interneuron in the telecephalon between pigeon and mouse

Authors: *C. JEONG-HWI[1], J. AHN[2], J. PARK[1], T.-K. LEE[1], I. KIM[1], K. SEO[3], M.-H. WON[1];
[1]Kangwon Natl. Univ., Chuncheon, Korea, Republic of; [2]hallym university, Chuncheon, Korea, Republic of; [3]Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: GABAergic interneurons regulate the degree of glutamatergic excitation and output of projection neurons. In this study, we compared the distribution of parvalbumin (PV) in the pallium of the pigeon with that in the cortex of the mouse using immunohistochemical method. Our results show different anatomical structures of telencephalon that showed that the pigeon pallium made up of 3 layers in the telencephalic level, although the mouse neocortex contains 6 distinct layers. In the pigeon pallium, PV-immunoreactive neurons were found to be broadly distributed in all layers, however, the density of PV-immunoreactive neurons were particularly prominent in the hyperpallium than in the other layers. On the other hand, in the mouse cortex, many PV-immunoreactive neurons were observed through all cortical layers, however, the density of CB-immunoreactive neurons were considerably higher in layers V and VI than in the

other layers. In brief, this study shows that the distribution pattern of PV-immunoreactive cell bodies in the pigeon is different from that in the mouse. This finding needs more studies regarding PV-related function in the avian telencephalon.

Title: Insulin modulates gaba-a receptor trafficking to membranes of prefrontal cortex

Authors: S. TRUJEQUE-RAMOS[1], G. ARENAS[2], S. MIHAILESCU[2], *S. L. HERNANDEZ[3]; [1]Fisiologia, [2]Fisiología, Facultad de Medicina, UNAM, Mexico; [3]Facultad de Med., Mexico, Mexico

Abstract: Insulin signaling to the brain is important not only for metabolic homeostasis; insulin also acts as a growth factor, it activates dendritic sprouting, cellular regeneration, stem cell proliferation and cell survival. Likewise, insulin receptors are widely distributed throughout the brain, they are particularly high in choroid plexus, hypothalamus, olfactory bulb and regions of the striatum and cerebral cortex. Recent studies, have shown that insulin regulates the expression of extrasynaptic $GABA_A$ receptors in the hippocampus, causing permanent changes in the neuronal circuits. This effect could explain the alterations of cognitive processes associated to changes in insulin signaling previously reported. Another structure that possess insulin receptors and is involved in cognitive functions is the prefrontal cortex. Here, we set out to examine the effect of insulin on the tonic $GABA_A$ receptor-mediated currents in the prefrontal cortex (layers 5-6) by using patch clamp recordings in brain slices. We found that insulin (10-500 nM) modulates not only the $GABA_A$ synaptic receptors but also promotes the trafficking of extrasynaptic $GABA_A$ receptors to membranes, increasing the inhibitory tonic current and that these receptors contain alpha-5 and delta subunits. Our data suggests that the increasing in the number of $GABA_A$ extrasynaptic receptors also affects the neuron firing and hence decreases neuronal excitability. This modulation is dependent on the activation of the PI3K enzyme, a key mediator of the insulin response within the brain, as previously shown in pyramidal neurons of

the hippocampus. Together this results suggest that the insulinic modulation of the $GABA_A$ receptors can permanently modify the activity of neural circuits.

Title: Electrophysiological studies of $GABA_A\alpha5$ negative allosteric modulators in naive and amyloid β-treated hippocampal neurons

Authors: M. NAKANISHI[1], S. KAWAHARADA[1], B. BADER[2], O. SCHRÖDER[2], *T. YASUHIRO[1], S. KATSUMATA[1];
[1]ONO Pharmaceut. CO.,LTD, Osaka, Japan; [2]NeuroProof GmbH, Rostock, Germany

Abstract: $GABA_A$ receptor α5 subtype selective negative allosteric modulators ($GABA_AR\alpha5$ NAMs) improve cognition in animal models. As hippocampus is believed to be involved in learning and memory, we examined effects of newly synthesized $GABA_AR\alpha5$ NAMs on neuronal network activity in mouse hippocampal cell cultures with or without $A\beta_{1-42}$ treatment using microelectrode array (MEA) neurochips. We also evaluated effects of these $GABA_AR\alpha5$ NAMs on long term potentiation (LTP) in hippocampal slices from normal and $A\beta_{25-35}$/ibotenate-treated rats.
Primary neuron and glia co-cultures were prepared from mouse hippocampus. After establishing a stable neuronal activity pattern on MEA chips, $GABA_AR\alpha5$ NAMs (ONO-A, ONO-B, MRK-016, RO4938581; NAM activities of ONOs were higher than those of others), benzodiazepine antagonist (flumazenil) and pro-cognitive compounds (donepezil, galantamine, memantine) were applied with or without $A\beta_{1-42}$. Neuronal network activity was analyzed in the four categories: general activity, burst structure, synchronicity and oscillatory behavior, according to the pattern recognition algorithm. Effects of the compounds on $A\beta_{1-42}$ were evaluated by a single parameter "effect score", in which multiparametric results of 204 parameters are projected. For LTP study, hippocampal slices were prepared from normal or $A\beta_{25-35}$/ibotenate-treated rats. Field EPSP (fEPSP) slopes induced by the test stimulus, which produces 30 % of maximal fEPSP, with 30 sec interval were recorded for 40 min after theta burst stimulus (100 Hz 4 times, 200 msec

interval, 10 times).
In hippocampal cultures, ONO-A and ONO-B were functionally more similar to RO4938581 than MRK-016 and flumazenil. Flumazenil exhibited a different profile as parameters were mainly affected into opposite directions. ONO-A exhibited higher similarity to pro-cognitive compounds than ONO-B. In $A\beta_{1-42}$-treated conditions, all $GABA_AR\alpha5$ NAMs and donepezil rescued $A\beta_{1-42}$-induced changes of the effect score. In hippocampal slices from rats, all $GABA_AR\alpha5$ NAMs significantly increased fEPSP slopes compared with control in normal and Aβ/ibotenate-treated rat.
$GABA_AR\alpha5$ NAMs show functional similarity to pro-cognitive compounds and rescue Aβ-induced changes of neural network activity in hippocampal cultures. The $GABA_AR\alpha5$ NAM with higher efficacy potentiates LTP more efficiently in rat hippocampal slices. Moreover the $GABA_AR\alpha5$ NAM rescues Aβ/ibotenate-induced impairment of LTP induction. These results suggest that $GABA_AR\alpha5$ NAMs with high efficacy could be potent cognitive enhancers.

Abstract: The neurotransmitter γ-amino butyric acid (GABA) is critically important for higher brain functions. Ionotropic receptors for GABA ($GABA_ARs$) are heteropentameric transmembrane protein complexes with a subunit configuration commonly of 2α+2β+1γ. This study reports the discovery of S 44819, a novel tricyclic oxazolo-2,3-benzodiazepine-derivative targeting extra-synaptic α5-$GABA_ARs$. The specific binding of ^{3}H-muscimol to recombinant $GABA_ARs$ (α5β3γ2) was inhibited by S 44819 ($K_i \approx 66$ nM), whilst having no effect on the binding of ^{3}H-flumazenil. In human embryonic kidney cells expressing recombinant $GABA_ARs$ (α5β2γ2), S 44819 was a competitive inhibitor of the GABA-induced depolarization ($K_b \approx 221$ nM). In mouse hippocampal slices S 44819 enhanced long-term potentiation (LTP), induced by submaximal theta-burst stimulation of the Schaffer collateral pathway in a concentration-dependent manner. A bicuculline-sensitive tonic current mediated by extrasynaptic α5-$GABA_ARs$ in CA1 pyramidal cells was selectively inhibited by ~ 80% by S 44819, with no effect of the drug on their phasic miniature inhibitory postsynaptic currents (mIPSCs). In contrast to CA1 neurons, S 44819 had no effect on the bicuculline-sensitive tonic current of mouse thalamic ventrobasal neurons, mediated by α4β2δ $GABA_ARs$. In male rats, object recognition memory was enhanced by S 44819 (1-3 mg/kg *p.o.*) given before the acquisition trial. Cognitive deficits caused by scopolamine were reversed by the drug (1-3 mg/kg *p.o.*) when tested in the eight-arm radial maze. Collectively, S 44819 is a potent competitive antagonist of recombinant and native (CA1) α5-$GABA_ARs$, with no effect on CA1, or VB synaptic receptors, or on thalamic extrasynaptic α4β2δ receptors. It is a potent enhancer of hippocampal synaptic plasticity (LTP) *in vitro* and shows pro-cognitive efficacy *in vivo*. In conclusion, S 44819 is a first-in-class compound that may show therapeutic efficacy to enhance cognitive function.

Title: Long-term effects of an acute treatment of adult mice modelling down syndrome with gaba-alpha5 inverse agonist.

Authors: *M.-C. POTIER[1], A. DUCHON[2], A. GRUART[3], C. ALBAC[1], J.-M. DELGADO6GARCIA[3], Y. HÉRAULT[2];
[1]CNRS INSERM UPMC, Paris, France; [2]IGBMC, CNRS, INSERM, Univ. de Strasbourg, Illkirch, France; [3]División de Neurociencias, Univ. Pablo de Olavide, Sevilla, Spain

Abstract: Down syndrome (DS) is the most common genetic cause of mental retardation resulting from an extra copy of chromosome 21. It is widely known that altered brain functions in DS patients and in mouse models result from impaired balance between inhibitory and excitatory neurotransmission. We have previously shown that a single injection of an inverse agonist of the α5 subunit containing GABA-A receptors can reverse cognitive deficits in Ts65Dn mice modelling DS (Braudeau et al. 2011). In this study we aimed to evaluate how long the effects of GABA α5 inverse agonist treatment of Ts65Dn adult mice lasted after a single injection. We first analyzed in vivo long term potentiation (LTP) in the hippocampus of Ts65Dn adult mice with a stimulus intensity set at 35% (0.05-0.1 mA) of values needed to evoke maximum field excitatory post-synaptic potentials fEPSPs. High frequency stimulation (HFS) protocol consisted of five trains (200 Hz, 100 ms) of pulses at a rate of 1/s, 6 times in total, at intervals of 1 min. Evolution of fEPSPs after the HFS protocol was followed for 60 min at the same stimulation rate (1 stimulus/20 s). Additional recording sessions (30 min) were carried out for five days. No LTP could be evoked in Ts65Dn mice. However, treatment with the α 5 inverse agonist (α5IA, 5mg/Kg i.p.) facilitated the induction of LTP in Ts65Dn mice and produced a long-lasting LTP both in Ts65Dn and euploid mice over 6 days. We then analyzed the long-term behavioral effects of α5IA in the Novel Object Recognition (NOR) test and in the Y-maze 6 and 7 days after treatment respectively. α5IA was able to significantly corrected memory defects of Ts65Dn still after 6-7 days. It is known that α5IAs increase adult neurogenesis and can restore the higher number of GABAergic neurons to normal levels. We thus investigated the long-term effects of α5IA on adult neurogenesis and density of GABAergic neurons. Ts65Dn mice crossed with GAD67-GFP transgenics were treated with α5IA and injected with BrdU before sacrifice. Results on the numbers of GFP positive and BrdU positive cells will be presented. In conclusion

we show that treatment of adult Ts65Dn mice with α5IA can restore LTP and memory deficits and that these effects last for at least 6 to 7 days. These long-term effects suggest a drastic change of plasticity in mice after a single injection of α5IA.

Title: A single restraint stress alters PACAP-38 modulation of GABA transmission in the rat central amygdala

Authors: *F. P. VARODAYAN[1], C. S. OLEATA[1], V. SABINO[2], M. ROBERTO[1];
[1]The Scripps Res. Inst., La Jolla, CA; [2]Boston Univ. Sch. of Med., Boston, MA

Abstract: The neuropeptide pituitary adenylate cyclase-activating polypeptide (PACAP-38) and its receptor PAC1 (PAC1R) are proposed to be critical mediators of the brain's response to anxiety and stress. Both PACAP-38 and PAC1R are abundantly expressed in the central nucleus of the amygdala (CeA), a primarily GABAergic nucleus that sends inhibitory projections to downstream target regions that regulate stress and fear responses. Here we investigated whether stress alters the effects of PACAP-38/PAC1R signaling on local CeA activity by performing whole-cell voltage-clamp electrophysiology in male Wistar naïve rats and rats subjected to restraint stress. We first assessed the effects of PACAP-38 on GABA transmission in the CeA of naïve rats and found a significant increase in both action potential-dependent and -independent GABA release. These effects were blocked by pretreatment with the PAC1R antagonist PACAP(6-38). Additionally, PACAP(6-38) alone reduced baseline action potential-dependent GABA release, revealing a tonic inhibition of the CeA via PAC1R activity. Notably, these effects of PACAP-38/PAC1R signaling on CeA inhibition were dampened in rats subjected to a single 1 hour restraint stress, but not in rats that experienced 1 hour of restraint stress for three consecutive days. Therefore, PACAP-38, acting via its receptor PAC1R, tonically regulates

GABAergic transmission in the CeA of naïve rats, demonstrating that this neuropeptide plays a critical role in maintaining basal CeA activity. Interestingly, a single restraint stress reduces the ability of the PACAP-38/PAC1R system to regulate local CeA inhibition, potentially leading to the dysregulation of downstream target regions that mediate anxiety and stress-related behaviors.

Title: Substance P, like ethanol, increases GABAergic transmission in the central nucleus of the amygdala

Authors: *S. KHOM, M. ROBERTO;
Committee on the Neurobio. of Addictive Disorders, The Scripps Res. Inst., La Jolla, CA

Abstract: Substance P (SP) plays a pivotal role in addictive behaviors, stress and anxiety. Genetic ablation of NK-1 receptors - the molecular target of SP - reduces ethanol intake in mice accompanied by increased alcohol sensitivity (George et al., 2008; Science 319:1536-1539) abolishes ethanol reward in animals (Thorsell et al., 2010; Psychopharmacology (Berl) 209:103-111) and most importantly, pharmacological blockade of NK-1 receptors suppress spontaneous alcohol cravings in human detoxified alcoholics(George et al., 2008; Science 319:1536-1539). However, despite the evidence that NK-1 system may be a potential therapeutic target for the treatment of alcoholism, there are no studies analyzing cellular alterations of SP/NK-1 receptor signaling induced by ethanol dependence in the central nucleus of the amygdala (CeA), the major output of the amygdala complex and a major player in the transition to alcohol dependence. Previous work in our laboratory has shown that acute and chronic alcohol significantly increases GABAergic synaptic transmission in rodent CeA. Here, we have investigated the effects of SP on GABAergic synaptic transmission in neurons located in the medial subdivision of CeA using whole-cell electrophysiology in rat brain slices. Our data indicate that SP significantly increases frequency -and in some neurons also amplitude - of

action-dependent spontaneous inhibitory postsynaptic currents (sIPSCs) in ethanol-naïve rats suggesting SP facilitates GABA release in the CeA. Currently, we are studying the interactions of substance P and its receptors with acute ethanol on sIPSCs in ethanol-dependent animals. Collectively, this study will provide valuable insights into the cellular effects of SP on neuronal excitability and synaptic transmission in the CeA of naïve and ethanol-dependent animals.

Title: CFTR is required for the NO dependent release of internal Cl^-

Authors: *T. RODRIGUEZ[1], V. S. KRISHNAN, PhD[2], J. W. MADDOX[1], E. GLEASON[1]; [1]LSU Biol. Sci., Baton Rouge, LA; [2]Johns Hopkins Med. Inst., Baltimore, MD

Abstract: The effect of GABA and glycine on the voltage of postsynaptic cells is dependent upon the Cl^- concentration in the postsynaptic cytosol. We have shown that nitric oxide (NO) can release Cl^- from acidic compartments in retinal amacrine cells (ACs, Hoffpauir et al. 2006,; Krishnan and Gleason 2015). Furthermore, the Cl^- release depends on cytosolic acidification (McMains and Gleason 2011). The cystic fibrosis transmembrane conductance regulator (CFTR) is a strong candidate for involvement in the NO-dependent release of Cl^- because it has been demonstrated to regulate cytosolic Cl^- in motor neurons (Ostroumov et al. 2010), to respond to NO with an increase in conductance (Dong et al. 1995) and to be sensitive to pH (Chen et al. 2009). To investigate the role of CFTR, cultured ACs were voltage-clamped, and voltage ramps were delivered in the presence of GABA to measure the reversal potential of the GABA-gated current (E_{GABA}). In control cells, NO elicited a positive shift in E_{GABA} (E_{GABA} (26.8 ± 4.5 mV) indicating release of Cl^- into the cytosol. However, in the presence of the CFTR inhibitors glibenclamide or CFTR (inh)-172, no shifts in E_{GABA} were observed (1.5 ± 0.8 mV and -0.3 ± 0.6 mV, $p < 0.05$). The expression of CFTR was investigated by RT-PCR on RNA harvested from single ACs, and sequencing of the PCR product confirmed *CFTR* mRNA expression. Polyclonal antibodies raised against the C-terminus of human CFTR labeled ACs in culture and in sections of adult retina. Western Blot analysis demonstrated that the antibodies against CFTR antibody recognizes a single band of protein at the predicted molecular weight for CFTR (168 kD). To

further assess the involvement of CFTR in the NO-dependent Cl^- release, a CRISPR/Cas9 strategy was developed to target the 7th exon of the *CFTR* gene. An *in vitro* assay and analysis sequencing of single cell genomic PCR products confirmed that the CFTR gene was disrupted. Transfected (GFP expressing) ACs were voltage clamped, and E_{GABA} was measured before and after exposure to NO. Non-transfected cells and cells transfected with a construct lacking the guide RNA both demonstrated NO-dependent positive shifts in E_{GABA} (19.8 ± 4.4 mV and 13.5 ± 2.9 mV) indicating an elevation in cytosolic Cl^- concentration. As with the inhibitors, NO-dependent positive shifts in E_{GABA} were suppressed when CFTR expression was disrupted (-3.6 ± 2.7 mV, $p < 0.05$). These results provide substantial evidence that intracellularly expressed CFTR plays a key role in the NO-dependent release of internal Cl^-. Furthermore, our findings suggest that regulation of CFTR function can influence the strength and the sign of postsynaptic responses at GABAergic and glycinergic synapses.

Title: Potential use of hiPSC-derived neurons for studying botulinum toxin mechanism of action.

Authors: *C. E. NICOLEAU, E. BOUDE, F. NOIRMAIN, E. RABAN, J. KRUPP; R&D-Neurology, IPSEN Innovation, Les Ulis, France

Abstract: Botulinum neurotoxins (BoNTs) are multi-modular proteins that inhibit acetylcholine release at the neuromuscular junction (NMJ) leading to muscle paralysis. BoNTs are widely used as pharmaceuticals for neuromuscular indications and in aesthetic applications. Their mode of action includes specific cell binding, internalization and endocytosis, translocation of the enzymatic light chain into the cytosol, and SNARE (Soluble N-ethylmaleimide-sensitive-factor Attachment protein REceptor) cleavage. Many mechanistic aspects of this multistep process remain unclear and show differences between neuronal cell types and species. Whereas the activity of BoNTs has traditionally been studied in rodent primary neuronal cultures or immortalized cell lines, neurons derived from human induced pluripotent stem cells (hiPSC) allow to study toxin function in a model system that has high relevance to the clinic. In this study we correlate the results from a longitudinal expression study using QrtPCR and Western Blot of three different human iPSC-derived neuronal models (iCell Neurons from Cellular Dynamics International ; Peri.4U neurons from Axiogenesis ; and hMNPs from LONZA) with the

sensitivity of these three models to BoNT serotypeA (BoNT/A). QrtPCR analyses showed that iCell Neurons represent a central neuronal phenotype of glutamatergic and GABAergic neurons, whereas Peri.4U neurons represent a peripheral phenotype and hMNPs a motoneuron phenotype. All three hiPSC models express known botulinum neurotoxin surface receptors and SNARE-substrates throughout the 4 weeks of culture. However, the expression levels vary over time and between models. All three hiPSC models exhibited different sensitivity to BoNT/A, and this differential sensitivity is reviewed in the light of the differential level of expression of BoNT receptors and SNARE exhibited by the three hiPSC models. These data show that different neuronal populations derived from hiPSCs provide a sensitive platform for studying BoNT intoxication mechanisms and for BoNT potency determination.

Title: $GABA_A$ α5 inverse agonism enhances long-term object recognition and contextual fear memory but not learning of a two-choice visual discrimination

Authors: B. MASATSUGU, S. XIA, R. BARIDO, B. PETROSKI, R. SCOTT, M. PETERS, *N. J. BROADBENT;
Dart Neurosci. LLC, San Diego, CA

Abstract: Transgenic, neuroanatomical and pharmacological studies support a role for the $GABA_A$ α5 receptor in cognition (Atack 2009). In particular, the preferential localization of α5 subtype in the hippocampus suggests that this receptor might be important for hippocampal-mediated learning and memory. Preclinical and clinical studies with selective inverse agonists of $GABA_A$ α5 have shown enhanced performance or reversal of pharmacologically-induced impairments on some memory tasks. Here we examined the effect of the Merck $GABA_A$ α5-selective inverse agonist MRK-016 (Atack 2009, J Pharmacol Exp Ther 2009, 331:470-484) on long-term memory with two benchmark memory tests in rodents; novel object recognition (NOR) and contextual fear conditioning (cFC). We also assessed the effects of MRK-016 on the learning of a two-choice visual discrimination (VD) using an automated touchscreen apparatus (Horner et al., 2013). MRK-016 (Ki=1 nM) 0.3, 1 or 3 mg/kg or vehicle was administered *p.o.* 60 min before training on the NOR and cFC tasks. Rats were then trained under conditions

yielding sub-maximal memory in vehicle-treated rats and memory was tested 24 h later. For the VD task, rats received 0.3 mg/kg *p.o*. MRK-016 or vehicle 60 min prior to training. Rats were first trained to nose poke stimuli presented on a touchscreen monitor for reward. Once responding reliably, rats received VD training daily until they reached a predefined level of performance. MRK-016 at 0.3 mg/kg enhanced long-term memory of weakly-trained rats on both the cFC and NOR tasks but did not enhance learning of the visual discrimination task. Our data suggest that $GABA_A$ α5 inverse agonists improve hippocampal-dependent contextual memory and spontaneous object recognition, but not visual discrimination learning.

Title: Behavioral characterization of the SNAP25Δ3 mouse, a putative mouse model deficient in the Gβγ-SNARE interaction.

Authors: *Z. ZURAWSKI[1], M. BUBSER[1], K. HYDE[1], S. RODRIGUEZ[2], S. ALFORD[2], C. JONES[1], H. HAMM[1];
[1]Pharmacol., Vanderbilt Univ., Nashville, TN; [2]Biol. Sci., Univ. of Illinois at Chicago, Chicago, IL

Abstract: $G_{i/o}$-coupled G-protein coupled receptors (GPCRs) can exert an inhibitory effect on vesicle release through several G-protein driven mechanisms, more than one of which may be concurrently present in individual presynaptic terminals. G protein βγ subunits inhibit exocytosis via directly binding to the synaptosomal-associated protein of 25 kDa (SNAP25), competing with the fusogenic calcium sensor synaptotagmin 1 (Syt1) in a calcium-dependent manner for binding sites on SNAP25. Here, we identify a SNAP25 C-terminal mutant that is deficient in Gβγ binding while retaining normal vesicle release. The SNAP25Δ3 mutant, in which residue G204 is replaced by a stop codon, features a partial reduction in $G\beta_1\gamma_2$ binding *in vitro* and a

partial reduction in the ability of the lamprey serotonin receptors to inhibit exocytosis in lamprey reticulospinal axons. We conclude that the extreme C-terminus of SNAP25 is a critical region for the Gβγ-SNARE interaction. A transgenic mouse has been made containing the SNAP25Δ3 mutation using the CRISPR-Cas9 reaction. SNAP25Δ3 mice are viable and fertile in the homozygous state, with a gross appearance not different from wild-type mice. We performed a battery of neurological and behavioral tests upon SNAP25Δ3 mice to identify preliminary phenotypes that could be linked to $G_{i/o}$-coupled GPCRs that signal via this mechanism. In these tests, SNAP25Δ3 mice were shown to have an elevated body temperature and very mild autonomic nervous system dysfunction. Most prominently, deficiencies in locomotor activity and ataxia were observed in SNAP25Δ3 mice relative to wild-type. Investigation of the determinants of this phenotype at the cellular and molecular level are ongoing.

Title: Role of intracellular calcium transients in the dopaminergic modulation of synaptic responses in layer II of the lateral entorhinal cortex

Authors: *I. GLOVACI, C. A. CHAPMAN;
Concordia Univ., Montreal, QC, Canada

Abstract: The lateral entorhinal cortex (LEC) plays an important role in the sensory and mnemonic functions of the medial temporal lobe, specifically in regard to non-spatial information processing and olfaction. Therefore, modulation of synaptic input to the LEC may have important implications for learning and memory processes. Dopaminergic inputs from the ventral tegmental area terminate in layer II of the LEC, and we have shown previously that dopamine modulates synaptic responses in layer II LEC neurons in a dose-dependent manner, wherein high concentrations of dopamine (DA; 50-100 μM) suppress excitatory synaptic transmission, and lower concentrations (1-10 μM) *facilitate* synaptic transmission via a

signalling cascade dependent upon activation of D_1-like receptors. The dopaminergic facilitation of AMPA, but not NMDA, receptor-mediated EPSCs in layer II LEC neurons was dependent on activation of the classical D_1-cAMP-PKA pathway as well as on activation of PI-linked-D_1 receptors that result in increases in PLC, IP_3, PKC, and intracellular calcium. In the present study, we combined electrophysiological recordings of evoked EPSCs with fluorescent imaging of intracellular calcium to assess the relative contributions of IP_3 and ryanodine receptors in the dopaminergic facilitation. Whole cell patch-clamp recordings were obtained from layer II LEC neurons in acute horizontal slices obtained from 4-9 week old Long-Evans rats. The fluorescent calcium indicator Fluo-4 was included in a K-gluconate-based recording solution to assess changes in Ca^{2+}-dependent fluorescence. Bath application of DA induced a reliable and reversible increase in fluorescence of approximately 20-30% in both fan and pyramidal cells, but not in interneurons (96 ± 3.7% of baseline). The increased fluorescence was correlated with a reversible increase in EPSC amplitude during application of either DA (1 μM) or the D_1-like receptor agonist SKF83959 (5 μM). We did not observe any increases in fluorescence during bath-application of the classical D_1-like receptor agonist SKF38893 (10 μM). The contribution of IP_3 and ryanodine receptors was assessed by including either heparin (1 mM) or dantrolene (20 μM) in the intracellular recording solution to block Ca^{2+} release from internal stores. Results demonstrate that blocking either IP_3 or ryanodine receptors abolishes both the previously observed Ca^{2+} transients *and* the dopaminergic facilitation of EPSC amplitude. Taken together, our results indicate a critical role for intracellular calcium in the dopaminergic facilitation of synaptic transmission in the lateral entorhinal cortex.

Title: Regulation of synaptic efficacy via the ubiquitin-proteasome system and tomosyn proteostasis

Authors: *J. J. SALDATE[1,2], J. SHIAU[3,1], E. L. STUENKEL[3,2,1];
[2]Neurosci. Grad. Program, [3]Mol. and Integrative Physiol., [1]Univ. of Michigan, Ann Arbor, MI

Abstract: Neurotransmitter release via synaptic vesicle fusion is largely mediated by SNARE family proteins, which form trans-complexes between the vesicle and presynaptic plasma membrane. SNARE core complex formation is a central point of regulation for neural activity and trans-synaptic signaling. Tomosyn, a soluble, SNARE domain-containing protein, is thought to regulate exocytosis by forming non-fusogenic complexes with syntaxin1A and SNAP25 that inhibit fusion and reduce release probability. Altering the expression of tomosyn has significant behavioral effects observed in mice, Drosophila, and *C. elegans*. Additionally, alterations in presynaptic tomosyn levels in *C. elegans* led to trans-synaptic scaling via the cell adhesion molecules neurexin and neuroligin (Hu et al., 2012). It remains unclear which mechanisms and signaling pathways direct the modulation of tomosyn. We hypothesize that the ubiquitin-proteasome system (UPS), which is known to influence synaptic strength, dynamically regulates tomosyn levels. In support of this hypothesis, we found that immunoprecipitated and affinity-purified tomosyn from cultured rat hippocampal neurons and HEK 293T cells was ubiquitinated. Mass spectrometry of purified tomosyn also identified multiple ubiquitinated lysine residues. Moreover, tomosyn protein levels and ubiquitination dramatically increased (165% and 380% of vehicle controls, respectively) upon pharmacological proteasome blockade via MG132 (50μM, 4H), an effect that was mimicked by lactacystin treatment (10μM, 4H). Furthermore, tomosyn ubiquitination appears to be mediated through an interaction with the E3 ubiquitin-ligase HRD1. Immunoprecipitation of tomosyn from neurons co-precipitated HRD1, and this interaction increased upon proteasome inhibition (370% of vehicle control). *In vitro* reactions demonstrated that tomosyn is subject to concentration-dependent ubiquitination by HRD1. Notably, lentivirus driven shRNA-mediated knock-down of HRD1 in hippocampal neurons also increased tomosyn protein levels (142% of vehicle control). In addition to the established effects of tomosyn on presynaptic release probability, we found that tomosyn levels influence post-synaptic spine density, independently of its R-SNARE-containing C-terminal domain. Overexpression of tomosyn increased dendritic spine density (5.4 vs. 3.8 spines/10μm), while knock-down resulted in the opposite effect (3.0 spines/10μm). In summary, our data indicate that the UPS is likely to participate in tuning synaptic efficacy and/or spine dynamics by precise regulation of tomosyn levels in neurons.

Title: Functional role of the Ca^{2+}-binding site of Synapsin I in synaptic transmission

Authors: ***S. SACCHETTI**[1], E. CASTROFLORIO[1], L. MARAGLIANO[1], P. BALDELLI[2], F. BENFENATI[1,2];
[1]NSYN, Inst. Italiano di Tecnologia, Genova, Italy; [2]Dept. Exptl. Med., Univ. of Genova, Genova, Italy

Abstract: Synapsin I (SynI) is a synaptic vesicle (SV) phosphoprotein playing multiple roles in synaptic transmission and plasticity by differentially affecting crucial steps of SV trafficking in excitatory and inhibitory synapses. Syn display two important binding sites, one for ATP in the central C-domain, shared by all Syn isoforms and one for Ca^{2+} that play a pivotal role for synaptic transmission and for regulating ATP binding. It has been shown that mutating ATP binding site using a K269Q mutant in inhibitory neurons enhances synaptic strength, increases the vulnerability to synaptic depression and a dysregulation of SV trafficking. We have focused on the Ca^{2+} binding site and the functional consequences of its alteration on synaptic transmission, short-term plasticity and ultrastructure of synapses. To do this, we have reintroduced in Syn I KO hippocampal neurons either native Syn I or its E373K mutant in which Ca^{2+}-binding is abolished via lentiviral vectors and performed electrophysiological recordings and electron microscopy analysis. Preliminary data show an increase frequency of miniature postsynaptic currents in both excitatory and inhibitory neurons, while the amplitude is not affected. Moreover, inhibitory neurons expressing the mutant display increased eIPSC amplitude and RRP size compared to wild type Syn I neurons.

Title: Paroxysmal behavior and excitation/inhibition imbalance in PRRT2 knockout mice

Authors: *C. MICHETTI[1], E. CASTROFLORIO[1], I. MARCHIONNI[1], N. FORTE[1], B. STERLINI[2], A. CORRADI[2], F. BENFENATI[1,2];
[1]Ctr. for Synaptic Neurosci. (NSYN)., Italian Inst. of Technol. (IIT), Genova, Italy; [2]Dept. of Exptl. Med., Univ. of Genova Med. Sch., Genova, Italy

Abstract: Proline-rich transmembrane protein 2 (PRRT2) has been identified as the single causative gene for a group of paroxysmal syndromes of infancy, including benign familial infantile seizures, paroxysmal kinesigenic dyskinesia/choreoathetosis and migraine. A large number of PRRT2 nonsense, frameshift, and missense mutations have been associated with diseases with a variable phenotypic spectrum, ranging from mild forms that improve with age to severe phenotypes. Previous studies using complementary experimental approaches, showed the topology of PRRT2 conforms to that of type II transmembrane proteins, with a large cytosolic N-terminal domain and a very short extracellular C-terminus (Ncyt/Cexo orientation). PRRT2 is enriched in presynaptic terminals and interacts with proteins involved in exo/endocytosis of synaptic vesicles, namely SNAP-25 and synaptotagmin 1/2. Acute silencing of PRRT2 in neurons by RNA interference was followed by a decreased density of synaptic contacts and a severe impairment of synchronous release, confirming a functional role of PRRT2 in synaptic transmission. Here, for the first time, we investigated the phenotype of the PRRT2 knockout (KO) mouse by means of biochemical, electrophysiological and behavioral studies. Biochemical analyses showed a regional expression of PRRT2 in the brain, particularly in the hippocampus and cerebellum, which are brain regions involved in epilepsy and motor disorders. Preliminary electrophysiological studies found an increased excitation in the dentate gyrus of the hippocampus, suggesting a key role for PRRT2 in the excitation/inhibition balance. At the behavioral level, a characterization of motor development from postnatal age to adulthood detected the presence of paroxysmal events in the spontaneous motor behavior in the absence of overt motor coordination problems. Overall, we detect the presence of paroxysmal traits in the PRRT2 KO mouse that seems to model some features observed in patients harboring PRRT2 mutations. The brain regions where PRRT2 is mainly expressed, suggestive for PRRT2-associated paroxysmal diseases, and the electrophysiological data indicating the presence of an excitation/inhibition imbalance, confirm a role for PRRT2 in the pathogenesis of paroxysmal neurological disorders.

Fndn., Oklahoma City, OK

Abstract: Synaptic vesicles (SVs) need to be replenished very quickly after they discharge in order to allow rapid and repeated responses and avoid SV depletion during sustained high frequency firing. This is achieved through SV reformation via clathrin-independent and clathrin-mediated pathways. After physiological stimulation at moderate frequencies, SVs fully collapsed in the presynaptic membrane are endocytosed via clathrin-coated pits. The most important structural components of the coat are clathrin and its AP2 (α-β2-μ2-σ2) heterotetrameric adaptor complex.
Coupling bioinformatics prediction analysis with pull-down, mass spectrometry and coimmunoprecipitation assays, we identified a novel component of the coat and AP2 interactor: APache (KIAA1107), a neuron-specific protein enriched in axonal processes and synaptic terminals. We found that APache is highly enriched in the central nervous system, especially in the cerebral cortex, hippocampus and striatum, and its expression is developmentally regulated in both mouse brain and primary neurons. To investigate the physiological role of APache, we silenced it in primary cortical neurons via RNA interference. Silenced neurons were stimulated with, either moderate (5 Hz) or high (40 Hz) frequency trains were rapidly fixed, and analyzed by electron microscopy. SVs endocytosis was monitored revealing the newly endocytosed SVs with soluble horseradish peroxidase (HRP). Under basal conditions, APache knocked-down (KD) neurons showed a markedly reduced SV density. Stimulation at 40Hz did not reveal major differences comparing control and KD neurons, however stimulation at 5 Hz induced a significant increase in the presynaptic area and a decrease in both density of clathrin-coated vesicles and HRP-positive SVs in KD neurons. Clathrin mediated endocytosis at the plasma membrane has been reported to predominate at low frequency (5hz) versus high frequency (40hz) stimulation, we therefore suggest that APache plays an important role during clathrin-mediated endocytosis and SV reformation.

Title: TNIK inhibition in neurons affects synaptic P120 and delta catenin

Authors: *L. C. JAMES[1], T. LANZ[1], M. WEBER[1], J. EDGERTON[1], C. BUZBY[1], A. SRNKA[1], V. REINHART[1], A. GUTTERIDGE[2], H. XI[2], B. KORMOS[1], P. O'DONNELL[1]; [1]NPRU, [2]Comp Sci., Pfizer Inc, WW R&D, Cambridge, MA

Abstract: TRAF2 and NCK interacting kinase (TNIK) is a serine/threonine kinase of the Ste20 kinase family. TNIK is highly expressed in neurons and enriched in the postsynaptic density at synapses, where it has been shown to interact with DISC1. Its localization, along with the recent discovery that its substrates include members of the delta catenin family, have suggested a role for TNIK in the development and/or stability of dendritic spines. The present studies used pharmacologic, genetic and shRNA knockdown strategies to understand the impact of reduced TNIK activity upon synaptic biology. Small molecule inhibitors of TNIK acutely reduced phosphorylation of P120 and delta catenin. Sustained reductions in phosphorylation of these substrates were observed in vivo in TNIK KO mice, and in vitro in primary neurons exposed to TNIK shRNA. As current TNIK inhibitor tools also inhibit the related kinases MAP4K4 and MINK1, both of which are expressed in neurons, shRNA directed against these kinases were developed and compared with TNIK. The phosphorylation of P120 and delta catenin was dominantly mediated by TNIK, though some reduction of catenin phosphorylation was produced by MAP4K4 knockdown. RNAseq profiling in primary neurons confirmed several common downstream changes of TNIK and MAP4K4 knockdown, such as enrichment of genes involved in synaptic transmission. Additionally, RNAseq profiling in the hippocampus of TNIK KO mice showed alterations in pathways consistent with a role in dendritic remodeling, such as ephrin receptor signaling and rac/rho family members. . Assessment of AMPA currents in primary neurons, however, revealed no significant effect of TNIK shRNA. Additionally, tool compounds failed to elicit changes in synaptic strength in mouse hippocampal slices. These data provide additional insight into the roles of TNIK, MINK and MAP4K4 in primary neurons, but highlight the need for additional studies to better understand how downstream molecular changes may relate to functional outcomes.

Title: Regulation of Neuronal SNAREs by accessory proteins

Authors: *S. JAKHANWAL[1], N.-A. LAKOMEK[2], C.-T. LEE[1], R. JAHN[1];
[1]Max Planck Inst. For Biophysical Chem., Goettingen, Germany; [2]ETH, Zurich, Switzerland

Abstract: Neuronal exocytosis lies at the heart of the process of synaptic neurotransmission. The process of
neuronal exocytosis is mediated by a conserved family of proteins called the SNARE proteins. There
are three different kinds of neuronal SNAREs. Syntaxin 1a and SNAP-25a are present on the plasma
membrane whereas Synaptobrevin is present on the synaptic vesicles. The SNARE-motifs of these
three proteins come together to form a four-helix bundle which pull the membranes together to mediate fusion. Years of works in this field have established that the SNARE proteins are extremely
critical for the occurrence of membrane fusion. Nonetheless, the precise molecular details of the steps
and the sequential order of events involved in the process still remains a mystery. Using in-vitro reconstitution of the SNARE fusion machinery, and by employing techniques like FRET,

Anisotropy and
NMR, we have tried to look into details of the steps underlying the exquisitely regulated process of
neurotransmitter release. Special emphasis has been made on the role of regulatory proteins like Munc18 and Munc13 that play a crucial role in SNARE-complex formation. The SNARE proteins and
the afore-mentioned regulatory proteins have been over-expressed in bacterial cells and purified by
several chromatographic steps like affinity purification followed by ion-exchange chromatography or
gel filtration chromatography. The purified proteins were reconstituted into liposomes in order to form
a minimal system to study SNARE-mediated membrane fusion. Different cysteine-mutants of the SNARE- proteins were also purified in order to incorporate fluorescent labels at specific positions in
the proteins. The fluorescent labeling on the proteins enabled us to monitor protein-protein interactions under different reaction conditions and helped us to assess any stimulatory or inhibitory
effects of the regulatory proteins involved in the SNARE-machinery. Subsequently, the effect of different proteins on the fusion mediated by the SNARE-proteins was studied by labeling the lipids
used for liposome formation. Anisotropy measurements were employed to assess the binding of ligands to proteins/ protein complexes. Using the above-mentioned techniques, we have been able to
assess very interesting aspects of the neuronal SNARE-fusion machinery and we believe that our findings will surely take us one step closer to understanding the enigma of SNARE-mediated neuronal
exocytosis.

Title: Atypical dopamine transporter inhibitors R-Modafinil and JHW007 differentially alter excitability of midbrain dopamine neurons and reduce the cellular effects of cocaine

Authors: *A. J. AVELAR[1], A. H. NEWMAN[2], M. J. BECKSTEAD[1];
[1]UT Hlth. Sci. Ctr. San Antonio, San Antonio, TX; [2]Medicinal Chem. Section NIDA-IRP, Natl. Inst. of Drug Abuse, Baltimore, MD

Abstract: Psychostimulants, such as cocaine, increase attention and induce euphoria, are commonly abused, and can damage human health up to and including death. Currently, there are no FDA approved pharmacological treatments for cocaine abuse. Cocaine, the prototypical dopamine (DA) transporter (DAT) inhibitor, produces hyperlocomotion and reinforcement in rodents. Recently, a separate class of compounds termed atypical DAT inhibitors have been shown to bind DAT with high affinity and block reuptake, but are less likely to induce cocaine-like behavioral effects. Evidence from behavioral studies supports that atypical DAT inhibitors reduce cocaine-induced hyperlocomotion and self-administration in rodents, which suggests potential therapeutic benefits for human cocaine users. However, the cellular actions of atypical compounds are unknown. Therefore, we are investigating the effects of atypical DAT inhibitors R-Modafinil and JHW007 on D2 autoreceptor-mediated currents and DA neuron excitability by performing patch-clamp electrophysiology of midbrain DA neurons in brain slices from DBA/2J mice. R-Modafinil increased D2 autoreceptor current amplitude and width and decreased DA neuron firing rate in a D2 autoreceptor dependent manner. Conversely, JHW007 primarily decreased D2 autoreceptor current amplitude and had little effect on width and DA neuron firing rate. These findings suggest that, despite both being atypical DAT inhibitors, these compounds exhibit profoundly different effects on DA neuron excitability. Additionally, both R-Modafinil and JHW007 decrease the effects of cocaine on D2 autoreceptor current amplitude, which supports that these compounds can partially block the effects of cocaine at the cellular level.

Title: Membrane-bound glucocorticoid receptors on distinct nociceptive neurons as potential targets for pain control by rapid non-genomic effects

Authors: S. A. MOUSA[1], M. SHAQURA[1], X. LI[1], M. AL-KHRASANI[2], S. FÜRST[2], A. BEYER[3], *M. SCHAEFER[4];

Berlin, CVK, Berlin, Germany

Abstract: Glucocorticoids were long believed to primarily function through cytosolic glucocorticoid receptor (GR) activation and subsequent classical genomic pathways. Recently, however, evidence is emerging that suggests rapid non-genomic GR-dependent signaling pathways within the brain, although this still remains elusive with regard to spinal and peripheral nociceptive neurons. In this paper, we aimed to systemically identify GR within the spinal cord and periphery, to verify their putative membrane location and to characterize possible G protein coupling and pain modulating properties. Double immunofluorescence confocal microscopy revealed that GR predominantly localized in peripheral peptidergic and non-peptidergic nociceptive C- and Aδ-neurons and existed only marginally in myelinated mechanoreceptive and proprioreceptive neurons. Within the spinal cord, GR predominantly localized in incoming presynaptic nociceptive neurons, in pre- and postsynaptic structures of the dorsal horn as well as in microglia. GR saturation binding revealed that these receptors are linked to the cell membrane of sensory neurons and - upon activation - they trigger membrane targeted [^{35}S]GTPγS binding indicating G protein coupling to a putative receptor. Importantly, subcutaneous dexamethasone immediately and dose-dependently attenuated acute nociceptive behavior elicited in an animal model of formalin-induced pain hypersensitivity compared to naive rats. Overall, this study provides firm evidence for a novel neuronal mechanism of GR agonists that is rapid, non-genomic, and dependent on membrane binding and G protein coupling and acutely modulating nociceptive behavior, thus, unraveling a yet unconsidered mechanism of pain relief. Title: Role of zinc on neuropeptide release from neurohypophysial terminals

Authors: ***J. R. LEMOS**, Q. C. CHAU, E. E. CUSTER, R. VILLANUEVA, S. ORTIZ-MIRANDA;
MaPS, Univ. of Mass Med. Sch., Worcester, MA

Abstract: Zinc (Zn^{2+}) is an essential trace metal and Zn^{2+} deficiency has long been recognized as playing a role in a number of physiological brain disorders. Previous studies have shown the presence of Zn^{2+} in the hypothalamus as well as uptake within the Neurohypophysis (NH). Many synaptic vesicles/neurosecretory granules appear to contain Zn^{2+}, and these vesicles can act as zincosomes. We now show that NH terminals exhibit punctate Zn^{2+} staining. We have also found the presence of the GPR39 receptor as well as Zn^{2+} transporters at nerve terminals in the NH. The functional effects of exogenous Zn^{2+} on AVP and OT release from isolated neurohypophysial terminals of Wistar rats were examined using ELISAs. An exogenous concentration of 6 μM Zn^{2+} was necessary to initiate neuropeptide release and a maximal response was obtained at a concentration of ≥200 μM. Since Zn^{2+} is a known agonist of P2X2, P2X3, and/or P2X4 receptors, which are present exclusively on AVP terminals, we explored the possibility that Zn^{2+} activation of these purinergic receptors was inducing AVP release. Exposure to PPADS, an antagonist for P2X2 and P2X3 receptors, significantly inhibited Zn^{2+}-induced AVP release but, surprisingly, this antagonist also inhibited Zn^{2+}-induced OT release. Terminals exposed to PPADS alone, exclusively block ATP-induced AVP release, never OT release. Several studies have shown that PPADS is also a potential inhibitor of G-protein coupled receptor-induced IP_3 release, and, thus, of intracellular Ca^{2+} concentration. Exogenous Zn^{2+}-induced AVP and OT release occurred even in the absence of extracellular Ca^{2+} and was reduced by pretreatment with caffeine or acidic (6.5) pH. These results suggest that a GPCR-dependent pathway is activated during Zn^{2+} stimulation of neuropeptide release. Finally, Ca-EDTA (10 mM), a Zn^{2+} chelator, decreased high K^+-induced release of both neuropeptides from the intact NH. Taken together these findings lead us to hypothesize that endogenous Zn^{2+} could modulate AVP and OT release by interacting with GPR39 and P2X receptors in the plasma membrane of nerve terminals in the NH.

Title: Inhibiting protein synthesis reduces the ability to maintain sustained synaptic transmission at the calyx of Held synapse

Authors: M. S. SCARNATI, *K. G. PARADISO;
Cell Biol. and Neurosci., Rutgers Univ., Piscataway, NJ

Abstract: Neurotransmitter release is fundamental to brain function, and sustained synaptic transmission requires the interaction and maintenance of thousands of proteins. While some synaptic proteins, ion channels for example, are stable for days, others undergo faster turnover. The rate of protein synthesis that is required to replenish the proteins that are necessary to maintain ongoing synaptic activity is not fully understood. We examine this question using electrophysiological recordings at the Calyx of Held, a large synapse in the mammalian auditory brainstem that allows presynaptic and postsynaptic electrical recordings of synaptic transmission. To study synaptic activity, we stimulate the presynaptic axon of this nerve terminal and record the postsynaptic response. We find that blocking protein synthesis by bath application of cycloheximide increases the delay between the presynaptic stimulation time and the postsynaptic response. Compared to control recordings, we find an approximately 2-fold increase in the latency of the excitatory postsynaptic current (EPSC) at the end of a 20 Hz stimulation train. We also find an approximately 50% reduction in the expected peak amplitude of the EPSC and a reduction in the slope of the EPSC resulting in a smaller but prolonged EPSC compared to control recordings. Finally, we find that synaptic transmission can be highly compromised or even abolished within an hour after adding cycloheximide to block protein synthesis. These results appear to involve the release of neurotransmitter, which indicates a presynaptic effect. Possible mechanisms include postsynaptic proteins that affect presynaptic activity. In addition, glial protein synthesis may be necessary to maintain presynaptic activity. Finally, local protein synthesis has been shown to occur in axons of other types of neurons. Therefore, local protein synthesis in the presynaptic axon or possibly the nerve terminal could be affected. We are currently testing the possible mechanisms.

Title: Serotonin depresses the excitatory postsynaptic potentials in the dentate granule cells

Authors: *K. NOZAKI[1], R. KUBO[2], Y. FURUKAWA[1];
[1]Grad. Sch. of Integrated Arts and Sci., Hiroshima Univ., Higashi-Hiroshima, Japan; [2]Grad. Sch. of Biomed. & Hlth. Sci., Hiroshima Univ., Hiroshima, Japan

Abstract: Serotonergic fibers from the median raphe nuclei project to many brain regions including hippocampal formation. Serotonin is known to modulate the inhibitory interneurons in the dentate hilus, which indirectly affects the excitability of the dentate granule cells. Although 5-HT receptor also exist in the dentate granule cells, the effects of 5-HT on the excitatory synaptic transmission in the granule cells are not well resolved. In the present study, we examined the effects of 5-HT on the excitatory postsynaptic potentials (EPSPs) in the dentate granule cells evoked by the selective stimulation of the lateral perforant path (LPP), the medial perforant path (MPP), or the mossy cell fibers (MCF). In the presence of the $GABA_A$ receptor antagonist, picrotoxin, 5-HT (1 μM) decreased the input resistance of the granule cells to ~65% of the control and shortened the decay time constant of EPSPs. These effects were completely blocked by 5-HT_{1A} receptor antagonist, WAY100635. 5-HT depresses the amplitude of unitary EPSPs (uEPSPs) evoked by the minimum stimulation of LPP or MPP, whereas uEPSPs evoked by MCF stimulation was little affected. Because the inhibitory effect was partially blocked by WAY100635, the effect was explained by the shunting effect of 5-HT, which was confirmed by computer simulations. We also found that the success probability of uEPSP by LPP stimulation but not MPP or MCF stimulation was reduced by 5-HT, and that the paired-pulse ratio (PPR) of LPP-evoked EPSP but not the PPR of the MPP- or MCF-evoked EPSP was increased by 5-HT. These effects were blocked by 5-HT_2 receptor antagonist, ritanserin, suggesting that the transmitter release in the LPP-granule cell synapse is inhibited by the activation of 5-HT_2 receptors. In summary, the present results suggest that 5-HT can modulate the EPSPs in the dentate granule cells by at least two distinct mechanisms.

Title: *In situ* determination of the binding capacity of calbindin

Authors: *E. A. MATTHEWS[1], D. DIETRICH[2];
[2]Exptl. Neurophysiol., [1]Univ. Clin. Bonn, Bonn, Germany

Abstract: Endogenous Ca^{2+} binding proteins play an important role in controlling the spatio-temporal domains of intracellular Ca^{2+}. One such protein is the relatively fast, mobile protein calbindin (Cb). Cb is expressed in subsets of neurons and interneurons, and has been implicated in neuronal survival and synaptic signaling. The affinity and binding kinetics of the EF-hand protein have been well characterized *in vitro*, but thus far the technical challenges of measuring the biophysical properties of the protein *in situ* have proven intractable. However, Cb also binds Mg^{2+}, and may also be affected by intracellular pH, or interactions with other proteins (there is evidence that Cb can act as a sensor in addition to its role as a buffer), thereby potentially altering its binding capacity and speed in neurons. We have developed a 2P laser scanning based approach to derive highly precise quantitative information about the resting Ca^{2+}, activity-induced increases in free Ca^{2+}, and dye concentration using time correlated single-photon counting fluorescent lifetime imaging (FLIM) and single cell electroporation in dentate granule (DG) cells, which express Cb at ~40uM. Two calibrations are required for this approach: 1) calibration of the fast and slow fluorescent lifetime decay constants with free Ca^{2+} concentration, and 2) calibration of the dye concentration in the cell based on a bead ratio. Dentate granule cells from P25-P35 wild-type and Cb-knockout were electroporated with OGB-1. The resulting dye concentration was intentionally kept low (<10uM) so that the majority of the buffering capacity in the wild-type cells is contributed by Cb. In control experiments, patching the cells after electroporation revealed that cells were healthy and capable of firing action potentials. A stimulating pipette in the hilus provided antidromic stimulation to induce dendritic calcium transients from back propagating action potentials. 2-P FLIM line scans (4-10 ms) from the dendrites were acquired during antidromic stimulation, and resting calcium concentration and free calcium concentration during stimulation were analyzed by biexponential reconvolution fitting. This approach enables us to precisely measure the real-time Ca^{2+} dynamics in a cell with unperturbed intracellular Cb. By inducing long trains of antidromic action potentials, we can elevate the intracellular Ca^{2+} to ~300nM, allowing Cb to reach equilibrium with the free Ca2+

concentration. After the train of action potentials, Cb releases the bound Ca^{2+} as the free Ca^{2+} returns to the resting state. From this decay back to resting Ca^{2+}, we can directly extrapolate the Ca^{2+} affinity of Cb *in situ*.

Title: *In vivo* striatal dopamine release is regulated by ACh in the nucleus accumbens and modulated by M4 Muscarinic Receptor Positive Allosteric Modulators (M4PAMs) and nicotinic antagonists.

Authors: *A. D. RAMIREZ, L. YAO, S. M. SMITH;
Neurosci., Merck, Lansdale, PA

Abstract: We utilized *in vivo* microdialysis in rats to explore the effects of selective muscarinic and nicotinic receptor compounds on the regulation of acetylcholine (ACh) and dopamine (DA) release in the nucleus accumbens (NAc). In these studies, basal levels of ACh were elevated by infusion of the acetylcholinesterase inhibitor neostigmine and cholinergic receptor activation was modulated by acute administration of the M4 PAM VU0152100, α7-nicotinic antagonist MLA and the α4β2 nicotinic antagonist DHβE. Neostigmine was infused via retro dialysis in a dose-dependent (25, 50, 75, 100, 200nM) manner to elevate levels of ACh in the NAc and to examine the subsequent effects on dopamine transmission. We also demonstrated that extracellular levels of DA in the NAc are elevated following infusion of 100 or 200nM of neostigmine. Neostigmine infusion increased peaks levels of DA by 150-200% and DA remained elevated throughout the duration of the study compared to vehicle treated controls. Lower concentrations of neostigmine (25-75 nM) failed to increase dopamine reliably even though ACh levels increased dose proportionally up to 1500-2000% of baseline values. Intraperitoneal (i.p.) injection of the M4PAM VU0152100 (30 mg/kg) significantly ($P<0.05$) attenuated neostigmine (100nM) induced DA release as demonstrated by area under the curve analysis for DA. To identify the type of cholinergic receptors responsible for regulating DA release, we investigated the effects of the α-7 nicotinic receptor antagonist MLA on neostigmine-induced DA release. In these studies, MLA (10 mg/kg, i.p.) significantly attenuated neostigmine (200nM) induced DA plus ACh release most likely by modulating α7-nicotinic receptors on cholinergic interneurons. Lastly, we explored the effects of DhβE, a α4β2 nicotinic receptor antagonist, on neostigmine induced DA

release to assess the selectivity the α-7 nicotinic receptor in modulating DA release in this brain region. Our studies revealed the high level of interaction between ACh and DA in the NAc. Especially, we demonstrated that elevating basal ACh through neostigmine infusion can stimulate DA release and that this release is attenuated by selective activation of the M4 muscarinic receptor and by antagonism of α-7 nicotinic receptors. Further understanding the regulation of these transmitters is of great interest for both basic mechanistic and clinical understanding.

Title: Rapid alkalinization of a glutamatergic synaptic cleft by a single action potential

Authors: *M. STAWARSKI, G. MACLEOD;
Dept. of Neurosci., Florida Atlantic Univ., Jupiter, FL

Abstract: The machinery that mediates neurotransmission is pH sensitive including Ca^{2+} channels and neurotransmitter receptors facing the synaptic cleft. While it is conceded that synaptic cleft pH might change during neural activity, the valence and kinetics of any changes are unknown. In this study, we use genetically-encoded ratiometric pH indicators to monitor activity-induced pH dynamics at the *Drosophila* larval neuromuscular junction. A single action potential can evoke a rapid alkalinization of the synaptic cleft of approximately 0.02 pH log units (~3% change in proton concentration) within ~20ms. Synchronous with cleft alkalinization, pre- and post-synaptic compartments acidify with postsynaptic compartment acidification being more rapid and to a greater extent. Cleft alkalinization decays rapidly (~60ms) and mirrors the decay of postsynaptic acidification. Alkalinization of the cleft can be blocked by desensitizing glutamate receptors which blocks postsynaptic acidification suggesting that action potential-evoked cleft alkalinization is a function of acid flux across the postsynaptic membrane. The rapid rise and decay of cleft pH transients suggests relevance to fast forms of short-term synaptic plasticity and although each transient is small they can summate rapidly in response to successive action potentials.

Abstract: Anxiety disorders are thought to reflect deficits in the regulation of fear memories. While the amygdala has long been considered a site of storage of fear memories, newer findings suggest that the prefrontal cortex is essential in the regulation of amygdala dependent memories and fear expression. Here, activation of the prelimbic cortex enhances the expression of fear, whereas an elevated activity in the infralimbic cortex enhances fear extinction. Despite the presence of these facts, we still know very little about the synaptic interconnectivity within the prefrontal cortex. The aim of the present study was to investigate the inhibitory circuits between prelimbic and infralimbic cortex. We provided the first experimental evidence that the pyramidal neurons in the prelimbic cortex received a direct inhibitory input mediated by long-range bipolar NPY^+ GABAergic projection neurons, but not by PV^+-interneurons in the infralimbic cortex. Our further immunohistochemical analysis revealed that the distribution of parvalbumin- (PV^+), neuropeptide Y- (NPY^+), and calretinin- (CR^+) positive GABAergic neurons was strikingly different within the prefrontal cortex. While the CR^+ GABAergic interneurons were predominant in the layers I to III, PV^+- and NPY^+-GABAergic interneurons were mostly expressed in the layers V/VI of prefrontal cortex. Furthermore, the distribution of different GABAergic interneurons was even different within the prelimbic cortex. Based on these data, we suggest to sub-divide the prelimbic cortex in two parts: the 'cortical type' dorsal and the 'prefrontal type' ventral part. We are convinced that this classification of the prelimbic cortex will help us to further understand the underlying neuronal circuits and their interconnectivity to different neocortical areas. Additional experiments are, thus, necessary to further characterize the

functional roles and synaptic interconnectivities of the diverse inhibitory neuronal circuits within the prefrontal cortex as the center of emotional control.

Title: Modulation of synaptic transmission: protein specificity of inhibitory adrenergic α_{2a} receptor

Authors: *Y. YIM[1], K. BETKE[1], W. MCDONALD[2], R. GILSBACH[3], Y. CHEN[4], K. HYDE[1], Q. WANG[4], L. HEIN[3], K. SCHEY[2], H. HAMM[1];

Abstract: Modulation of neurotransmitter exocytosis by activated Gi/o-type G-protein coupled receptors (GPCRs), such as the α_{2a} adrenergic receptor (α_{2a}-ARs), is a universal regulatory mechanism used both to avoid overstimulation and to influence circuitry. One of the known modulation mechanisms is Gβγ interaction with soluble N-ethylmaleimide-sensitive factor attachment protein receptor (SNARE). There are 5 Gβ and 12 Gγ subunits, but whether specific Gβγs are activated by a given GPCR *in vivo* are not known. Presynaptic α_{2a}-ARs in both adrenergic (auto α_{2a}-ARs) and non-adrenergic neurons (hetero α_{2a}-ARs) inhibit neurotransmitter release and have various physiological functions such as anesthetic sparing and working memory enhancement. In this project, we examine the levels of each Gβ and Gγ in whole brain synaptosomes and in various fractions of synaptosomes. In whole brain synaptosome, we identify Gβ1 and Gγ2 as dominant subunits present. Although all Gβs and Gγs are highly present in "cytosolic" fractions, Gγs vary in different subcellular fractions. We also investigate whether auto α_{2a}-ARs in sympathetic neurons use the same Gβγ subunits as hetero α_{2a}-ARs in other

neuronal types to inhibit exocytosis by interacting with SNARE. Using several mouse models including transgenic Flag-α_{2a}-ARs, knock-in HA-α_{2a}-ARs, co-immunoprecipitation, mass spectrometry analysis, we have identified the Gβ and Gγ subunits that interact with α_{2a}-ARs and SNARE. Of these G proteins, we found Gβ2 and Gγ13 preferentially interacting with activated auto α_{2a}-ARs. We found no significant change in Gβγ specificity to SNARE following α_{2a}-ARs activation. Further understanding Gβγ specificity may offer new insights into the normal functioning of the brain, as well as better understanding of disease progression.

Title: Effects of glucagon-like peptide-1 (9-36) on de novo protein synthesis in mouse hippocampus

Authors: *S. M. DAY[1], S. E. EWIN[1], T. MA[2];
[1]Integrative Physiol. & Pharmacol., [2]Gerontology and Geriatric Med., Wake Forest Sch. of Med., Winston Salem, NC

Abstract: Glucagon-like peptide-1 (GLP-1) is an incretin hormone released from intestinal L-cells in response to nutrient ingestion. Until recently the GLP-1 cleavage product, GLP-1 (9-36), was considered biologically inactive. We have previously shown that GLP-1 (9-36) treatment rescues synaptic plasticity impairments and memory deficits in an Alzheimer's disease (AD) mouse model. However it is unclear by what molecular mechanisms GLP-1 (9-36) exerts those effects. *De novo* protein synthesis is critical for long-term synaptic plasticity and memory formation, and is impaired in Alzheimer's disease. Therefore, GLP-1 (9-36) may influence *de novo* protein synthesis and associated signaling pathways in the central nervous system. Acute

(400 μm) hippocampal slices were prepared from mice and treated with GLP-1 (9-36) (1 μM - 100 pM doses). We used Surface Sensing of Translation (SUnSET), to assess *de novo* protein synthesis; newly synthesized proteins were detected via western blot analysis. We examined signaling proteins involved in *de novo* protein synthesis in the hippocampus, specifically those associated with eukaryotic elongation factor-2 (eEF2), mammalian target of rapamycin complex 1 (mTORC1), and AMP-activated protein kinase (AMPK), which is a well-known central cellular energy sensor. To further determine whether the changes in *de novo* protein synthesis in GLP-1 (9-36) treated slices were due to protein synthesis or degradation pathways, we cotreated hippocampal slices with GLP-1 (9-36) and β-lactone, a proteasome inhibitor. We observed: (1) administration of GLP-1 (9-36) to hippocampal slices decreased *de novo* protein synthesis as assessed by SUnSET; (2) GLP-1 (9-36) treatments led to increased levels of AMPKα phosphorylation, which is consistent with decreased *de novo protein synthesis*; (3) cotreatment of β-lactone did not alter the effects of GLP-1 (9-36) on *de novo* protein synthesis or AMPKα phosphorylation. This study provides a potential mechanism by which GLP-1 (9-36) influences synaptic plasticity and memory. In the future, we will elucidate the molecular mechanisms by which GLP-1 (9-36) influences synaptic plasticity in models of chronic GLP-1 (9-36) exposure and other mouse models of cognitive impairment.

Title: Interactions between the eIF2α and mTORC1 signaling pathways

Authors: *H. R. ZIMMERMANN, B. BECKELMAN, W. YANG, T. MA;
Neurosci., Wake Forest Univ. Sch. of Med., Winston-Salem, NC

Abstract: Maintenance of long-lasting synaptic plasticity and long-term memory requires *de* novo protein synthesis. Two signaling pathways which control protein synthesis have been shown to play important roles in synaptic plasticity, learning, and memory: the eukaryotic initiation factor 2α (eIF2α), and the mammalian target of rapamycin complex1 (mTORC1)

pathways. Whether there interactions exist between these two pathways in neuronal systems remains unclear. Taking advantage of genetic and pharmacological approaches, here we investigated in mouse the effects of repressing eIF2α kinases, GCN2 and PERK, on the mTORC1 signaling pathway. We found (1): Genetic deletion of eIF2α kinase PERK in mice yielded increased phosphorylation of 4E-Binding Protein 1 (4E-BP1), and genetic deletion of GCN2 yielded increased phosphorylation of p70S6 kinase (p70S6K). (2) Genetic deletion of PERK yielded decreased phosphorylation of Akt and amp-activated protein kinase (AMPK), while genetic deletion of GCN2 resulted in increased phosphorylation of Akt and AMPK[W1] [WSoM2] . (3) Deletion of either PERK or GCN2 genes led to increased levels eukaryotic elongation factor 1A (eEF1A). (4) In contrast, incubation of hippocampal slices with PERK Inhibitor, GSK 2606414, did not impact the components of the mTORC1 pathway, except increasing eEF1A levels. (5) Further, hippocampal long-term potentiation (LTP) failure induced by mTORC1 inhibitor rapamycin was reversed by GCN2 genetic deletion. Our results indicate the mTORC1 and eIF2α pathways clearly interact in neurons and are more closely interwoven than previously thought. Our study provides evidence of an additional layer of complexity to the mechanisms of long-term synaptic plasticity and memory formation.

Title: The role of adenylate cyclase 1 in reinforcement synaptic plasticity: a modeling and experimental study

Authors: *H. URAKUBO[1], K. AOKI[2], S. YAGISHITA[3], H. KASAI[3], S. ISHII[1];
[1]Kyoto U, Kyoto, Japan; [2]Natl. Inst. for Basic Biol., Okazaki, Japan; [3]U Tokyo, Tokyo, Japan

Abstract: Animals actively operate on external environment to obtain a reward, and the reward (reinforcer) increases the occurrence probability of the operation that successfully brings about a reward. As a synaptic basis of such action-reward association (operant conditioning), we have

recently discovered that dopaminergic (DA; reward expectation) signal promotes spine enlargement only during a narrow time window (a few seconds) after pre-post spiking (action) signal in the medium spiny neurons (MSNs) of the striatum (Yagishita 2014, Science 345, pp. 1616-1620).
In such reinforcement plasticity, DA signal activates dopamine D1 receptors (D1R), which results in the activation of adenylate cyclase 1 (AC1). In turn, the pre-post spiking signal increases intracellular Ca^{2+} level, which also results in the activation of AC1. Thus, AC1 would work as a coincidence detector to associate DA with pre-post spiking. This scenario was supported because we found that a downstream enzyme of AC1, protein kinase A (PKA), encodes the timing information in the reinforcement plasticity.
To precisely capture the AC1 kinetics for the reinforcement plasticity, we reconstituted the AC1 signaling in HeLa cells. In the HeLa cells, we first observed that AC1 was activated synergistically by DA and Ca^{2+} signals. Further, AC1 was activated rapidly by the DA signal, whereas slowly by the Ca^{2+} signal. The slow activation of AC1 by Ca^{2+} reflected the waveform of the Ca^{2+} signal itself, i.e., the delay time of AC1 activation was highly correlated with the decay time of the Ca^{2+} signal. Mutation analysis revealed that such slow response of AC1 was mediated by a direct binding site of Ca^{2+}, which led to Ca^{2+} inhibition in the other type of AC. Based on those pieces of experimental evidence, we built a computational model of the whole signaling of the reinforcement plasticity, including the AC1 kinetics. Because of the delayed activation of AC1 specific to the Ca^{2+} signal, AC1 worked as not only the coincidence detector of the Ca^{2+} and DA signals, but also the causality detector of them. Further, the whole signaling model successfully reproduced a series of experimental results in the reinforcement plasticity. The model simulation thus suggested that the delayed AC1 activation would provide individual spines with robust mechanism to detect causality between action (Ca^{2+}) and reward expectation (DA) signals during operant conditioning.

Title: Rational engineering of sensors for hierarchical and orthogonal Ca^{2+} signaling

Authors: *H. FUJII[1], M. INOUE[2], H. BITO[2];
[1]Dept of Neurochemistry, Univ. of Tokyo Sch. of Med., Tokyo, Japan; [2]Dept of Neurochemistry, Univ. of Tokyo Grad Sch. of Med., Tokyo, Japan

Abstract: Ca^{2+} signaling pathways play key roles in decoding of neural input parameters to regulate functional properties of neurons. CaMKII and calcineurin are major Ca^{2+} dependent kinase and phosphatase that regulate synaptic functions and their physiological significance in neuronal and cognitive functions have been demonstrated both in vitro and in vivo, using pharmacological and genetic manipulations. However, how seemingly similar Ca^{2+} transients triggered at the spine, dendritic, or cellular levels leads to differential usage of two enzymes of opposing functions and distinct localizations remains unknown. In particular, quantitative parameters of Ca^{2+} signaling transduction, such as activation time courses and spatial spread have been difficult to investigate. To begin to address these issues, we developed mutually tolerant color variants of geneticallly encoded indicators for Ca^{2+}, CaMKII and calcineurin activities. Using large-Stokes-shift and red-shifted fluorescent proteins as FRET pairs, we developed dFOMA (dual FRET with Optical Manipulation) imaging approach, which enabled us to measure two different FRET probes simultaneously, while also performing optical manipulations through UV uncaging in living neurons. dFOMA imaging thus revealed distinctive spatial and temporal relationship between Ca^{2+}, CaMKII and calcineurin activities during high-frequency glutamate uncaging photo-stimulations. Information processing analysis further revealed that CaMKII functions as input frequency/number decoder, whereas calcineurin acts as a sensitive input number counter. This latter new finding prompted us to further ameliorate the performance of the calcineurin FRET sensor, based on structural biological and genomic evidence. Rationally engineering of calcineurin probes based on fluorophore insertions showed improved dynamic ranges both in vitro and in living neurons. In combination with R-CaMP2, a red genetically encoded Ca2+ indicator, the new calcineurin sensors permitted us to simultaneously visualize spontaneous Ca2+ and calcineurin activity in single spines in cultured hippocampal neurons. Taken together, our novel sensor engineering approach provides substantial advantage for future investigations of cellular and subcellular computation achieved by biochemical signaling within neuronal circuits.

Title: The Angelman syndrome protein UBE3A regulates mTOR signaling and synaptic plasticity by ubiquitinating P18

Authors: *J. SUN, Y. LIU, J. TRAN, X. HAO, M. BAUDRY, X. BI;
Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Angelman syndrome (AS) is a neurogenetic disorder caused by deficiency of maternally expressed UBE3A, an E3 ligase, which targets specific proteins for proteasomal degradation. We previously reported that over-activation of mechanistic target of rapamycin complex 1 (mTORC1) may contribute to synaptic pathology, learning deficits and motor impairment in AS. However, how UBE3A deficiency results in mTORC1 over-activation remains unknown. We report here that UBE3A ubiquitinates P18, a member of the Ragulator complex, which plays crucial roles for lysosomal recruiting and activation of mTORC1, and facilitates its degradation through the proteasome. UBE3A regulated P18 levels in heterologous cells through ubiquitination, and His-ubiquitin pull down assays confirmed that P18 was ubiquitinated by UBE3A. P18 co-immunoprecipitated with other members of the Ragulator, P14 and MP1, and with Rag GTPase/RagA in lysates from cultured hippocampal neurons or mouse hippocampus. Immunofluorescence staining showed that P18 was localized to puncta labeled with the lysosomal marker, LAMP2, in cell bodies and dendrites of hippocampal neurons. P18 levels were significantly increased in hippocampus of AS mice, as compared to wild-type (WT) mice. Immunoprecipitation under denaturing conditions showed that levels of P18 ubiquitination were reduced in hippocampus of AS mice, as compared to WT mice. Treatment with MG132, a proteasome inhibitor, significantly increased P18 levels in acute hippocampal slices from WT mice, suggesting that UBE3A ubiquitination of P18 facilitates its degradation through the proteasome. In cultured hippocampal neurons, increased mTORC1 and decreased mTORC2 activation, as well as actin polymerization impairment resulting from UBE3A deficiency were reversed by P18 shRNA knockdown. Finally, AAV siRNA-mediated P18 knockdown in

hippocampal CA1 neurons from AS mice reduced mTORC1 activity, increased mTORC2 activity, and improved long-term potentiation (LTP) and dendritic spine morphology in AS mice. These results suggest that P18 levels are regulated by UBE3A-mediated ubiquitination and proteasomal degradation, and that the lack of this regulation results in increased P18 levels, which could account for abnormal mTOR signaling and synaptic plasticity impairment in AS mice.

Title: Role of microglia in long-term potentiation and synaptic tagging / capture

Authors: *R. RAGHURAMAN[1], P. RANGARAJAN[2], S. T. DHEEN[3], S. SREEDHARAN[4]; [1]Physiol., [2]Anat., Natl. Univ. of Singapore, Singapore, Singapore; [3]Anat., [4]PHYSIOLOGY, NATIONAL UNIVERSITY OF SINGAPORE, SINGAPORE, Singapore

Abstract: Altered microglia function has been believed to cause synaptic dysfunctions. We tried to understand the possible role of microglia in the process of long-term functional plasticity models such protein synthesis dependent late-long-term potentiation (late-LTP) and its associative process, Synaptic Tagging Capture (STC). Our preliminary data showed impairments in late-LTP following the perfusion of Clodronate, a drug that obliterates microglia in a specific manner, which is also confirmed by our imaging studies. Results from Synaptic tagging and capture phenomenon also cemented the observations of the electrophysiological and image technique methods. This led us to hypothesize that microglia has a role to play with either Plasticity-Related Proteins (PRP's) or in the process of setting of the synaptic tag process in STC. Overall, our results provide compelling evidence for the role of microglia in associative long-term plasticity.

Title: Applying proximity ligation assay to study interaction of PP1 with I-2 or CREB in response to neuronal activity

Authors: *H. YANG[1], H. HOU[1], H. XIA[1,2];
[1]Neurosci., [2]Cell Biol. and Anat., Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA

Abstract: Reversible phosphorylation is a fundamental regulatory mechanism for many biological processes, such as synaptic plasticity, a cellular model for learning, memory and other experience-dependent brain functions. Synaptic plasticity is regulated by protein kinases as well as protein phosphatases. Protein phosphatase-1 (PP1), in particular, is required for long-term depression (LTD). Inhibition of PP1 is necessary for long-term potentiation (LTP) to occur. However, how PP1 activity is regulated and how PP1 access its plasticity substrate during synaptic plasticity is not well understand. Being able to elucidate how neural activity affects interaction between PP1 and its binding proteins or its substrate is critical for our understanding of the underlying molecular mechanisms of synaptic plasticity. Inhibitor-2 (I-2) is one of the most interesting PP1 binding proteins, facilitating PP1 function during LTD. CREB is a known substrate of PP1 that is essential in synaptic plasticity. However how I-2 or CREB interact with PP1 during synaptic plasticity is not well characterized. In this study, we applied proximity ligation assay (PLA) to detect the interaction between PP1 and I-2 or CREB in hippocampal neurons with subcellular resolution. I-2-PP1 interaction is readily detected in the nucleus and we found that low dose (20uM) NMDA treatment can robustly modulate nuclear I-2 and PP1 binding. We also found that synaptic activity elicited by short-term bath NMDA or bicuculline application lead to PP1 and CREB dissociation in the nucleus, suggesting that PP1 may be targeted out of the proximity of CREB during synaptic activity. This study characterized activity-dependent interaction between PP1 and I-2 or CREB by proximity ligation assay, and thus provided a novel model of PP1 regulation and function during synaptic plasticity.

Title: PKA-dependent phosphorylation of GluN2B on hippocampal plasticity and cognition

Authors: *M. W. PORCH, J.-Y. HWANG, A. E. CHÁVEZ, R. S. ZUKIN;
Albert Einstein Col. of Med., Bronx, NY

Abstract: NMDARs are glutamate-gated ion channels and are enriched at excitatory synapses, where they are strategically positioned to play a crucial role in regulation of synaptic function. A unique feature of NMDARs is their high permeability to Ca^{2+}. Ca^{2+} influx through NMDARs is essential for synaptogenesis, plasticity of neural circuitry, and higher cognitive functions, such as learning and memory. Emerging evidence reveals that PKA signaling represents a fundamental mechanism by which NMDAR-mediated Ca^{2+} influx is modulated in neurons. Direct activation of PKA promotes NMDAR Ca^{2+} permeability, Ca^{2+} signaling in dendritic spines, and induction of LTP at Schaffer collateral to CA1 pyramidal cell synapses. Consistent with this, extracellular signals that modulate cAMP bidirectionally regulate Ca^{2+} permeation through NMDARs and Ca^{2+} transients in spines in a PKA-dependent manner. We recently identified phosphorylation of GluN2B at Ser1166 to be the molecular target of PKA relevant to NMDAR Ca^{2+} permeability. Whereas the impact of PKA induced phosphorylation of Ser1166 on NMDAR Ca^{2+} permeability is well-established, its impact on NMDAR-dependent synaptic plasticity is unclear. To address this issue, we generated a mouse with a S1166A mutation knocked-in by means of the CRISPR method. These mice developed and bred normally and did not exhibit any gross morphological phenotypes. We first assessed basal synaptic transmission by monitoring the input/output relation at Schaffer collateral to CA1 synapses. We observed that this mutation does not impact basal transmission compared to wild-type controls. Next we investigated presynaptic function by means of paired-pulse facilitation at CA1 synapses. We found that paired-pulse facilitation was not altered in these mice compared to wild-type controls. We then examined synaptic plasticity in the form of theta-burst stimulation induced LTP at the CA1 synapse. We observed that theta-burst stimulation led to a significantly reduced potentiation in the knock-in slices compared to wild-type animals. We next examined hippocampal based memory by means of the novel object recognition assay and found that it was significantly impaired in these mice compared to wild-type controls These findings indicate a novel role for PKA phosphorylation of the GluN2B subunit in the potentiation and cognition.

Title: New synthesis of persistent PKMζ is crucial for spatial long-term memory

Authors: *C. HSIEH[1], P. TSOKAS[1,2], P. A. SERRANO[4], A. A. FENTON[5], T. C. SACKTOR[1,2,3];
[1]Dept of Physiol. and Pharmacol., [2]Dept. of Anesthesiol., [3]Dept. of Neurol., SUNY Downstate Med. Ctr., Brooklyn, NY; [4]Dept of Psychology, CUNY Hunter Col., New York, NY; [5]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: The autonomously active, atypical PKC isoform, PKMζ, has been proposed to play a fundamental role in the maintenance of long-term potentiation (LTP) and long-term memory (LTM)[1,2]. Although results from PKCζ/PKMζ-null mice have questioned this hypothesis[3,4], recent pharmacogenetic studies of wild-type and PKMζ-null mice reveal that persistent PKCι/λ activation compensates for the loss of PKMζ in mutant mice, whereas PKMζ is essential for LTP and LTM in wild-type mice[5]. To further characterize the persistent action of PKMζ during LTM, here we examined active place avoidance, a hippocampus-dependent, spatial conditioned behavior that is rapidly learned and can persist for 1 day to 1 month.
After a habituation trial, adult male Long-Evans rats were trained by eight 10-min shock trials with 10 min inter-trial intervals on Day 1 and spatial LTM tested on Day 2. We found that the amount of dorsal hippocampal PKMζ increased and significantly correlated with 1 day LTM retention. In contrast, no PKMζ increase was detected after either short-term memory retention or an unavoidable shock control group, in which animals received the same number and timing of shocks as the avoidance-training group, but without association with the animals' location. After 1 month, retention testing showed that spatial LTM had faded, and no PKMζ increase was detected in the dorsal hippocampus of the trained animals. However, if the animals received a second 8 training trials on Day 8 and tested one month later, both spatial LTM and the persistent

increase of hippocampal PKMζ were retained. Analogous to late-LTP, intrahippocampal injections of PKMζ-antisense oligodeoxynucleotide during the conditioning disrupted both the persistent increase of PKMζ and 1 day LTM. These results indicate that new synthesis of PKMζ is crucial for late-LTP and spatial LTM, and the increase of PKMζ formed during learning is highly stable and maps the persistence of memory for at least a month.

Title: Exposure to stressors facilitates long-term synaptic potentiation in the lateral habenula

Authors: *H. PARK[1], J. RHEE[1], K. PARK[1], J.-S. HAN[1], R. MALINOW[2], C. CHUNG[1]; [1]Konkuk Univ., Seoul, Korea, Republic of; [2]Univ. of California at San Diego, La Jolla, CA

Abstract: The lateral habenula (LHb) is a small part of the epithalamus that projects to monoamine centers in the brain. Previously, neurotransmission onto the LHb was shown to be abnormally potentiated in animal models of depression. However, synaptic plasticity in this brain

area and the effect of stressor exposure on long-term potentiation of the LHb have not been investigated. Thus, we explored whether the LHb undergoes dynamic changes in synaptic efficacy or not. First, we observed that a moderate long-term potentiation (LTP) occurs in a fraction of LHb neurons obtained from naive animals. Interestingly, a single exposure to acute stressors such as inescapable footshock (FS) or restraint plus tailshock (RTS) significantly enhances LTP in the LHb. We also observed increased levels of phosphorylated cAMP response element-binding protein (CREB) after theta-burst stimulation in acute slice preparations of the LHb obtained from RTS-exposed animals. Taken together, we showed that LHb neurons have heterogeneous propensity for synaptic potentiation at rest; however, a single exposure to stressors greatly facilitates LTP induction in the LHb, suggesting that fundamental alterations in synaptic plasticity in the LHb may occur in animal models of depression or post-traumatic stress disorder.

Title: Regulation of synaptic plasticity by syngap and its roles in neurodevelopmental diseases

Authors: ***Y. ARAKI**[1,2], R. L. HUGANIR[1,2];
[1]Solomon H. Snyder Dept. of Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD;

Abstract: SynGAP is a Ras-GTPase activating protein highly enriched at excitatory synapses in the brain. Previous studies have shown that CaMKII and the RAS-ERK pathway are critical for

several forms of synaptic plasticity including LTP. NMDA receptor-dependent calcium influx has been shown to regulate the RAS-ERK pathway and downstream events that result in AMPA receptor synaptic accumulation, spine enlargement and synaptic strengthening during LTP. However, the cellular mechanisms whereby calcium influx and CaMKII control Ras activity remain elusive. Using live-imaging techniques, we have found that SynGAP is rapidly dispersed from spines upon LTP induction in hippocampal neurons and this dispersion depends on phosphorylation of SynGAP by CaMKII. Moreover, the degree of acute dispersion predicts the maintenance of spine enlargement. Thus, the synaptic dispersion of SynGAP by CaMKII phosphorylation during LTP represents a key-signaling component that transduces CaMKII activity to small G protein mediated-spine enlargement, AMPA receptor synaptic incorporation and synaptic potentiation. Recent advances of next generation sequencing have identified myriads of de novo deleterious SynGAP mutations in patients of intellectual disability (ID) and autism spectrum disorder (ASD). Interestingly, almost all non-sense mutations of SynGAP found in these patients lack the domain critical for SynGAP dispersion. Furthermore, SynGAP heterozygote knockout mice recapitulate pathophysiology of these disorders; in preliminary results we have found that small molecular compounds ameliorates the synaptic plasticity and behavioral deficits in these model mice.

Title: Defining S6K1's translational program

Authors: ***S. ARYAL**[1,2], E. KLANN[1];
[1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]Dept. of Biochem. and Mol. Pharmacol., New York Univ. Sch. of Med., New York, NY

Abstract: Learning is thought to modulate subsequent behavior by changing the activity of neural circuits through long-lasting changes in the strength of synaptic connections. Many forms

of such long-lasting synaptic plasticity require rapid translation of pre-existing dendritic mRNAs at the synapse. Therefore, it is unsurprising that several major neuropsychiatric disorders such as autism and schizophrenia, as well as neurodegenerative diseases such as Alzheimer's disease have been shown to involve aberrant neuronal translation.
p70 S6 Kinase 1 (S6K1) is critical in coupling synaptic activity to the translational machinery. It is activated by mTORC1, a hub kinase that integrates synaptic signaling. S6K1 regulates translation initiation by stimulating eIF4A helicase activity via the phosphorylation of eIF4B. It also regulates elongation by phosphorylating and consequently inhibiting eEF2 kinase, which leads to enhancement of eEF2-mediated translocation of nascent polypeptide chains on the ribosome.
In this study, we sought to identify messenger RNAs whose basal translation is regulated by S6K1. To this end, we carried out ribosome profiling on cortical lysates of adolescent wild-type (WT) and S6K1 knockout mice, as well as on WT mice intraperitoneally injected with PF-4708671, a selective inhibitor of S6K1. Ribosome profiling uses deep sequencing of ribosome footprints (ribosome-protected mRNA fragments) to produce 'snapshots' of actively translating ribosomes on individual mRNAs. We normalized ribosome footprint counts with the abundance of the corresponding transcript, hence dissociating translational efficiency from transcriptional artifacts. We have quality controlled the sequencing datasets and are currently carrying out differential expression analysis using DeSeq2 to identify the set of mRNAs whose translation is sensitive to either deletion or inhibition of S6K1. Our findings will reveal systems-level insights on the regulation of basal protein synthesis by S6K1 in mouse brains.

Title: Upregulation of Src homology 2 domain-containing phosphotyrosine phosphatase 2 (Shp2) is critical for ERK signaling mediated AMPA receptor surface trafficking during synaptic activity

Authors: *Q. YANG, B. ZHANG, Y.-L. DU, W. LU, X.-Y. YAN, W. YANG, J.-H. LUO; Sch. of Basic Med. Sci., Zhejiang Univ., Zhejiang, China

Abstract: Long term synaptic plasticity, such as long term potentiation (LTP), has been widely accepted as cellular mechanism underlying memory. Recently, it has been unraveled that Shp2 plays a role in synaptic plasticity and memory in Drosophila and mice, revealing significant and conserved effects of Shp2 in cognitive function. However, the exact mechanism underlying Shp2 function in synaptic plasticity and memory still remains elusive. In this study, we examined the regulation of Shp2 in response to synaptic activity using both in vitro and in vivo models. We found that Shp2 was rapidly recruited into postsynaptic sites after chemical LTP (cLTP) treatment in cultured hippocampal neurons or LTP induction in hippocampal slices. Meanwhile, the phosphorylation level of Shp2 at Y542 was significantly upregulated under these two conditions. Notably, contextual fear conditioning also increased phosphorylation level of Shp2 at Y542 in the hippocampus. By using Shp2 specific inhibitor and AAV-Cre mediated Shp2 knock-out in cultured neurons, we provide evidence that the phosphatase activity of Shp2 is critical for activity dependent AMPA receptor surface trafficking. Collectively, our results have revealed a regulatory mechanism of Shp2 underlying ERK signaling mediated AMPA receptor surface trafficking during LTP and memory, broadening our understanding of Shp2 in cognitive function.

Title: LRP1 signaling occurs in lipid rafts

Authors: E. LAUDATI, 92093[1], A. GILDER[1], M. LAM[1], R. MISASI[2], M. SORICE[2], *S. L. GONIAS[1], E. MANTUANO[1,2];

Abstract: LDL receptor-related protein-1 (LRP1) is an endocytic receptor for diverse ligands, which also functions in phagocytosis and efferocytosis. In neurons and neuron-like cells, ligand-binding to LRP1 initiates cell signaling. Understanding the function of LRP1 in cell-signaling is important, especially in neurons because LRP1-activated cell-signaling has been implicated in neuronal survival, neurite outgrowth, growth cone navigation, synaptic transmission, and long-term potentiation. In cerebellar granule neurons (CGNs) and neuron-like cell lines, activation of cell-signaling proteins downstream of LRP1, including Src family members (SFKs), ERK1/2, Akt, and RhoA, depends on the assembly of a system of co-receptors that includes the NMDA Receptor, Trk receptors, and/or p75 NTR. Herein, we show that in PC12 and N2a neuron-like cells, LRP1 distributes into lipid rafts and non-raft plasma membrane fractions. When lipid rafts are disrupted, activation of SFKs and ERK1/2 by the LRP1 ligands, tissue-type plasminogen activator and activated α_2-macroglobulin, is blocked. Biological consequences of activated LRP1 signaling, including neurite outgrowth and cell growth, also are blocked. The effects of lipid raft disruption on ERK1/2 activation and neurite outgrowth, in response to LRP1 ligands, were replicated in experiments with CGNs. Lipid raft disruption does not affect the total ligand-binding capacity of LRP1 (B_{max}), the affinity of LRP1 for ligands (K_D values), or its endocytic activity. These latter activities probably represent the function of LRP1 localized to clathrin-coated pits. Our results demonstrate that well-described activities of LRP1 require localization of this receptor to more than one distinct plasma membrane microdomain.

Abstract: The postsynaptic site of neurons has the capacity to couple the activation of neurotransmitter receptor cascades using a complex signaling machinery within a collection of more than 1,500 proteins. Individual components of these networks have been described as key regulators of synaptic plasticity, in particular hippocampus long-term potentiation (LTP). However, it is not know whether the induction of LTP can modulate these signaling networks. Here we combine patterns of high frequency stimulation in mouse hippocampus CA1 region, together with large-scale phosphorylation and interactomic assays, and suggests that the induction of LTP uses a combinatorial writer-eraser-reader toolkit to modulate the core-scaffold component of the postsynaptic density (PSD), linking glutamate receptors to a variety of kinases, phosphatases and protein binding domains modulated by protein phosphorylation. Phosphorylation of highly-connected nodes are co-regulated with modulation of protein interaction networks. Regulated nodes contain the PSD risk for psychiatric disease, suggesting functional units within the PSD network.

Title: The protein kinase A-dependent form of LTP specifically involves an increase in the unitary channel conductance of AMPA receptor in the hippocampus

Authors: *P. PARK[1], Z. A. BORTOLOTTO[1], M. ZHUO[2], B.-K. KAANG[3], G. L. COLLINGRIDGE[1,2,4];

Abstract: Long-term potentiation (LTP) is considered to be the cellular basis of learning and memory. We recently reported that the protein kinase A (PKA)-dependent form of LTP

transiently expresses calcium-permeable AMPA receptors (CP-AMPARs) at hippocampal CA1 synapses (Park et al., 2016). This was induced using a spaced theta-burst stimulation (TBS) protocol (sTBS; 3 episodes with a 10 min inter-train interval) or 1 episode of TBS in the presence of rolipram (0.1 μM; rTBS), a PDE4 inhibitor. In contrast, a compressed TBS protocol (cTBS; 3 episodes with a 10 s inter-train interval) induces a PKA-independent form of LTP that did not involve CP-AMPARs. We wondered whether PKA-dependent LTP is also associated with a change of single channel conductance (γ) of AMPA receptor since CP-AMPARs have a higher γ than calcium-impermeable forms (Swanson et al., 1997).
We used somatic whole-cell recording and stimulated two inputs in area CA1 of hippocampal slices from 4-6 weeks rats. The unitary conductance of AMPARs was estimated using peak-scaled, non-stationary fluctuation analysis (non-SFA) as described by Benke et al., 1998. Here we found that the γ was not affected by the cTBS protocol. On the other hand, LTP, induced by sTBS or rTBS, was associated with higher γ of AMPARs.
In conclusion, our results suggest that PKA-dependent LTP increases the unitary channel conductance of AMPARs via synaptic expression of CP-AMPARs. We expect the current findings help to understand the cellular mechanism of our previous report (Benke et al., 1998) that LTP expression was often associated with an increased AMPAR conductance in immature animals (P13-P15).

Title: Pharmacogenetic analysis demonstrates compensation for PKMζ function by PKCι/λ in long-term potentiation and spatial long-term memory in PKMζ-null mice

Authors: *P. TSOKAS[1], C. HSIEH[2], Y. YAO[2], E. LESBURGUÈRES[4], A. A. FENTON[4], T. C. SACKTOR[3];
[1]Furchgott Ctr. for Neural & Behav. Sci., Physiol. & Pharmacol., Anesthesiol., SUNY Downstate Med. Ctr. Col. of Med., Brooklyn, NY; [2]Furchgott Ctr. for Neural & Behav. Ctr., Brooklyn, NY; [4]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: PKMζ is a brain-specific, persistently active, atypical PKC isoform proposed to mediate late-LTP (L-LTP) and long-term memory (LTM). But in PKMζ-null mice L-LTP and LTM appear normal and are still disrupted by PKMζ-inhibitor ZIP. These findings can be accounted for by two hypotheses. First, PKMζ is unimportant for LTP or memory. Second, PKMζ is essential for the maintenance phase of late-LTP and the consolidation of long-term memory in wild-type mice, and compensatory mechanisms are recruited by PKMζ-null mice during these two processes.
We used a pharmacogenetic approach to distinguish between these two hypotheses. First, we block de novo synthesis of PKMζ during protein synthesis-dependent L-LTP using PKMζ-antisense oligodeoxynucleotides, and find that whereas the PKMζ-antisense blocks L-LTP in wild-type mice, the same PKMζ-antisense has no effect on LTP in mutant mice that lack the antisense's target mRNA. We also find that PKCι/λ, another atypical PKC inhibited by ZIP that becomes transiently active during the induction of LTP in wild-type mice, becomes persistently active in PKMζ-null-LTP. Moreover, the PKCι/λ-selective antagonist ICAP reverses the maintenance of PKMζ-null-LTP, but not the maintenance of wild-type-LTP.
Pharmacogenetic analysis of spatial LTM reveals the same double dissociation: acute applications of PKMζ-antisense block LTM in wild-type, but not PKMζ-null mice, and, conversely, ICAP disrupts LTM maintenance in PKMζ-null, but not wild-type mice.
Remarkably, when both conditioned and unreinforced place memory tasks are made more difficult, PKMζ-null mice perform poorly compared to wild-type mice, suggesting that with high cognitive demand PKCι/λ cannot adequately compensate for normal PKMζ function.
Thus, the molecular mechanisms for L-LTP maintenance and spatial LTM consolidation in wild-type and PKMζ-null mice are different. Under normal physiological conditions in wild-type

mice, PKMζ is essential for L-LTP and LTM; in mutant mice without PKMζ, persistent PKCι/λ activation compensates for PKMζ loss.

Title: FRET-based cGMP imaging in cerebellar granule neurons reveals cGMP/Ca^{2+} crosstalk via a cGKI-independent mechanism

Authors: *M. PAOLILLO, S. PETERS, R. FEIL;
Univ. of Tuebingen, Tuebingen, Germany

Abstract: We study the role of the second messenger 3',5'-cyclic guanosine monophosphate (cGMP) in neuronal processes like learning and memory. One tool we utilize is a transgenic mouse line that expresses a fluorescence resonance energy transfer (FRET)-based cGMP sensor (cGi500). cGMP is synthesized from GTP by NO-sensitive soluble guanylate cyclases as well as by transmembrane guanylate cyclases, which are activated by peptide ligands such as natriuretic peptides (ANP, BNP, and CNP). In the present study, we have combined live-cell imaging with genetic and pharmacological tools to investigate the role of cGMP in cerebellar granule neurons (CGNs), specifically its crosstalk with Ca^{2+} signaling. FRET-based cGMP imaging in cGi500-expressing CGNs revealed an elevation of intracellular cGMP upon exposure to NO, while no increase in cGMP was observed upon exposure to natriuretic peptides. Furthermore, we looked at Ca^{2+} signaling as a proxy for neuronal activity. By simultaneously imaging cGMP and Ca^{2+}, we found that NO-induced cGMP potentiated glutamate-induced Ca^{2+} responses in CGNs. This indicates a crosstalk between these two signaling pathways that augments neuronal Ca^{2+} responses. Interestingly, Western blot analysis with a highly specific antibody indicated that CGNs do not express cGMP-dependent protein kinase I (cGKI), the principle cGMP effector in many types of neurons. In summary, live-cell imaging with cGi500 sensor mice demonstrated a novel NO/cGMP/Ca^{2+} pathway in CGNs that does not involve cGKI. It is our goal to further elucidate the molecular details and functional relevance of cGMP signaling in CGNs.

Title: Paclitaxel increases presynaptic NMDA receptor activity through protein kinase c in the spinal dorsal horn

Authors: J.-D. XIE[1], H.-L. PAN[2], *S.-R. CHEN[2];
[1]MD Anderson Cancer Ctr., Houston, TX; [2]Anesthesiol. & Perioperative Med., Univ. of Texas MD Anderson Cancer Ctr., Houston, TX

Abstract: Painful peripheral neuropathy is a severe adverse effect many cancer patients experience during treatment with chemotherapeutic drugs such as paclitaxel (Taxol). The glutamate N-methyl-D-aspartate receptors (NMDARs) at the spinal cord level are critically involved in the synaptic plasticity associated with neuropathic pain. However, paclitaxel treatment does not alter the postsynaptic NMDAR activity of spinal dorsal horn neurons. In this study, we determined whether paclitaxel affects the activity of presynaptic NMDARs by recording excitatory postsynaptic currents (EPSCs) of dorsal horn neurons in spinal cord slices. In paclitaxel-treated rats, the baseline frequency, but not the amplitude, of miniature EPSCs (mEPSCs) was significantly increased; the NMDAR antagonist 2-amino-5-phosphonopentanoic acid (AP5) completely normalized this frequency. Also, AP5 significantly reduced the amplitude of monosynaptic EPSCs evoked by dorsal root stimulation in paclitaxel-treated, but not vehicle-treated, rats. Blocking GluN2A-containing, but not GluN2B-containing, NMDARs largely decreased the frequency of mEPSCs and the amplitude of evoked EPSCs of dorsal horn neurons in paclitaxel-treated rats. Furthermore, inhibition of protein kinase C fully reversed the increased frequency of mEPSCs and the amplitude of evoked EPSCs in paclitaxel-treated rats. In addition, intrathecal injection of AP5 or systemic administration of memantine profoundly attenuated mechanical allodynia and hyperalgesia induced by paclitaxel. Our findings indicate that paclitaxel treatment induces the tonic activation of presynaptic NMDARs in the spinal cord through protein kinase C to potentiate nociceptive input from primary afferent nerves. Targeting presynaptic NMDARs at the spinal cord level may be an effective strategy for treating chemotherapy-induced neuropathic pain.

Title: High affinity copper I chelator suppresses long-term potentiation in mouse hippocampal neurons

Authors: *B. YANG[1], T. MORGAN[2], C. J. FAHRNI[2], C. R. FOREST[1];
[1]Mechanical Engin., [2]Chem. and Biochem., Georgia Inst. of Technol., Atlanta, GA

Abstract: As a cofactor in enzymes, copper plays critical roles in the mammalian central nervous system (CNS) and has been suggested to be involved in signaling functions and synaptic transmission.
Numerous studies reveal complex effects of endogenous copper on synaptic transmission; however, all of these efforts focused exclusively on supplying copper in its divalent oxidation state (Cu(II)) at concentrations up to 100 μM. Not only are such high concentrations of limited physiological significance, it remains unclear to what extent Cu(II) plays a role in synaptic transmission as copper is likely released in the form of Cu(I).
To identify the role of Cu(I) in neurotransmission, we have applied our recently developed Cu(I) selective chelating agents (TM4-68, TM4-66, etc.) and to intercept Cu(I) induced synaptic transmission. Long term potentiation (LTP) has been widely utilized to study synaptic properties, associated with learning and memory, and involves measuring a persistent strengthening of synapses based on recent patterns of activity. We examined the effects of these agents on LTP in adult mouse hippocampus by measuring changes of local-field potential (extracellularly) while superfusing hippocampal slices with ACSF or these chelating agents.
Field potentials (FP) were registered in hippocampal CA1 neurons after delivering a tetanic stimulation consisting of two trains of high frequency stimuli (100Hz, 1s duration) to the stratum radiatum. Amplitudes of FP were measured under various experimental conditions. Compared to the control, LTP of FP was significantly suppressed in TM4-68 treated slices while a paired-pulse test did not show significant differences between two conditions. Additional preliminary experiments show that the combination of TM4-68 (chelator) and CuCl can occlude TM4-68's effect on LTP in hippocampus CA1 region. Results from this study indicate that Cu(I) contributes to the induction of LTP in hippocampal CA1 region. This novel Cu(I) chelator and electrophysiological methodology can be used as promising tools to modulate hippocampal neuronal excitability and elucidate copper's role in it.

Title: Regulation of intracellular pH in dendritic spines: role in NMDA receptor-CaMKII signaling

Authors: T. WIESNER[1], T. JINADASA[1], L. TRUDEL[1], K. SEHGAL[1], V. CLAVET-FOURNIER[1], *P. DE KONINCK[2];
[1]Inst. universitaire en santé mentale de Québec, [2]Cell. Neurobio., Univ. Laval, Quebec, QC, Canada

Abstract: Synaptic plasticity involves activity-dependent recruitment of different proteins to synaptic compartments. The spatial dynamics and interactions of proteins is thought to be regulated by pH. While intracellular pH (pH_i) is believed to be tightly regulated, the homeostatic mechanisms that could contribute to maintenance of pH at, or near, synapses is still not clear. However, it has been suggested that the sodium-proton exchanger (NHE) family can influence presynaptic vesicle release and spine morphology. Therefore, we are testing the hypothesis that regulation of intracellular pH modulates Ca^{2+} signaling in spines, by combining optical imaging of pH and Ca^{2+}, whole cell electrophysiology and biochemical assays.
Using genetically-encoded ratiometric pH indicators, we have estimated the pH values in compartments, such as soma, dendrites and dendritic spines. Our measurements suggest that spines show a more alkaline level compared to dendrites. We also observed a high variability of proton concentrations across individual spines. We then asked whether strong synaptic stimulation leading to long term potentiation in hippocampal cultures (cLTP) has an effect on pH_i. We found that cLTP stimulation caused a significant acidification in soma, dendrites and dendritic spines with differential recovery times.
We previously showed that the activity-dependent clustering of CaMKII is influenced by pH_i. Therefore, the heterogeneity of pH_i that we observed amongst spines prompted us to investigate the relationship between pH regulation and the recruitment of CaMKII to spines. We found that spines with a lower pH prior to cLTP stimulation exhibited a stronger acidification. In those spines in particular, we observed that clustering of CaMKII was more pronounced. These results suggest that spines have differences in their buffering capacity. An important regulator of

neuronal pH is the Na^+/H^+ exchanger NHE5. Evidence suggests that the trafficking of NHE5 is regulated by phosphorylation. We are thus examining whether CaMKII regulates trafficking of NHE5 in spines.
Upstream of CaMKII activation and of spine acidification is the activation of NMDA receptors and influx of Ca^{2+}. We wondered whether the concentration of protons in spines has an impact on Ca^{2+} influx. We thus blocked NHE5 to trigger intracellular acidification and found a dramatic reduction in spontaneous cytosolic Ca^{2+} elevation, using GCaMP6 optical imaging. We are now investigating the mechanism underlying this effect. For example, we are looking into whether NMDA receptor function is also modulated by pH_i. Our experiments may determine the importance of spine pH regulation in synaptic plasticity.

Title: Interplay between excitatory and inhibitory synaptic plasticity at dendritic synapses

Authors: *T. RAVASENGA, C. ROSILLO, E. PETRINI, A. BARBERIS;
NBT, Inst. Italiano Di Tecnologia, Genova, Italy

Abstract: Learning and memory are believed to depend on plastic changes of neuronal circuits due to activity-dependent potentiation or depression of specific synapses. Traditionally, inhibitory synapses were assumed to be relatively invariant while network plasticity was hypothesized to mainly rely on the flexibility of glutamatergic excitatory synapses. Nevertheless, an increasing body of evidence has revealed that inhibitory synapses undergo several types of plasticity, raising the important question of how GABAergic and glutamatergic plasticity contribute to determine the excitation to inhibition balance during neuronal activity. Here, we characterized a form of inhibitory postsynaptic potentiation (iLTP) induced by depolarizing protocols delivered to pyramidal cells in hippocampal cultures. Indeed, we show that either depolarizing pulses (40 s, 0 mV) or action potential trains (40 s, 2 Hz) applied to the postsynaptic neuron induced a stable IPSCs potentiation that persisted up to 45 minutes. Photolysis of caged GABA and imaging techniques revealed that this iLTP is expressed at post synaptic level. Interestingly, the aforementioned depolarizing protocols induced depression at glutamatergic synapses (LTD), indicating a non-homeostatic relation between inhibitory and excitatory

plasticity. In order to further explore this issue we investigated how plasticity induced at glutamatergic spines interferes with the strength of neighboring GABAergic synapses by using simultaneous photolysis of caged glutamate and GABA. We report here that glutamatergic LTP induced by pairing postsynaptic depolarizations with repetitive glutamate uncaging at individual spines heterosynaptically affected the strength of neighboring GABAergic synapses probed with GABA uncaging. In particular, we found that such "plasticity spreading" from glutamatergic spine was mediated by calcium influx through L-type voltage gated calcium channels. Our findings suggest that, following the induction of synaptic plasticity, dendritic E/I balance can be selectively tuned in spatially restricted dendritic sub-regions.

Title: Dicer conditional knock out in mature Muller glia leads to upregulation of Brevican and disorganization of the retina structure.

Authors: *S. G. WOHL, T. A. REH;
Dep. of Biol. Structure, Univ. of Washington, Seattle, WA

Abstract: The depletion of Dicer in astrocytes leads to severe consequences, such as reduced brain size, seizures, and eventually reduced life spans of the mice. However, the role of miRNAs in the mature glial cell state and function are not well characterized. Here we show the impact of the loss of miRNAs in differentiated Müller glia in the neural retina.
To reduce levels of miRNAs in Müller glia (MG), we carried out a conditional knock out of Dicer1 (Dicer-CKO_{MG}). To delete Dicer1, we injected Tamoxifen into mice expressing a Müller glia-specific cre-recombinase (Rlbp1-CreER) and floxed alleles of Dicer1 from postnatal day 11 to 14. The tissue was analyzed 4 weeks after the last Tamoxifen injection.

In the Dicer-CKO_{MG}, we found greater cell number of Müller glia as compared to the wild type. Moreover, the Müller glia were displaced from their normal position in the inner nuclear layer. The Dicer-CKO_{MG} retinas also displayed disruptions of the neuronal networks and functional testing for visual acuity, by means of the Optomotry method, showed that vison was impaired in Dicer-CKO_{MG} mice. In order to analyze Müller glia specific changes of mRNA after Dicer deletion, we isolated the Müller glia from adult wild type and Dicer-CKO_{MG} mice by means of fluorescent activated cell sorting (FACS). Samples of at several sorts were pooled and analyzed by RNA-seq, and validated by RT-qPCR. RNA-seq revealed that Brevican (encoded by Bcan) was significantly upregulated in the Müller glia that lacked Dicer, and *in vitro* assays implicate Brevican to cause an abnormal behavior of the cells.
Overall, our data demonstrate the importance of miRNAs for normal Müller glia cell state and neural tissue organization in the adult retina.

Title: The effect of pH and potassium channel block on growth of glioma cell lines

Authors: C. OKOREN, *E. PETROFF;
Montclair State Univ., Montclair, NJ

Abstract: Glioma, the most common and aggressive type of brain cancer, involves faster glial proliferation. Increased activity of large conductance calcium and voltage-activated potassium (BK) channels has been shown to accelerate glial proliferation. Our previous studies have shown that acid sensing ion channels (ASICs) inhibit BK current at physiological pH levels, and that this inhibition can be relieved at acidic pH. ASICs can therefore act as endogenous pH-dependent regulators of BK channel activity. Both normal glia and glioma tissue express BK and ASIC channels. Our previous data demonstrate that, in both neonatal and wild type glial cells, the proliferation in culture was increased at pH 7.0 as compared to normal pH conditions (7.4), and that CTX inhibited glial growth at both pH levels.This study was undertaken to determine if

this ion channel interaction and growth regulation also occurs in glioma cell lines. We used five glioma cell lines, both astrocytoma and glioblastoma. The cells were cultured at pH of 7.4 or pH of 7.0. Charybdotoxin was used to inhibit potassium channels. It was hypothesized that at a lower pH and in the absence of charybdotoxin, the most growth would occur. The results showed that there was not a significant difference in the growth of the glioma cell lines in regards to pH or the presence of charybdotoxin. These results suggest that the cancerous cells lines examined here behaved differently than previously studied normal glia, and that the mechanisms of growth regulation by pH and potassium channel activity in glioma cells are different from normal glia. Title: Mechanisms of CO_2/H^+ sensitivity of astrocytes

Authors: *N. MARINA[1], E. TUROVSKY[2], V. KASYMOV[1], S. KASPAROV[3], A. GOURINE[1]; [1]Univ. Col. London, London, United Kingdom; [2]Inst. of Cell Biophysics,, Russian Acad. of Sci., Pushchino, Russian Federation; [3]Sch. of Physiol. & Pharmacology,, Univ. of Bristol, Bristol, United Kingdom

Abstract: Ventral regions of the medulla oblongata of the brainstem are populated by astrocytes which are sensitive to physiological changes in $PCO_2/[H^+]$. These astrocytes respond to decreases in pH with elevations in intracellular Ca^{2+} and facilitated exocytosis of ATP-containing vesicles. Released ATP propagates Ca^{2+} excitation among neighbouring astrocytes and activates neurones of the brainstem respiratory network triggering adaptive increases in breathing. The mechanisms linking increases in extra- and/or intracellular $PCO_2/[H^+]$ with Ca^{2+} responses in chemosensitive astrocytes remain unknown. Fluorescent imaging of changes in $[Na^+]_i$ and/or $[Ca^{2+}]_i$ in individual astrocytes was performed in organotypic brainstem slice cultures and acute brainstem slices of adult rats. It was found that astroglial $[Ca^{2+}]_i$ responses triggered by decreases in pH are preceded by Na^+ entry, markedly reduced by inhibition of Na^+/HCO_3^- cotransport (NBC) or Na^+/Ca^{2+} exchange (NCX) and abolished in Na^+-free medium or by combined NBC/NCX blockade. Acidification-induced $[Ca^{2+}]_i$ responses in astrocytes were

not affected by inhibition of Na^+/H^+ exchange or blockade of phospholipase C. These results suggest that in pH-sensitive astrocytes acidification activates NBC which brings Na^+ inside the cell. Raising $[Na^+]_i$ activates NCX to operate in a reverse mode leading to Ca^{2+} entry followed by activation of the downstream signalling pathway(s). Coupled NBC and NCX activities are, therefore, suggested to be responsible for functional CO_2/H^+ sensitivity of astrocytes which contribute to homeostatic regulation of brain parenchymal pH and control of breathing.

Title: Histamine as a modulator of astrocyte signaling

Authors: *A. KARPATI[1], T. YOSHIKAWA[1], T. NAKAMURA[2], F. NAGANUMA[2], T. IIDA[1], Y. MIURA[1], K. YANAI[1];
[1]Pharmacol., Tohoku Univ. Grad. Sch. of Med., Sendai-Shi, Miyagi, Japan; [2]Pharmacol., Tohoku Med. and Pharmaceut. Univ., Sendai-Shi, Miyagi, Japan

Abstract: Astrocytes far outnumber neurons in the central nervous system, and they significantly contribute to brain homeostasis and neural activity. Previous studies have shown that astrocyte-neuron signaling does not only depend on the release of neurotransmitters, but also on gliotransmitters released from astrocytes. The cell-cell communication is initiated by exogenous neurotransmitters, binding to membrane receptors on astrocytes and hereby activating their intracellular signaling. Activated cell signaling is often indicated by an increased intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$) and elevated $[Ca^{2+}]_i$ is known to trigger the release of gliotransmitters, such as ATP and glutamate and D-serine. These can in return act on neurons and hereby shape synaptic plasticity and dendrite formation. In contrast, uncontrolled gliotransmitter release contributes to neurodegeneration in disorders, such as Alzheimer's disease. Many studies investigating astrocyte signaling and subsequent gliotransmitter release focused on glutamate, the major excitatory neurotransmitter. A scarce of studies has examined the importance of the neurotransmitter histamine in intracellular astrocyte signaling, and its molecular mechanism still remains unknown. Histamine is crucial in physiological processes such as sleep-awake cycle, learning and memory, and therefore unraveling its impact on astrocyte signaling is of great interest. Using the human astrocytoma-derived cell line 1321N1

we could show that histamine was capable of increasing $[Ca^{2+}]_i$ in a dose-dependent manner. Pharmacological assays revealed only histamine H1 receptor (H_1R), but not H_2R, played a crucial role in the histamine-induced $[Ca^{2+}]_i$ elevation, and moreover the signaling was G protein-coupled. Phospholipase C and inositol trisphosphate-receptor inhibitors, namely U73122 and 2-APB, led to the extinction of the Ca^{2+} response. We also showed histamine significantly increased the H_1R mediated glutamate release from cultured astrocytes in a dose-dependent manner. Finally, a co-culture system utilizing 1321N1 cells, and glutamate receptor overexpressing CHO biosensor cells demonstrated that glutamate released from astrocytes adequately activated the biosensor cells. We confirmed these results by using cultured primary rat astrocytes, which responded to histamine with increased $[Ca^{2+}]_i$ and an elevated concentration of released glutamate. The obtained data indicate the importance of histamine in astrocyte signaling and subsequent gliotransmitter release. These findings shed light on the potential impact of histamine on brain activity through astrocyte-neuron signaling.

Title: Polyamines facilitate connexin43-mediated gap junctional communication during hypercalcemia- and acidosis-like conditions

Authors: L. Y. KUCHERYAVYKH[1], *J. BENEDIKT[1], L. A. CUBANO[1], F. F. BUKAUSKAS[2], S. N. SKATCHKOV[1], Y. V. KUCHERYAVYKH[1];
[1]Univ. Central Del Caribe, Bayamon, PR; [2]Albert Einstein Col. of Med., New York, NY

Abstract: Background: Pathological changes in regulation, formation and gating of connexin (Cx)-based gap junction (GJ) channels are involved in ischemic injury to the CNS, traumatic brain injury, epilepsy and cancer, among other diseases. Intracellular ions, such as H^+ and Ca^{2+}, are key factors determining GJ communication and functional state of the tissue during different metabolic states. Intracellular acidification, as occurs in ischemia, leads to the closure of GJs and reduces the propagation of ions and small molecules via the network of cells in the brain and the heart tissue. We have previously demonstrated that endogenous polyamine spermine facilitates GJ-based communication in astrocytes. In this study, we investigate the role of polyamines spermine (SPM) and spermidine (SPD) in the regulation of the GJ channels consisting of Cx43, during ischemia-like states, characterized by elevated concentrations of intracellular hydrogen and calcium. **Methods:** Calcium- and pH-dependent regulation of Cx43 by polyamines was studied using whole-cell voltage-clamp technique and by measuring the cell-to-cell transfer of fluorescent dyes in the Novikoff and A172 glioblastoma cells, cell lines natively expressing Cx43 GJs. **Results:** We have found that polyamines prevented down-regulation of Cx43-mediated intercellular communication, caused by elevated levels of Ca^{2+} and H^+ ions. The siRNA knock-down of Cx43 reversed this effect, indicating that SPD and SPM regulation is Cx43-specific. **Conclusion:** Endogenous polyamines are essential for sustaining Cx43-mediated electrical and metabolic GJ coupling under ischemia-like conditions.

Abstract: Cannabis Sativa has been used in folk medicine to treat pain, gastrointestinal disturbances, depression and other conditions. Cannabis also has undesirable effects such as memory impairment and hyperphagia. Tetrahydrocannabinol, a psychoactive terpenoid in cannabis, activates 2 G-protein coupled receptors (CB1/CB2). Endocannabinoids anandamide and 2-arachidonoyl glycerol (2-AG) are partial (anandamide) or full (2-AG) cannabinoid receptor agonists. Anandamide and 2-AG are primarily hydrolyzed by fatty acid amide hydrolase (FAAH) and monoacylglycerol lipase (MGL), respectively. FAAH/MGL inhibitors offer a strategy to transiently increase local endocannabinoids by inhibiting their degradation. Recent data also show MGL inhibitors block the secretion of cytokines and PGE2 by mouse astrocytes *in vitro*, suggesting this system is linked to neuroinflammation. Peripheral dosing of 20 mg/kg LPS to mice has been shown to increase the brain content of inflammatory cytokines and prostaglandins. MGL inhibitor JZL184 blocks these effects and analogous results have been obtained in MGL knockout mice (Nomura et al, Science 2011). JZL184 is a covalent MGL inhibitor with a slow on rate, requiring at a 45 minute pre-incubation in vitro to be fully active. A high affinity, selective and reversible MGL inhibitor (JNJ-42226314; US Patent US2013/0102584) has been found which does not require pre-incubation in vitro. We have performed experiments analogous to Nomura et al, comparing JZL184 with JNJ-42226314 and testing a lower dose of LPS. Mice were dosed ip with 40 mg/kg JZL184 or 30 mg/kg JNJ-42226314 and then with 0.1 or 20 mg/kg LPS 30 minutes later. Plasma and brains were collected 6 hours after LPS dosing. Brain samples were analyzed for drug exposure, 25 cytokines, arachidonic acid and prostaglandin E2. The lower dose of 0.1 mg/kg LPS produced little or no stimulation of central inflammatory factors, while the higher dose of 20 mg/kg increased brain content of PGE2 and many cytokines. JZL184 blocked increased brain content of prostaglandin E2 and Il-1B in mice dosed with 20 mg/kg LPS; JNJ-42226314 was more efficacious than JZL184, showing reductions in the brain content of additional LPS stimulated cytokines. These results confirm MGL inhibitors are capable of reducing brain inflammatory factors in a murine model and show improved efficacy for a reversible MGL inhibitor.

Title: Decreased levels of GLAST lead to alterations in cortical development and inhibitory neurotransmission

Authors: *J. SHIH[1], E. L. HANSON[1], N. C. DANBOLT[2], Y. YANG[1], C. G. DULLA[1]; [1]Neurosci., Tufts Univ., Boston, MA; [2]Inst. of Basic Med. Sci., Univ. of Oslo, Oslo, Norway

Abstract: The astrocytic glutamate transporters GLAST and GLT-1 are responsible for the bulk of glutamate uptake in the cortex, control ambient glutamate levels, and shape excitatory neurotransmission. Interestingly, glutamate transporter expression and function change greatly during development. GLAST predominates in the neonatal cortex, while GLT-1 plays a larger functional role as the cortex matures. Because of this unique developmental expression profile, we hypothesized that changes in GLAST during early development may induce long term changes in cortical network structure and function. Our own studies of the freeze lesion model of developmental cortical malformation suggest that injury-induced disruption of astrocytic glutamate uptake does in fact lead to altered synaptic function and network level hyperexcitability. We utilized mice heterozygous for either GLAST or GLT-1 (GLAST+/- or GLT-1+/-, respectively) to alter glutamate uptake without brain injury. These mice are viable and have roughly 50% of wild-type glutamate transporter protein levels. We recorded astrocytic glutamate transporter currents in acute cortical slices and show that glutamate uptake depends on GLAST at younger ages (P7-10) and GLT-1 at older ages (P21-24), functionally confirming the developmental profile of these two transporters. We next recorded extracellular field EPSPs in acute cortical slices and found that GLAST +/-, but not GLT-1 +/- mice, had epileptiform responses, similar to responses seen in the FL model. By recording NMDA currents in layer 5 pyramidal neurons, we found that GLAST +/- mice have enhanced ambient glutamate levels during neonatal development. This may lead to altered activation of glutamate receptors during critical developmental windows. Additionally, our preliminary studies suggest that spontaneous and miniature IPSCs are decreased in layer 5 pyramidal cells in GLAST +/-, but not GLT-1 +/- mice. This may result in a loss of inhibition which could lead to aberrant network activity in the

mature cortex. Taken together, our findings indicate that during development, there is a distinct role of GLAST, compared to GLT-1, and that decreasing GLAST during this critical developmental window may lead to aberrant network formation and hyperexcitability.

Title: Tracking astrocyte-synapse proximity dynamics in the striatum

Authors: *J. OCTEAU, B. S. KHAKH;
Deparment of Physiol., UCLA, Los Angeles, CA

Abstract: Astrocytes are ubiquitous glial cells that serve a variety of important homeostatic roles within neural circuits, such as regulating synapse formation/removal, and sensing synaptic transmission (1). Astrocytes are juxtaposed to synapses and increasing biochemical and imaging evidence suggests that astrocytes may modulate synaptic activity. However, it is unclear how astrocyte proximity to synapses directly influences synaptic transmission and if the spatial and functional interactions between fine distal astrocyte extensions called processes and synapses are dynamic. Progress in this regard has been severely limited by the lack of available methods that directly explore physical interactions between neurons and astrocytes. We report a new approach that remedies this shortfall. First, we report the rationale, design and testing of an approach that we call the Neuron-Astrocyte Proximity Assay (*NAPA*). This assay provides spatial information below the optical diffraction limit by exploiting cell surface probes of different length that undergo fluorescence resonance energy transfer between cognate donors and acceptors targeted to astrocyte processes and presynaptic axon terminals. Furthermore we use this assay to characterize, for the first time, the spatial interactions between astrocyte processes and synapses from distinct neural inputs in the striatum in live tissue. We report data on the testing and validation of this approach and employ this technique to interrogate intact circuits within the brain; we aim to provide a tool-kit to determine the dynamics and reveal the molecular basis of

functional interactions between fine astrocyte processes and synapses. The systematic use of this approach will help to unravel a number of questions that relate to the dynamic relationships between astrocytes and neurons within intact neural circuits as well as the effect of astrocyte-synapse proximity and dynamics on synaptic signaling.

Abstract: The functional and molecular similarities and distinctions between human and murine astrocytes are poorly understood. Here we report the development of an immunopanning method

to acutely purify astrocytes from fetal, juvenile, and adult human brains, and to maintain these cells in serum-free cultures. We found that human astrocytes have similar abilities to murine astrocytes in promoting neuronal survival, inducing functional synapse formation, and engulfing synaptosomes. In contrast to existing observations in mice, we found that mature human astrocytes respond robustly to glutamate. We next performed RNA-sequencing of healthy human astrocytes along with astrocytes from epileptic and tumor foci, and compared these to human neurons, oligodendrocytes, microglia, and endothelial cells. With these profiles, we identified novel human-specific astrocyte genes, and discovered a transcriptome-wide transformation between astrocyte precursor cells and mature post-mitotic astrocytes. These data represent some of the first cell type-specific molecular profiles of the healthy and diseased human brain.

Title: Functional and molecular profile of ventral midbrain astrocytes

Authors: *W. XIN[1,2], K. SCHUEBEL[3], K.-W. JAIR[3,4], D. GOLDMAN[3], A. BONCI[2,1]; [1]Neurosci., Johns Hopkins Univ., Baltimore, MD; [2]Cell. Neurobio., Natl. Inst. on Drug Abuse IRP, Baltimore, MD; [3]Lab. of Neurogenetics, Natl. Inst. on Alcohol Abuse and Alcoholism IRP, Bethesda, MD; [4]Epidemiology and Biostatistics, George Washington Univ., Washington, DC

Abstract: The ventral tegmental area (VTA) is a midbrain region critical for motivated behaviors. VTA neurons undergo profound intrinsic and synaptic changes following exposure to natural rewards, stress, and drugs of abuse. Astrocytes - the most abundant cell type in the brain - uptake and metabolize glutamate, buffer extracellular potassium levels to maintain ionic

gradients, and release neurotrophic factors to promote neuronal plasticity and survival. A comprehensive understanding of changes occurring in the VTA following stress or exposure to drugs will require the study of its resident astrocytes. Yet, very little is known about the properties of astrocytes in the VTA. Thus, we set out to define the basal characteristics of ventral midbrain astrocytes and determine whether they are functionally distinct from astrocytes in other brain regions. Because changes in astrocytic calcium levels have been linked to the release of various signaling molecules, we injected GFAP-cre animals with a cre-dependent virus to get preferential expression of the calcium indicator GCaMP6m in astrocytes. Using two-photon microscopy in acute slices, we observed distinct patterns of calcium elevations in hippocampal and VTA astrocytes in response to various agonists. To expand upon these observations, we made whole cell patch clamp recordings in tissue slices prepared from Aldh1L1 eGFP mice, in which eGFP selectively labels astrocytes. Similar to what we observed in calcium activity patterns, VTA and hippocampal astrocytes exhibited significantly different basal membrane properties. To better define the extent and nature of regional differences, we isolated astrocytes from both regions by fluorescence assisted cell sorting. Global transcriptional profiling by RNA sequencing revealed gene expression patterns sufficiently distinct to allow individual samples to cluster by region in principal component analysis. Collectively, these results demonstrate that VTA astrocytes are unique in their functional and molecular properties. This work provides the first direct comparison of functional properties between ventral midbrain astrocytes and those in more extensively studied brain regions, and lays the groundwork for future studies looking at the role of VTA astrocytes in reward-related behaviors, stress, and substance abuse disorders.

Title: Heterogeneity of glial populations in hippocampal dentate gyrus

Authors: *G. NASERI KOUZEHGARANI[1,2], M. U. GILLETTE[3,1,2];
[1]Neurosci. Program, [2]Beckman Inst., [3]Dept. of Cell & Developmental Biol., Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: Two distinct populations of astrocytes have been reported in the CA1 and CA3 layers of the hippocampus: (1) “Passive astrocytes” display linear voltage-current (IV) curves, express glutamate transporters, and are coupled through gap junctions; (2) “Complex astrocytes” show voltage-dependent currents, express AMPA-type glutamate receptors, and lack gap-junction coupling. NG2 (neuron-glia chondroitin sulphate proteoglycan 2) glial cells, also known as oligodendrocyte precursor cells, were initially categorized under “complex astrocytes” based on their voltage-gated ion conductance and expression of AMPA receptors. However, more recently they have been recognized as a separate class of glial cells. Direct somatic contacts between two NG2 glial cells and NG2-astrocyte pairs have been observed in the CA1 layer, but no dye-coupling was detected in these doublets (Xu *et al., Hippocampus* 2014). NG2 glial cells also have been found in the molecular layer of the adult hippocampal dentate gyrus, where a distinct population of astrocytes reside. However, little is known about structural, electrophysiological, and coupling dynamics of these two glial populations in this region, specifically with regards to the time of the day. Using whole-cell patch clamp recording, sulforhodamine-B (SR-B), a gap-junction permeable dye, was injected to a single cell and its spread to the neighboring cells was analyzed. In the case of astrocytes, the number of coupled cells was significantly higher during the night than the daytime. These coupled cells displayed linear voltage-current profiles with low resistances (<50 MΩ) at both time points. However, in cases where the injected dye was not transferred to other cells, indicating the lack of gap junctions, the injected astrocyte showed a non-linear voltage to current response with a high resistance value (250-350 MΩ). Non-coupled astrocytes were more prevalent during the daytime. We also found NG2 doublets in the dentate gyrus that were dye-coupled and exhibited linear IV profiles with low resistances. No coupling was observed between NG2 glial cells and astrocytes. Immunohistochemistry of the recorded slices post-fixation confirmed the identity of the injected cell as either astrocytes (GFAP-positive) or NG2 glial cells (NG2-positive). Our results demonstrate distinct physiological and coupling properties of two glial populations within the molecular layer of the hippocampal dentate gyrus with heterogeneous astrocytic subpopulations. These findings will facilitate studies to understand the functional dynamics of the NG2 glia and astrocytes.

Title: PreBötzinger complex astrocytes contribute to homeostatic control of breathing at rest and during exercise

Authors: *S. SHEIKHBAHAEI[1,2], E. TUROVSKY[2], N. MARINA[2], S. KASPAROV[3], J. C. SMITH[1], A. V. GOURINE[2];
[1]Cell. and Systems Neurobio. Section, Natl. Inst. of Hlth. (NIH)- NINDS, Bethesda, MD; [2]Neuroscience, Physiol. and Pharmacol., Univ. Col. London, London, United Kingdom; [3]Dept. of Physiol. and Pharmacol., Univ. of Bristol, Bristol, United Kingdom

Abstract: Release of gliotransmitters by astrocytes is implicated in the control of synaptic transmission and activities of neuronal networks. In mammals, breathing is generated by the preBötzinger complex (preBötC) - a group of brainstem interneurons that form respiratory rhythm-generating circuits. The signaling mechanisms and functional significance of preBötC control by astrocytes in vivo remain unknown. In this study, we genetically targeted preBötC astrocytes with adenoviral vectors to express the light chain of tetanus toxin (TeLC) or dominant-negative SNARE (dnSNARE) proteins. Either TeLC or dnSNARE expression was found to be sufficient to effectively block the mechanisms of vesicular release in transduced cultured astrocytes. Experiments performed in conscious adult rats demonstrated that bilateral expression of either TeLC or dnSNARE in preBötC astrocytes significantly reduced the resting respiratory rate by 11% (92 vs 103 min^{-1} in control rats expressing GFP in the preBötC astrocytes, n=12, p=0.011) and by 11% (94 vs 106 min^{-1} in controls, n=5, p=0.016), respectively. Moreover, the frequency of functionally important augmented breaths (sighs), produced by increased inspiratory effort was reduced in rats transduced to express TeLC or dnSNARE by 23% (n=12, p=0.001) and 26% (n=5, p= 0.002), respectively. Since exercise is associated with an augmented inspiratory effort to meet increased oxygen demands, we next determined whether compromised preBötC astrocyte signaling impairs exercise capacity (determined by the treadmill distance run by an animal to exhaustion). Expression of either TeLC or dnSNARE in preBötC astrocytes dramatically reduced exercise capacity (by 42%, n=12, p=0.001; and 58%, n=5, p=0.016, respectively). Cardiovascular responses during exercise were not affected by TeLC or dnSNARE expression, suggesting that reduced ability to exercise in conditions of impaired astroglial function within the preBötC is due to a respiratory deficit. These results suggest that vesicular release of signaling molecules by astrocytes provides tonic excitatory drive to the preBötC rhythm-generating circuits, contributes to generation of sighs, and is essential for an appropriate respiratory response to meet the increased metabolic demands of exercise.

Title: Immunohistochemical visualization of glycogen reveals age-dependent astrocytic distribution in the mouse brain

Authors: *Y. OE[1], O. BABA[2], H. ASHIDA[3], K. C. NAKAMURA[4], H. HIRASE[1,5];
[1]RIKEN BSI, Wako / Saitama, Japan; [2]Tokushima Univ., Tokushima, Japan; [3]Kobe Univ., Hyogo, Japan; [4]Univ. of Oxford, Oxford, United Kingdom; [5]Saitama Univ., Saitama, Japan

Abstract: Enzymatic breakdown of glycogen is an important process of anaerobic metabolism in low glucose conditions. In addition to supplying energy substrate, glycogen breakdown has been implied in synaptic plasticity and learning. Although astrocytes have been known to store high amounts of glycogen, glycogen distribution in the brain has not been described. Here, we investigate the distribution of cerebral glycogen by immunohistochemistry using two monoclonal antibodies that differ in affinity to glycogen of different sizes, in the awake-fixed mouse brain. The resultant staining displayed punctate distribution localized in astrocytes, which showed region-dependent and the cortical layer-dependent glycogen distribution patterns. Whereas cerebral cortical glycogen puncta are uniformly distributed at the macroscopic level, glycogen-rich astrocytes in the CA3-CA1 region of the hippocampus had a patchy distribution. Furthermore, we demonstrate that such hippocampal patchy distribution of glycogen disappears in aged mice.

Title: Prodromal events in the propagation of cortical spreading depression

Authors: *P. M. SAWANT, J. M. MENDEZ, P. SURYAVANSHI, J. THERIOT, K. C. BRENNAN;
Neurol., Univ. of Utah, Salt lake city, UT

Abstract: Cortical spreading depression (CSD) is involved in migraine, stroke, and brain injury. The mesoscopic electrical and hemodynamic changes caused by CSD have been extensively described, but this knowledge is not paralleled by a detailed understanding at cellular resolution. The clearest signature of CSD is the propagating wavefront, characterized by a simultaneous increase in extracellular glutamate concentration, intracellular calcium, and complete cellular depolarization, coincident with the classically defined direct current (DC) shift of CSD. However there has been some evidence of activity preceding this commonly accepted wavefront. We used a combination of *in vivo* whole-cell recordings of neurons and astrocytes, and optical techniques in mice to study the sequence of cellular events during CSD. We found that astrocytes exhibit both membrane depolarization and elevations in intracellular calcium tens of seconds before the CSD wavefront. Other changes those follow astrocytic activity, but still precede the wavefront are increases in extracellular potassium, neuronal volume changes, and tissue displacement. Finally, in whole cell recordings we found that neurons themselves exhibited a ramped depolarization that preceded paroxysmal changes in membrane potential at the wavefront, and appeared to correspond with elevations in extracellular potassium. Our data provides a deeper understanding of CSD as a complex multicellular phenomenon. Importantly, it suggests failure of astrocytic reuptake as a tipping point in CSD propagation.

Title: The role of SOC channels and other calcium fluxes in astrocyte calcium signaling investigated through mathematical modeling

Authors: G. HANDY[1], M. TAHERI[1], J. A. WHITE[2], *A. BORISYUK[1];
[1]Univ. of Utah, Salt Lake City, UT; [2]Dept. of BME, Boston U., Boston, MA

Abstract: Astrocytes make up approximately 50% of human brain volume and are roughly as numerous as neurons in the mammalian brain. Further, astrocytes have been shown to serve a number of critical roles in brain function, and calcium is believed to be a crucial second messenger in many of these pathways. Experimental evidence has shown that glutamate and ATP can evoke these calcium transients in astrocytes. However, the key mechanisms controlling these calcium transients remain under investigation.
Using two-photon microscopy, we collected experimental evidence of calcium activity in astrocytes, and used this data to develop a minimal ODE model of calcium transients evoked by short ATP applications. Our open-cell, single compartment model captures the diversity of calcium transients experimentally observed between trials and between astrocyte subcompartments. By varying key channel parameters, mimicking blockers used by experimentalists, we manipulate the underlying bifurcation structure of the full ODE system and investigate the specific roles of individual calcium fluxes located on the ER and the plasma membrane. Importantly, our model predicts that while store-operated calcium (SOC) channels remain relatively inactive during evoked responses, they are necessary for sustained calcium oscillations in astrocytes and for maintaining a diversity set of calcium responses. Further, our model also predicts a significant difference between using a partial and a complete blocker of SOC channels. Variation in the maximum flow in SOC and other channels and pumps in the model is also shown to significantly affect the range of stable oscillations, as well as the range of the intrinsic frequency of calcium responses. Moreover, by conducting a randomized search through the parameter space and recording the resulting calcium responses, we create a database

that can be used by experimentalists to help determine the underlying channel distribution in their cells.

Title: Diversity of GPCR-evoked calcium signaling in astrocytes investigated through experimental measurements and mathematical modeling

Authors: *M. TAHERI[1], G. HANDY[1], A. BORISYUK[1], J. A. WHITE[2];
[1]Univ. of Utah, Salt Lake City, UT; [2]Biomed. Engin., Boston Univ., Boston, MA

Abstract: Astrocytes, through their intracellular calcium signaling, can modulate synaptic transmission and play other important roles in the CNS. Yet, the mechanisms underlying astrocyte calcium signaling, and how these signals contribute to such functions, remain unclear. By pursuing coordinated experimental and modeling studies, our goal is to provide insight into the mechanisms and effects of astrocyte calcium signaling.
Experimentally, we use two-photon microscopy to measure calcium activity in astrocytes from crosses based on our novel PC::G5-tdT transgenic mice (available from JAX labs, stock no. 024477). These crosses express the genetically-encoded calcium indicator GCaMP5G in astrocytes. We evoke calcium activity through brief (<250 ms), focal applications of GPCR (G-protein coupled receptor) agonists with varying application durations and time intervals between applications. In parallel with experiments, we have developed a mathematical model for astrocyte calcium dynamics. Using our experimental and modeling results, we categorize calcium responses into four types: Single-Peak, Multi-Peak, Plateau, and Long-Lasting. We use calcium response types and kinetics (e.g. duration, rise and decay times) to quantify variability observed in astrocyte responses, such as the response variability between the astrocyte soma,

large processes, and small processes. Using our model, we examine in detail the underlying mechanisms of this response variability, which can be attributed to: (1) temporal dynamics of IP3, and (2) relative calcium flux rates through various channels/pumps. With this analysis, we predict that the IP3 kinetics and the relative level of calcium fluxes through different channels/pumps varies systematically between different astrocyte subcompartments. Lastly, we are examining the responses of astrocytes to repeated stimuli, and using the data and model to understand the refractory behavior of calcium transients in the cell body and processes.

Title: Panglial calcium signaling in the olfactory bulb

Authors: *C. LOHR, A. B. BEIERSDORFER, D. DROSTE;
Univ. of Hamburg, Hamburg, Germany

Abstract: Olfactory ensheathing cells (OECs) ensheath axon bundles of olfactory receptor neurons (ORN) in the peripheral olfactory nerve and the nerve layer, the superficial layer of the olfactory bulb. The nerve layer is considered to be devoid of synapses, however, extrasynaptic release of glutamate and ATP from ORN axons and subsequent activation of metabotropic glutamate receptor mGluR1 and ATP receptor P2Y1 evokes calcium signaling in OECs (Thyssen et al., PNAS, 2010). In brain slices, suppressing this axon-OEC communication by antagonists of mGluR1 and P2Y1 entirely blocks calcium signaling in OECs. We recently developed an olfactory bulb *in-toto* preparation, in which long-range connections within the OB remain intact, in contrast to brain slices. In the present study, we compaired cell-cell communication between brain slices and the *in-toto* preparation using confocal calcium imaging. In the *in-toto* preparation, neuronal activation either by electrical stimulation of ORN axons or application of NMDA evoked calcium transients in OECs that were not significantly inhibited by antagonists of mGluR1 and P2Y1, in contrast to brain slices. NMDA-evoked calcium signals first appeared in deeper layers of the olfactory bulb, in particular in juxtaglomerular cells such as astrocytes, and with a delay in OECs. We found that blocking calcium-permeable AMPA receptors in juxtaglomerular astrocytes not only suppressed NMDA-evoked calcium signaling in astrocytes,

but also in OECs. Laser photolysis of caged t-ACPD, an agonist for mGluR, evoked calcium transients in juxtaglomerular astrocytes that propagated into OECs with a delay. Both astrocytes and OECs express connexin 43, and inhibition of gap-junctions with carbenoxolone suppressed calcium wave propagation from astrocytes into OECs, whereas calcium signaling in astrocytes remained unaffected. We conclude that neuronal release of glutamate in glomeruli activates calcium signaling in astrocytes via calcium-permeable AMPA receptors and mGluR5. These calcium transients are transferred through the panglial network into OECs via gap junctions. The panglial network is largly disconnected in brain slices, in which calcium signal propagation from astrocytes to OECs could not be detected.

Abstract: Astrocytes exhibit increases in calcium concentration both in their cell bodies and fine processes in response to certain neurotransmitters. Few studies have examined astrocyte calcium signals in the hippocampus of awake, behaving animals. We express GCaMP in astrocytes using viral vectors, and image their calcium signals during behavior using in vivo two-photon microscopy. We are examining their calcium signals specifically in response to various stimuli, and during navigation on a cue-rich treadmill belt. We are determining which stimuli astrocytes respond to, and whether their responses change during goal-oriented reward learning of a hidden rewards task. In addition, astrocytes in visual cortex, barrel cortex and cerebellum have been shown to respond to norepinephrine - we expect astrocytes in the hippocampus to respond to norepinephrine as well. We are imaging calcium activity in axon terminals projecting from the locus ceruleus, which makes norepinephrine and projects to the hippocampus, to determine the response to reward in these terminals. In addition, we are examining whether this activity

changes over time, and whether calcium activity in axons projecting from the locus ceruleus is correlated with calcium responses in astrocytes.

Title: Computational modeling of Ca^{2+} signals in astrocytic processes

Authors: *F. OSCHMANN[1,2], K. OBERMAYER[1,2];
[1]Neural Information Processing Group, Berlin, Germany; [2]Bernstein Ctr. for Computat. Neurosci., Berlin, Germany

Abstract: Ca^{2+} signals in astrocytes are evoked by neurotransmitters like glutamate. Binding of glutamate to metabotropic glutamate receptors (mGluRs) induces the production of a second messenger (IP_3), which then evokes Ca^{2+} release from internal Ca^{2+} stores, the endoplasmatic reticulum (ER).
However, different experimental results showed not only a clear attenuation of Ca^{2+} signals during an inhibition of the IP_3 mediated pathway, but also during the block of the glutamate transporter (GluT). Those various experimental results can be explained by different signaling mechanisms in the astrocytic soma and in the processes. Ca^{2+} signals in the soma are mainly evoked on the IP_3 mediated pathway, whereas in processes most Ca^{2+} signals are evoked by Ca^{2+} entry over the plasma membrane (Srinivasan et al., 2015). This assumption is supported by the finding, that perisynaptic astrocytic processes (PAPs) are devoid of intracellular Ca^{2+} stores and the volume ratio of the ER increases towards the soma (Patrushev et al., 2013).
Most mathematical models describing Ca^{2+} signals in astrocytes focus on the IP_3 mediated pathway and completely neglect the impact of the GluT and Ca^{2+} entry over the plasma membrane. To fill this gap, we extended a model for IP_3 mediated Ca^{2+} signals in astrocytes with a mechanism including the GluT. Our extension is based on the hypothesis that sodium entry via the GluT activates the Na^{+}-Ca^{2+} exchanger (NCX) in the reverse mode bringing Ca^{2+} into the cytosol. In addition we included the volume ratio of the ER into the model in order to analyze Ca^{2+} signals either in the soma or in astrocyte processes.

Our model results confirm that Ca^{2+} signals in the soma mainly depend on the IP_3 mediated pathway, whereas in processes Ca^{2+} signals are evoked by Ca^{2+} entry over the membrane. The model does not only allow to study the binary Ca^{2+} response during a block of either of both pathways, but also the reduction of channel densities and their impact on the interaction of both pathways and on the Ca^{2+} signal.
Thus, the model serves as a description of a single astrocyte compartment with respect to the volume ratio of the ER, which can be extended to a multi-compartment model describing the spread of Ca^{2+} signals within a single astrocyte or a network of astrocytes.

Title: Astrocyte calcium signals show distinct cellular compartmentation and cortical layer-dependent responses to sensory stimulation *In vivo*

Authors: *K. D. FERRARI[1,2], J. L. STOBART[1,2], M. J. P. BARRETT[1,2], B. WEBER[1,2]; [1]Inst. of Pharmacol. and Toxicology, Univ. Zürich, Zuerich, Switzerland; [2]Neurosci. Ctr. Zurich, Univ. and ETH Zurich, Zuerich, Switzerland

Abstract: Astrocytes are the main glial cell population in the central nervous system and respond to neuronal activity with intracellular calcium fluctuations. Recent studies with genetically encoded calcium indicators (GECIs) have shown that localized, heterogeneous calcium transients occur throughout astrocytes, but how this signalling responds to sensory stimulation remains unclear. Here, we used the GECI, GCaMP6s, in combination with two-photon microscopy and an automated, activity-based image analysis scheme to monitor astrocyte calcium signals in the somatosensory cortex *in vivo*. We observed spontaneous activity in astrocyte processes, somata and endfeet, but the signalling characteristics varied between the different sub-cellular compartments. Both electrical hindpaw stimulation and brief single-whisker deflection evoked an increase in astrocyte calcium. Closer examination of the individual signals showed that sensory stimulation elevated the number of specific types of calcium peaks within astrocyte fine processes and somata in a layer-dependent manner, and that the signals became more synchronous upon sensory stimulation. We also followed the same astrocyte

populations over two months and found that endfeet and somata responded to stimulation on multiple days, while different processes were activated. These results help to characterize the complexity of astrocytic calcium signalling and suggest that astrocytes may integrate and encode local neuronal network activity through different calcium signalling mechanisms.

Title: Origin and dynamics of astrocytic Ca^{2+} signals at activated hippocampal CA3-CA1 synapses of adult mouse

Authors: *W. TANG, G. F. VINDEDAL, J. B. HJUKSE, V. JENSEN, E. A. NAGELHUS; Letten Ctr. and GliaLab, Div. of Physiology, Dep. of Mol. Med., Inst. of Basic Med. Sciences,University of Oslo, Oslo, Norway

Abstract: Modern neuroimaging technology has revolutionized our knowledge on the function of astrocytes, the predominant glial cell type in the brain. The advent of ultrasensitive genetically encoded fluorescent activity sensors opens for monitoring neural circuit function at subcellular resolution in mature animals. Taking advantage of the optimized red and green fluorescent Ca^{2+} sensors jRGECO1a and GCaMP6f we performed dual color 2-photon imaging of neurons and astrocytes in acute hippocampal slices during electrical stimulation of the Schaffer collateral pathway. We report that the latency of astrocytic Ca^{2+} signals depended on the stimulation protocol, being only ~ 1 s during theta burst stimulation and twice as long during 20 Hz stimulation. In experiments using iGluSnFR we revealed that extracellular glutamate levels also differed between the two stimulation protocols, reaching higher levels following theta bursts than after 20 Hz stimulation. The stimulation-evoked Ca^{2+} transients in all astrocytic compartments were prominently reduced in mice lacking the inositol triphosphate type 2 receptor. In conclusion, our study shows that the dynamics of astrocytic Ca^{2+} signals is dependent on the neuronal activity pattern and that Ca^{2+} release from internal stores are the predominant source of astrocytic Ca^{2+} signals at activated CA3-CA1 synapses.

Title: Both chemical and genetically encoded Ca^{2+} indicators reveal fast Ca^{2+} responses in astrocyte processes and end-feet to somatosensory stimulation.

Authors: *B. L. LIND, S. JESSEN, M. LØNSTRUP, M. LAURITZEN;
Univ. Copenhagen, Copenhagen, Denmark

Abstract: Cerebral blood flow (CBF) is regulated by the activity of neurons and astrocytes. Knowledge of how these cells control activity-dependent rises in CBF by Ca^{2+} signals is crucial for an understanding of functional neuroimaging signals. The relative importance of neurons and astrocytes is much debated and there is a controversy as to the functional implications of fast Ca^{2+} changes in astrocytes versus neurons. We here assessed Ca^{2+} changes in the neuropil, astrocytic processes and end-feet in response to whisker pad stimulation in mice by 2-photon-microscopy. We used a pixel-based analysis which we have developed to improve detection of fast Ca^{2+} signals in these sub-cellular compartments. Though the astrocytic responses were within 150 ms after the stimulation they still differed from neuropil Ca^{2+} changes with regards to response frequency, onset time and peak time. To affect Ca^{2+} rises in neuropil and astrocytes without affecting CBF we used low doses of the NMDA receptor antagonist MK801. MK801 attenuated fast Ca^{2+} responses in neuropil and astrocytic processes, but not in astrocytic end-feet. In addition we found that THIP, an agonist for the extrasynaptic $GABA_A$ receptor, at a low dose increased both CBF responses and fast Ca^{2+} response in astrocytic end-feet, while Ca^{2+} responses in astrocyte processes and neuropil were unaffected. To verify that the fast astrocytic Ca^{2+} signals were not a contamination from neurons, but indeed astrocytic we used AAV9-cyto-GCamP6f under the GFAP promoter. We report similar fast Ca^{2+} responses in astrocytes using the genetically encoded cell-specific Ca^{2+} indicator as when using OGB-1 that labels all cell types. Our work supports the finding that astrocytes respond to synaptic transmission. The fast Ca^{2+} rises in neuropil and astrocytic process were sensitive to NMDA receptor activity, but

neither was necessary for the development of a full stimulation-induced CBF response. In comparison, local Ca^{2+} mechanisms in astrocytic end-feet were unaffected by MK801, but increased by $GABA_AR$ dependent mechanisms in parallel with increased CBF responses. We hypothesize that the production of fast Ca^{2+} rises in end-feet adjusts CBF during rises in synaptic activity.

Title: External K+ elevation causes a decrease in astrocyte resting calcium

Authors: *S. S. SHIN, G. R. GORDON;
Univ. of Calgary, Calgary, AB, Canada

Abstract: Astrocytes rely on rapid changes in free intracellular Ca2+ to regulate neuronal function via their fine processes that wrap synapses, as well as to regulate the blood supply through their endfoot processes that appose blood vessels. An important initiator of some key astrocyte functions is a change in the external K+ concentration, which occurs from changes in neuronal action potential signaling. However, links between external elevations in K+ and astrocyte Ca2+ signalling remain poorly defined. For instance, only upon reaching extremely high extracellular K+ (>20 mM) in pathology do astrocytes exhibit large, rapid increases in free intracellular Ca2+. We pondered whether astroctyes could respond to smaller, physiological increases in K+ with slower or subtler changes in free Ca2+. Using a two-dye, ratio-metric imaging approach with two-photon fluorescence microscopy, we examined the resting free Ca2+ concentration in astrocytes in response to bath application of isosmotic high K+ solution. Specifically, acute neocortical brain slices from Sprague Dawley rats were bulk loaded with a bright, orange-red Ca2+ indicator - Rhod-2/AM, as well as with a green morphological dye - Calcein/AM. By taking the ratio of Rhod-2/Calcein, we could measure relative changes in resting Ca2+ in the soma while controlling for any changes in signal that result from fluctuations

in cell volume. We found that an elevation from 2.5 mM to 5 mM external K+ caused a significant decrease in astrocyte Ca2+ (-11.9 +/- 1.8%, n=9, p<0.0001). The effect was dose dependent, showing an even larger drop (-28.2 +/- 6.8%, n=5, p<0.05) in response to an increase to 7.5 mM external K+. The decrease in astrocyte Ca2+ lasted only for the K+ application, with Ca2+ fully recovering to baseline values after 20 minutes of washout. Our data demonstrate a previously unrecognized phenomenon in astrocytes, in which relatively small elevations in external K+ decrease resting astrocyte Ca2+ levels. We speculate that this cell-wide change to the resting cytosolic Ca2+ concentration will impact Ca2+-dependent astrocyte control pathways in the regulation of synapses and vasculature.

Title: Calcium signaling in fibroblast growth factor receptor 1 knockout astrocytes from cortex, hippocampus and tanycyte cultures

Authors: *D. J. ROGERS[1], B. BERGERON, 70504[2], M. SIDES[2], L. GATHANGA[2], K. M. SMITH, 70504[2];
[1]Univ. of Louisiana at Lafayette, Rayville, LA; [2]Biol., Univ. of Louisiana at Lafayette, Lafayette, LA

Abstract: Fibroblast Growth Factor Receptor 1(FGFR1), a plasma membrane receptor, is a focal point for multiple intracellular pathways. One involves calcium signaling through phosphorylation of one of its substrates, Phospholipase C (PLC). Phospholipase C is intricately involved with intracellular calcium signaling through Inositol 3 Phosphate (IP3) pathway resulting in a release of calcium from intracellular stores. Astrocytes have been shown to express their communications through calcium signaling. Tanycytes, a type of astrocytes that line the third ventricle, have long processes that extend into the arcuate nucleus of the hypothalamus, placing these cells in a dynamic homeostatic connection between somatic body and the brain via the cerebrospinal fluid. Using fluorescent calcium indicator, Fluo 3 AM, intracellular calcium signaling was investigated in Tanycyte cultures harvested from p2-4 C57BL6 mice, $FGFR1^{Flox/Flox;NestinCre}$, and control $FGFR^{+/+}$ or $FGFR1^{+/-;NestinCre}$ littermates. Preliminary results

show no significant differences in number of peaks between these three groups. Compared to cortical and hippocampal astrocyte cultures, the tanycyte nuclear signaling appears to be less intensive whereas cytoplasmic signaling appears to be more.
Cortical astrocyte cultures from *FGFR1*$^{Flox/Flox;NestinCre}$ mice showed a mean intensity difference from baseline = 39 grey values ± 35.8. ; control mean intensity difference from baseline = 63 grey values ± 44.6 p=0.6. The calcium wave duration at the nucleus was compared. The *FGFR1*$^{Flox/Flox;NestinCre}$ astrocytes exhibited about a 4 times slower wave than the control. *FGFR1*$^{Flox/Flox;NestinCre}$ wave duration = 14.1 sec ± 5.6. Control wave duration = 3.7 sec ± 2.34 p=1.98x10^{-11}.
Anxiety behavior was tested on *FGFR1*$^{Flox/Flox;NestinCre}$ and control littermates. Previous studies involving 2-4 month old FGFR1 Knock out mice using HGFAP driver was shown by Smith et al (2008) to decrease Parvalbumin GABAergic interneurons and increase hyperactivity. The HGFAP Cre recombinase driver knocks out FGFR1 beginning at E13.5, whereas, the Nestin cre driver knocks out FGFR1 in the stem cells. In this study using the Elevated Plus Maze, 2-4 month old *FGFR1*$^{Flox/Flox;NestinCre}$ mice demonstrated a significantly less anxious behavior. *FGFR1*$^{Flox/Flox;NestinCre}$ mice had fewer freezing episodes (p=0.0366**FGFR1*$^{Flox/Flox;NestinCre}$ = 7, control = 4) and less time freezing (p=0.0167* *FGFR1*$^{Flox/Flox;NestinCre}$ = 7, control = 4) than control littermates.
These preliminary results indicate that the decreased function of astrocytes in the *FGFR1*$^{Flox/Flox;NestinCre}$ may contribute to their altered behavioral profile.

Title: Mediators of astrocyte Ca^{2+}-independent neurovascular coupling

Authors: *A. INSTITORIS, G. R. GORDON;
Dept. of Physiol. & Pharmacology, Cumming Sch. of Medicine, Univ., Hotchkiss Brain Inst., Calgary, AB, Canada

Abstract: Ca^{2+} dependent pathways in neurons and astrocyte endfeet can initiate arteriole diameter changes to control local blood perfusion. Discrepancies between the clear involvement of Ca^{2+} transients in astrocyte endfeet in brain slices versus controversial endfeet signals *in vivo* during functional hyperemia (or lack of signals), prompted us to determine whether astrocytes are essential contributors to synaptic activation-induced arteriolar dilation. Imaging synthetic and genetic (GCaMP) Ca^{2+} indicators in acute rat brain slices of the sensory cortex with 2-photon fluorescence microscopy, we discovered a threshold of synaptic activation below which astrocyte endfeet Ca^{2+} transients are absent in response to brief, moderate electrical stimulation (5s 20Hz, minimal voltage) that evokes arteriole dilation (termed 'subthreshold stimulation'). Subthreshold stimulation-evoked neuronal Ca^{2+} transients and vasodilation was significantly reduced by α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)-receptor blockage but not by N-methyl-D-aspartate receptor inhibition. Blocking nitric oxide (NO) synthesis attenuated vasodilation but had no effect on Ca^{2+} signals. Phospholipase A_2 and D inhibition, as well as inward rectifier and Ca^{2+}-sensitive potassium channel inhibitors had no effect. Surprisingly we observed an almost complete inhibition of subthreshold stimulation-induced vasodilation with intact Ca^{2+} responses in the presence of an andenosine A2 receptor blocker. In awake, active mice, two-photon imaging of astrocyte endfeet through a closed cranial window showed no elevation in endfoot Ca2+ prior to the dilation of penetrating arterioles in the barrel cortex in response to a 5s air puff to the whiskers. In summary we provide evidence that sensory stimulation does not recruit astrocyte endfeet to mediate functional hyperemia and postulate that neuronal AMPA receptors, NO and adenosine are key regulators of activity-dependent vasodilation.

Title: Fast scanning 2-photon microscopy of the blood-brain barrier properties in single capillaries in living mice

Authors: *N. KUTUZOV[1], H. FLYVBJERG[2], M. LAURITZEN[1];
[1]Univ. of Copenhagen, Kobenhavn N, Denmark; [2]Tech. Univ. of Denmark, Copenhagen, Denmark

Abstract: The present study aimed to provide a quantitative methodology to study the transport of fluorescent tracers at the BBB in single capillaries in living mice. Measurements were performed on anesthetized C57bl6/j mice. Different types of fluorescent tracers were injected into the bloodstream intravenously and visualized using a two-photon microscope. Using fast 2-photon imaging of single brain capillaries filled with a fluorescent tracer, we were able to show that recorded data contains spatio-temporal information, which can be used to study the transport at the BBB level. Numerical solutions of the diffusion equation were used to fit the experimentally measured data and obtain estimates for the diffusion coefficients of different fluorescent tracers. Machine learning-based image analysis algorithms were employed to extract the information about the glycocalycal layer, which comprises an important initial barrier for every compound in the circulation which is targeted to the brain.Developed tools allows to analyse the transport process of a fluorescent substance from the capillary lumen to the extravascular space.

Abstract: Astrocytic G protein-coupled receptors (GPCRs) have been demonstrated to be a key regulator of synaptic plasticity. While Gq signal activation in astrocytes can be visualized by Ca^{2+} imaging because of the robust IP_3-dependent Ca^{2+} release from internal stores, Gs and Gi signaling has not been well characterized in the mouse cortex *in vivo*. Here we image cAMP levels of astrocytes using a monochromatic fluorescent cAMP indicator Flamindo 2 in living

mice. Flamindo2 was expressed in cortical astrocytes using a recombinant AAV vector with a human GFAP promoter. In urethane-anesthetized mice, brain surface application of folskolin and IBMX decreased Flamindo2 fluorescence signal by ~25 percent in the somata, suggesting an increase of cAMP level. Moreover, adenylyl cyclase inhibitor SQ22536 application resulted in an increased Flamindo2 fluorescence signal indicating a decrease of cAMP level. These fluorescent signal changes occur in a time course of several minutes. Next we compared the astrocytic cAMP level between awake and isoflurane-anesthesia states. Preliminary results show that astrocytic Flamindo2 fluorescence decreased by ~20 percent in isoflurane-anesthetized states, indicating an increase of cAMP. These data suggest that astrocytic cAMP levels are differentially regulated in distinct brain states. Moreover, Flamindo2 is useful to monitor Gs and Gi GPCR activation *in vivo*.

Abstract: Astrocytes are electrically non-excitable cells that can integrate synaptic transmission by dynamic increases in cytosolic calcium. The mechanistic details of astroglial calcium signaling are hotly debated now. Physiological implications of diverse spatial, temporal and biochemical activators and modulators of astroglial calcium signals and their age-related alterations are yet to be fully understood. The functional abilities of astrocytes are critically depend on the level of expression and the subtypes of receptors on their membrane. The expression values of different receptors and their exact contribution to calcium signaling are still to be fully understood.
In the present study we demonstrate region- and age-dependent heterogeneity in the expression values of genes involved in the calcium signaling pathway. We performed differential gene

expression (DGE) analysis (by DESeq2) of RNA-Seq data obtained from cortex and brainstem of P3 and P11-12 rats. Cortical astrocytes of P3 rats compared to P11-12 show statistically significant elevation in the expression of the receptors of Gs-dependent signaling pathway (such as adrenoreceptors Adrb1, Adrb2, Adrb4, adenosine receptors Adora2a, Adora2b), particularly cAMP-dependent protein kinase A (PKA), as well as increased expression of cAMP-dependent protein kinase A (PLCε) and PLCγ, the latter might be a target for different growth factors, and sphingosine kinase, which is involved in the corresponding SPHK/S1P signaling pathway. Brainstem astrocytes of P3 rats compared to P11-12 show statistically significant increase in the expression values of the receptors of Gs-dependent signaling pathway, particularly cAMP-dependent PKA and adenylate cyclase (ADCY); elevated expression of the receptors of Gq-dependent signaling pathway (such as adenosine receptors Adora1b, adrenoreceptors Adra1d, Adra1a, metabotropic glutamate receptors Grm1, Grm5), as well as expression values of CaV2 and CaV3 and PLCε. Cortical astrocytes of P3 rats show increased expression of CaV2, CaV3, components of Gs-dependent signaling pathway and ryanodine receptor RYR compared to brainstem astrocytes of P3 rats. Cortical astrocytes of P11-12 rats compared to brainstem astrocytes of P11-12 rats show increased expression of both Gs- and Gq-dependent signaling pathways as well as receptor-operated channels (ROC), such as purinergic receptors P2RX and ionotropic glutamate receptors Grin1 and Grin2.
Altogether obtained data indicate on functional region- and age-dependent heterogeneity of astrocytes regarding the expression of receptors involved in calcium signaling.

Title: Quantitative evaluation of optogenetically-induced calcium signaling in astrocytes

Authors: *L. BALACHANDAR[1], D. BORREGO[1], J. CHAMBERS[2], J. DIAZ[1];
[2]Herbert Wertheim Col. of Med., [1]Florida Intl. Univ., Miami, FL

Abstract: Optogenetics, a modern technique in neuroscience to control excitable cells with light, has recently been used on electrically non excitable cells like astrocytes (Figueiredo et-al., 2010). Our recent studies have been on evaluating the mechanisms by which light-activated channelrhodopsins affect the behavior of such non-excitable cells and aim to clearly identify and

quantify it. We have established and discussed methodologies, to stimulate astrocytes with light *in vitro* and formulated the protocol to find the ideal light stimulation parameters to achieve calcium signals in the cells conferred with light sensitivity by transfection of astrocytes with the optogenetic construct. A biophysical model (Stefanescu et al., 2012) was employed to quantify the spontaneous calcium oscillations in astrocytes. Based on this, we found that there is a particular light stimulation window, within which astrocytes are activated. While low light leads to no activation, very high levels of light leads to saturation of the astrocytic calcium signaling. Transduction using viral vectors of various serotypes led to poor efficiencies *in vitro*, at different serotypes and at various Multiplicity of infections (MOIs). However, due to the to the lack of a systematic study to determine the ideal serotype and dosage and due to a plethora of experimental variation of parameters *in vitro*, an *in vivo* study to optimize these parameters is essential. Our current research is focused on finding the ideal serotype and dosage of the optogenetic virus in a rat model to target astrocytes. The plausible ones are AAV1 and AAV8 (Aschauer et al., 2013, Petrosyan et al., 2014), which would bring about desired expression of the gene conferring light sensitivity to the astrocytes, and thereby allowing us to control them, using light. The validation will be done by post mortem histological analysis to determine viral expression. This approach using optogenetics would help in gaining control over astrocytes via light, and we hypothesize in our study that this could be crucial in controlling seizure perpetuation in epilepsy and other brain disorders involving neuroinflammation like autism, epilepsy, traumatic brain injury etc.

Title: Layer specific adult astroglia subtypes: influenced by neuronal subtypes and promote neuronal health

Authors: *S. J. MILLER, J. D. ROTHSTEIN;
Neurology/Cellular & Mol. Med., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: Astroglia are the most elaborate, abundant, and diverse cell type in the CNS. To date, we recognize that astroglia are heterogeneous but we restrict this cell type to two groups: fibrous and protoplasmic. We have now reliability identified a unique cortical layer specific population of astroglia defined by molecular and physiological properties. These studies highlight the fact

that adult astroglia, although morphologically similar, are in fact a diverse group of subgroups subserving varied and regional functions. During our efforts to uncover astroglia subtypes, we employed various astroglia GLT1/EAAT2 promotor reporter (TdTom) mice with various promotor construct sizes. These in vivo tools were able to reveal a subset of cortical astroglia, which were then FACS and molecularly and proteome profiled. Genes and proteins highly unique to these cortical astroglia were identified. These molecularly defined astroglia were validated by examining human cortical tissue and human iPS derived astroglia. Now we show that in both murine and human that multiple markers are capable of consistently labeling this subtype. Furthermore, we explored their physiological influence of this subset on neurons and vice versa. We uncovered that this subpopulation, enriched in layer II/III and V in the adult cortex, secretes neurotrophins responsible for modulating synapse formation. Additionally, we found that neuronal-subgroups in corresponding layers to tdTom-astros distribution, secrete a ligand that promotes the proliferation of tdTom-astros. In aggregate, we are beginning to establish that these layer V tdTom-astros are a unique subtype of astroglia that play influential roles to neighboring cells and in return, these neighboring cells such as neurons, promote their abundance.

Abstract: Although reactive astrocytes are rapidly generated following brain injuries and neurodegenerative and neuroinflammatory diseases, their role in trauma and disease states is not well understood. Previously we distinguished two reactive astrocyte subclasses based on the kind of inducing injury. We named these classes “A1” and “A2”. Based on their gene profiles we hypothesized that they were harmful and helpful respectively. Here we show that the harmful A1 reactive astrocytes are induced by classically-activated neuroinflammatory microglia. We further found that activated microglia induce A1s by secreting Il-1α, TNFα, and C1q, and that these factors together are necessary and sufficient to induce A1s both *in vitro* and *in vivo*. We demonstrate that A1s have little ability to promote neuronal survival, outgrowth, synaptogenesis or phagocytosis and instead are powerfully neurotoxic to neurons and oligodendrocytes, rapidly inducing apoptosis. We further show that A1s are present in human Alzheimer’s disease, Huntington Disease, Amyotrophic Lateral Sclerosis, and Multiple Sclerosis, and that death of axotomized CNS neurons is prevented when A1 formation is blocked with neutralizing antibodies to Il-1α, TNFα, and C1q. Taken together our findings explain why CNS neurons die after axotomy, strongly suggest that A1s drive death of neurons and oligodendrocytes in neurodegenerative disorders, and point the way forward for developing new treatments for these diseases.

Title: Astrocytes in the brain and chondrocytes in the joints are target cells of inflammation

Authors: *E. L. HANSSON[1], E. SKIÖLDEBRAND[2];
[1]Inst. of Neurosci. and Physiol., Goeteborg, Sweden; [2]Inst. of Biomedicine, Gothenburg, Sweden

Abstract: Inflammation can be initiated *in vivo* after traumatic injury or in response to mechanical overload. Gap junction coupled cells may be targets for co-morbidity leading to spread of inflammation and changes in biochemical cellular parameters. These cells are excitable but do not express action potentials. They are equipped with Ca^{2+} signaling systems, which can be intercellular and/or extracellular. The transport of small molecules between the cells occurs through gap junctions comprising connexin 43 (Cx43). Examples of cells coupled into networks include astrocytes, keratinocytes, chondrocytes, synovial fibroblasts, osteoblasts, connective tissue cells, cardiac and corneal fibroblasts, myofibroblasts, hepatocytes, and different types of glandular cells. Astrocytes in the CNS are the most well studied network coupled cells which play a pivotal role in chronic neuroinflammation.
During inflammation, the expression and affinities of several receptors are changed. The cytoskeleton is disrupted into more diffuse and ring-structured actin filaments. Ca^{2+} signaling is elevated, resulting in increased ATP production and increased Ca^{2+} release from internal stores thereby changing the balance of Ca^{2+}-regulating processes. This causes reduced communication via gap junctions. Sodium transporters are downregulated. Increased release of pro-inflammatory cytokines is seen.
Osteoarthritis is a chronic progressive low-grade inflammatory disease that involves several structures in the joint leading to impaired joint mobility and pain. The chondrocytes in the superficial layer of the articular cartilage form cellular processes containing gap junctions that enable cell-to-cell communication and form three-dimensional networks. Chondrocytes are part of the inflammatory reactive network-coupled cells in the body. They produce synchronized Ca^{2+} waves and are excitable in response to stimulation with several transmitters. Expression of Cx43 is changed and expression of TLR4 is increased as well as the active form of MMP-13.
Our data show that the cell functions of healthy chondrocytes as well as inflamed, resemble the astrocyte networks.

Paris 06, Paris, France

Abstract: Alexander disease is a primary astrocytic disorder due to dominant mutation in the Glial fibrillary acidic protein (GFAP) gene, encoding the main intermediate filament of astrocyte. Several clinical forms have been described for this progressive disorder of the CNS, ranging from early-onset forms with severe leucodystrophy and forms with predominant lesions in the hindbrain and spinal cord and less white matter involvement. However, whatever the clinical form, Alexander disease is characterized by the presence of cytoplasmic protein aggregates of astrocytes called Rosenthal fibers containing GFAP and other proteins. The accumulation of GFAP with Rosenthal fibers, in patients and several animal models, seems to be the starting point of the degenerative process. To explain how this primary astrocytic dysfunction affects the function of other CNS cells several in vitro and in vivo models have been studied. Inhibition of proteasome activity, activation of stress kinase pathways, activation of mTOR and inflammatory response have been described in several animal models with no defect in myelination. We have generated new knock-in mice with missense mutations homologous to those found in humans, one in the rod domain (R85C) and one in the tail (T409I) of GFAP, to study the pathology of Alexander disease. We showed that mice with GFAP-R85C and -T409I mutations developed Rosenthal fibers and gliosis. By immunohistochemistry and Western analysis, GFAP expression was increased in both mice mutants compared to littermate controls at 10 weeks of age, expression being highest in homozygous mutant mice. Also at this age, microglial activation with increased levels of Iba1 and microglial cells density were demonstrated. Astrogliosis and microglial activation were prominent in the hippocampus and we also observed decreased density of Doublecortin positive cells in the dentate gyrus of both mutant mice. Nevertheless, in the subgranular zone we noticed different morphological changes of radial glia-like cells between the two mutants with a near absence of astrocytic processes through the granular zone in mice with mutation in the tail domain. In conclusion, our two knock-in mice models display astrogliosis associated with microglial activation and impaired adult hippocampal neurogenesis. Interestingly, some differences were observed between the rod domain and the tail mutants. Thus these mice are good models to try several therapeutic strategies for this devastating neurological disease.

Title: Gene silencing of adenosine kinase in astrocytes reverses cranial radiation-induced cognitive impairments

Authors: *M. M. ACHARYA[1], J. E. BAULCH[1], B. D. ALLEN[1], Z. WANG[2], N. RU[1], T. H. NGUYEN[1], A. D. BADDOUR[1], V. K. PARIHAR[1], C. L. LIMOLI[1,2], D. BOISON[2];
[1]Dept of Radiation Oncology, Univ. of California Irvine, Irvine, CA; [2]Legacy Res. Inst., R. S. Dow Neurobio. Lab., Portland, OR

Abstract: The unintended neurocognitive sequelae resulting from clinical radiation therapy (RT) for CNS malignancies are both progressive and debilitating. An increasing number of cancer survivors, especially children, endure persisting cognitive decrements that adversely affect quality of life with no clinical recourse. However, the molecular mechanisms underlying RT-induced cognitive decline (RICD) have not been resolved. Since cranial RT causes astro-glial activation, we hypothesized that adverse changes in astrocyte function might be implicated in RICD. Among other gliotransmitters, astrocytes control the availability of adenosine, an endogenous neuroprotectant and modulator of cognition, via metabolic clearance through adenosine kinase (ADK). Our previous data showed that pharmacologic inhibition of ADK pre-RT prevented development of RICD and astrogliosis (Acharya et al., 2016). To better understand the mechanistic regulation of astrocyte-mediated adenosine modulation, we utilized the AAV8-based Adk-miRNA vector (Adk-KO) to study the CNS-radiation response and its impact on cognitive function. Adk-KO vector (under gfaABC1D promoter), designed to knock down astrocytic ADK, provides a powerful tool to mechanistically dissect the role of ADK in the pathology of RICD. Adult WT mice receiving cranial RT (9 Gy) and stereotaxic (intra-hippocampal) injection of control (scrambled) vector showed significant decline in the performance in frontal cortex- and hippocampal-dependent cognitive function tasks (novel object

recognition, object in place, contextual fear conditioning) 6 weeks post-RT. Irradiated animals spent less time exploring a novel place or object. Cranial RT also led to reductions in freezing behavior compared to controls in a fear conditioning task. Irradiated brains showed significant elevation of the hippocampal ADK immunoreactivity that was correlated with hypertrophic astrocytes. Conversely, mice receiving the Adk-KO vector 2-days post-RT showed significantly improved behavioral performance in all cognitive tasks 6 weeks post exposure. The Adk-KO vector selectively transduced astrocytes and showed >80% knockdown of ADK throughout the hippocampus and attenuated radiation-induced astrogliosis and increases in ADK expression. Our gene silencing approach provides direct evidence in support of our hypothesis that cranial RT disrupts adenosine metabolism and interventions targeted to reduce astrocytic ADK may prove beneficial for ameliorating radiation-induced cognitive dysfunction.

Title: The differential role of DRP1-mediated mitochondrial fission in the regional specific astroglial death in the rat brain

Authors: S.-J. MIN, A.-R. KO, H.-W. HYUN, T.-C. KANG, *J.-E. KIM;
Dept. of Anat. and Neurobiology, Hallym Univ., Chuncheon, Korea, Republic of

Abstract: The response and susceptibility to astroglial degenerations are relevant to the distinctive properties of astrocytes in a hemodynamic-independent manner. Because of the emerging relationship between the dynamin-related protein 1 (DRP1)-mediated mitochondrial fission and cell viability, we investigated whether mitochondrial dynamics involves the differential astroglial vulnerability in response to status epilepticus (SE). In non-SE animals, pDRP1-S616/pDRP1-S637 ratio in astrocytes within the CA1 region was higher than that within the molecular layer of the dentate gyrus. Following SE, mitochondrial length was reduced in the molecular layer of the dentate gyrus, while mitochondria were elongated in the CA1 region. Mdivi-1 (a DRP1 inhibitor) effectively alleviated astroglial death in the molecular layer of the dentate gyrus following SE, while WY14643 (an enhancer of mitochondrial fission) aggravated it. In the CA1 region, Mdivi-1 accelerated clasmatodendrosis (lysosome-derived astroglial

autophagy), although neither Mdivi-1 nor WY14643 affected the number of astrocytes following SE. To the best of our knowledge, the present data demonstrate for the first time the novel role of DRP1-mediated mitochondrial fission in astroglial loss. Thus, the present findings suggest that the differential astroglial mitochondrial dynamics may involve the distinct characteristics of astroglial death following by SE.

Title: Inflammatory signaling pathways up-regulate the cystine/glutamate antiporter system x_c^- in cortical murine astrocytes *In vitro* and in the brain *In vivo*

Authors: *J. LEWERENZ[1], F. APPELT[1], R. KLAUS[1], G. ALBERTINI[2], H. SATO[3], I. SMOLDERS[2], A. MASSIE[2];
[1]Univ. of Ulm, Ulm, Germany; [2]Vrije Univ. Brussel, Bruxelles, Belgium; [3]Niigata Univ., Niigata, Japan

Abstract: Background: The cystine/glutamate antiporter system x_c^-, with xCT as specific subunit, takes up cystine into cells while exporting glutamate. In the brain, system x_c^- controls extracellular glutamate levels. Neuroinflammation is observed in Alzheimer's disease, amyotrophic lateral sclerosis and multiple sclerosis, diseases where system x_c^- is upregulated and may contribute to excitotoxicity.
Aim: The aim of this study was to characterize pathways that lead to inflammatory upregulation of system x_c^-.
Methods: In murine astrocytes and mouse embryonic fibroblasts (MEF), system x_c^- activity was measured as radiolabelled glutamate uptake upon stimulation with tumor necrosis factor α (TNFα), bacterial lipopolysaccharide (LPS) and polyinosinic:polycytidylic acid (Poly I:C). For immunoblotting, astrocytic membranes were used. For luciferase reporter promoter assays, astrocytes were transiently transfected using constructs containing xCT promoter fragments of different length. Mice were injected intraperitoneally with 5 mg/kg LPS and 750 µg/kg Poly I:C. One week later, hippocampal homogenates were used for immunblotting.
Results: Within 24 hours, 100 ng/ml TNFα and 100 µg/ml Poly I:C upregulated system x_c^- activity 3.3-fold and 3.6-fold, while 100 ng/ml LPS 6.6-fold, respectively. Statistically significant upregulation was detected not earlier that after 12 hours suggesting a transcriptional

mechanism. Correspondingly, xCT promoter activity was increased by 2.2-fold and 2.0-fold upon stimulation with LPS and Poly I:C, respectively, and xCT protein was upregulated by LPS and Poly I:C within 24 hours. In mice both peripheral LPS and Poly I:C induced hippocampal xCT protein levels by 1.3-fold and 1.4-fold, respectively, 7 days post-injection. System x_c^- was not upregulated in MEF deficient in the TNFα receptor (TNFR) 1 but upregulation was preserved in TNFR2-deficient MEF. Pharmacological inhibition of NFκB slightly increased the induction of system x_c^- activity. In line with this, NFκB-deficient MEFs showed higher system x_c^- activity compared to wild-type MEF. Luciferase reporter promoter assays indicated that an inhibitory region might be located between base pair -266 and -664 where a putative NFκB site is located.
Conclusion: Inflammatory stimuli initiated by activating TNFR1, TLR3 and 4 upregulate system x_c^- in the murine brain and astrocytes in vitro. This is mediated by increased transcription of xCT, the specific subunit of system x_c^-. Counterintuitively, signaling via NFκB might rather represent an inhibitory feed back loop in the inflammatory induction of system x_c^- downstream of the activation of TNFR1 and both TLR3 and 4.

Title: Hypoxia-induced changes in the phosphorylation and function of Cx43 are associated with degeneration of astrocytes in ischemic retinopathies

Authors: *N. SLAVI, A. H. TOYCHIEV, S. A. BLOOMFIELD, M. SRINIVAS;
Biol. Sci., SUNY COLLEGE OF OPTOMETRY, NEW YORK, NY

Abstract: Retinal astrocytes influence the abnormal growth of blood vessels in ischemic retinopathies. In the oxygen induced retinopathy (OIR) mouse model, astrocytes degenerate after exposure to hypoxia, whereas preservation of the astrocytic template is correlated with accelerated revascularization of retinal plexuses and reduced intravitreal neovascularization. The reason why astrocytes of the inner retina degenerate is not fully defined. We hypothesize that Gap junction channels (GJs) composed of connexin 43 (Cx43), which extensively couple retinal astrocytes, may facilitate the propagation of cytotoxic signals within the astrocytic network leading to its degeneration. Therefore, we examined the effects of retinal hypoxia on the

expression and function of Cx43, and determined whether the absence of Cx43-mediated coupling can prevent the loss of astrocytes and the abnormal vessel growth in OIR. Mouse litters were exposed to 75% oxygen from postnatal day (p) 7 to p12, causing obliteration of the vascular plexus, and then returned to room air. The relative hypoxia leads to neovascularization by p17. Cx43 expression was tested at various time points after exposure to hypoxia using Western blot. Dye spread to adjacent cells was used as a measure of Cx43-mediated astrocytic coupling in GFAP-Cre;TdTomato mice. The effects of genetic ablation and pharmacological inhibition of Cx43 channels on astrocytic density and pathological neovascularization were examined with immunohistochemistry on retinal whole-mounts from WT and GFAP-Cre;$Cx43^{fl}$ (knockout) mice. Hypoxia induced the transition of Cx43 from a dephosphorylated state to its fully phosphorylated form within 6 hours, changes that were associated with recruitment of Cx43 into GJ plaques and an increase in intercellular coupling. The absence of astrocytic coupling provided by Cx43 reversed the pathological changes observed in OIR. Intravitreally injected Cx43 inhibitors increased the density of astrocytes in the vaso-obliterated zone and significantly reduced the avascular retinal area and the formation of neovascular tufts. Similarly, conditional deletion of Cx43 markedly increased revascularization and reduced neovascularization compared to WT. Our results demonstrate a significant role of astrocytic coupling in the progression of ischemic retinopathies and suggest that Cx43 is a potential therapeutic target to control neovascularization.

Title: Olfactory ensheathing cells and neuroregeneration: identification of the molecular mechanism(s)

Authors: *A. SAGLAM[1,2], S. WRAY[1];
[1]NIH, Bethesda, MD; [2]Neurosci. & Cognitive Sci. Program, Univ. of Maryland, Col. Park, College Park, MD

Abstract: Neurogenic zones in the mammalian brain are strong candidates for neuroregenerative strategies due to their ability to give rise to new neurons. The mammalian olfactory system

shows robust neurogenesis throughout life, with neurosensory cells of the olfactory mucosa capable of renewal and differentiation. Data suggest that both neural niche signals and the surrounding glia give the olfactory mucosa this unique capability. Recent studies have transformed our perception of glia from being simply a structural support network for neurons; to the ‘star’ cells that regulate synaptic transmission, plasticity and neural excitability. With the revelation that glia communicate with each other as well as with neurons, interest in understanding the role of glia-neuron interactions during injury and disease is increasing. There is growing evidence that the regenerative properties of olfactory nerves are due to a distinct type of glial cell, called olfactory ensheathing cells (OECs). As a stress response to injury, hypertrophic astrocytes present in the glial scar transform into a reactive state and not only act as a physical barrier to regenerating axons, but also secrete nerve growth-inhibitory chondroitin sulfate proteoglycans (neurocan, phosphacan, versican, etc). OECs can mix with astrocytes, migrate through scar tissue and exhibit axon growth-promoting properties after the injury. Therefore studying the OECs' role during regeneration and the cross talk between the OECs and astrocytes holds promise for understanding neuroregeneration mechanisms. Here we examine the possible molecular mechanisms OECs communicate with astrocytes using both primary OECS from PN2 mice as well as several immortalized olfactory ensheathing cell lines (1). Consistent with reports in the literature, primary OECs decrease NFkB nuclear translocation in astrocytes exposed to a LPS insult. To date, we examined two immortalized cell lines and neither is able to mimic the primary OEC effect on astrocyte stress response. We focus on comparison of molecules with altered expression levels in primary OECs vs immortalized OEC lines. This comparison may enable identification of pathways that primary OECs activate upon exposure to reactive astrocytes during a neuroregenerative challenge.

Title: The molecular mechanism underlying the cross talk between post-traumatic spinal axons and scar-forming cells

Authors: *Y. LIU;
Inst. of Neuroscience, Soochow Univ., Jiang Su, China

Abstract: Little is known about the molecules mediating the cross-talk between post-traumatic axons and scar-forming cells after spinal cord injury. We found that a sustained NB-3 induction was simultaneously present in the terminations of post-traumatic corticospinal axons and scar-forming cells at the spinal lesion site, where they were in direct contact when axons tried to penetrate the glial scar. The regrowth of corticospinal axons was enhanced *in vivo* with NB-3 deficiency or interruption of NB-3 *trans*-homophilic interactions. Biochemical, *in vitro* and *in vivo* evidence demonstrated that NB-3 homophilically interacted in *trans* to initiate a growth inhibitory signal transduction from scar-forming cells to neurons by modulating mTOR activity via CHL1 and PTPσ. NB-3 deficiency promoted BMS scores, electrophysiological transmission and synapse reformation between regenerative axons and neurons. Our findings demonstrate that NB-3 *trans*-homophilic interactions mediate the cross-talk between post-traumatic axons and scar-forming cells and impair the intrinsic growth ability of injured axons.

Title: Neurovascular astrocyte dysfunction as a key mediator of vascular cognitive impairment

Authors: *T. L. SUDDUTH[1], J. L. GOOCH[2], E. M. WEEKMAN[2], A. WOOLUMS[3], M. PLEISS[3], C. M. NORRIS[3], D. M. WILCOCK[2];
[1]Sanders Brown Ctr. On Aging, Univerisity of Kentucky, Lexington, KY; [2]Physiol., [3]Univ. of Kentucky, Lexington, KY

Abstract: Background:
Vascular cognitive impairment and dementia (VCID) is the second leading cause of dementia behind Alzheimer's disease (AD). In addition, VCID is a frequent co-morbidity with AD, complicating the diagnosis and treatment of AD for a significant proportion of AD patients.

Despite its prevalence, VCID remains relatively understudied compared to AD, and little is known about the molecular mechanisms underlying the cognitive dysfunction resulting from cerebrovascular disease.
The astrocytic end-feet almost completely surround intraparenchymal blood vessels in the brain and express a variety of channels and markers indicative of their specialized functions in the maintenance of ionic and osmotic homeostasis and gliovascular signaling. The channels enriched at the astrocytic end-feet are the aquaporin 4 water channel (AQP4), the inward rectifying potassium channel Kir4.1 and the calcium-dependent potassium channel BK. An essential function of the astrocytes surrounding the neurons is to maintain the neuronal resting membrane potential by controlling the extracellular potassium concentration, a process termed potassium buffering.
Methods:
Wildtype mice were placed on HHcy-inducing diet for a period of 6, 10 or 14 weeks. We examined the tissue histologically for astrocytic end-foot markers AQP4, Kir4.1, BK and dystrophin-1 (Dp71). Further, we performed some elctrophysiological measurements of LTP.
Results:
We found that there was significant astrocytic end-foot disruptions in the HHcy model. AQP4 becomes dislocalized from the end-feet, there is a loss of Kir4.1 and BK protein expression, as well as a loss of the Dp71 protein known to anchor the Kir4.1, BK and AQP4 channels to the end-foot membrane. We have examined mice who have been on the HHcy-inducing diet for 6, 10 and 14 weeks and find that these end-foot changes become more severe the longer the mice are on the diet. These histological astrocyte changes are very similar to changes we previously showed in a CAA mouse model. Accompanying these intriguing histological findings are indications of electrophysiological dysfunction in the HHcy mice.
Conclusions:
HHcy and CAA both result in disruption of the astrocytic end-foot connection. These changes could represent a common cellular mechanism of VCID and, therefore, may be a target for therapeutic development.

Title: Enhanced astroglial GABA release via Best-1 channel in epileptic hippocampus

Authors: K.-A. PARK[1,2], S. PANDIT[1,2], *J. PARK[1,2];
[1]Dept. of Physiol., [2]Dept. of Med. Sci., Col. of Med. Chungnam Natl. Univ., Daejeon, Korea, Republic of

Abstract: Activation of extrasynaptic $GABA_A$ receptors ($eGABA_ARs$) generate persistent tonic inhibitory currents (I_{tonic}), while their synaptic counterparts mediate conventional inhibitory postsynaptic currents in the brain. In addition to the expression and/or composition of $eGABA_ARs$, I_{tonic} is under tight control of the extracellular GABA of synaptic and non-synaptic origin. Here, we showed that astrocytic GABA release through bestrophin-1 (Best-1) channel among others could suppress the neural circuit in epileptic hippocampus. Intracerebroventricular injection of kainic acid (KA) produced typical seizure activity increased GABA and Best-1 expression in GFAP-positive cells of mice hippocampi. KA injection induced 5-nitro-2-(3-phenylpropylamino) benzoic acid (NPPB)-sensitive I_{tonic} in CA1 pyramidal neurons. Interestingly, KA injection failed to induce NPPB-sensitive I_{tonic} in Best-1 KO mice. Similarly, I_{tonic} facilitation by a GABA transporter blocker (NO-711) was enhanced by KA injection in wild type but not in Best-1 KO mice. In an agreement, NPPB increased the CA1 neuronal firing activity in KA-injected wild type mice, but not in Best1 KO mice. Finally, KA-injected Best1 KO mice showed increased spontaneous seizure activity and behavioral seizure after the electrical stimilus compared with those in wild type mice. Overall, our results suggested the Best1-mediated astrocytic GABA release could contribute to stabilize the hippocampal neural circuit after epileptic insults.

Title: Role of astroglial α7 nicotinic acetylcholine receptors in neuroinflammation and oxidative stress

Authors: *H. PATEL[1,2], A. W. DUNAH[1], R. H. LORING[2];
[1]Neurol. Res., Biogen, Cambridge, MA; [2]Pharmaceut. Sci., Northeastern Univ., Boston, MA

Abstract: α7 nicotinic acetylcholine receptors (nAChRs) are widely distributed throughout the central nervous system (CNS) and periphery. Within the CNS, these receptors are expressed in neurons and glia cells, and are actively involved in learning, memory and attention. A majority of the studies evaluating the role of α7nAchRs in the CNS have focused on neurons. However, these receptors are also present on astrocytes, which are key regulators of neuroinflammation and oxidative stress in several neurodegenerative diseases including Alzheimer's disease, Parkinson's disease and amyotrophic lateral sclerosis. Less evidence exists regarding the potential anti-inflammatory properties of these receptors in astrocytes. Therefore, we evaluated the role of astroglial α7 nAChR activation in an *in vitro* model of neuroinflammation. We observed that treatment with α7 nAChR agonists, GTS21 and PNU282987, significantly reduced lipopolysaccharide (LPS)-mediated secretion of the inflammatory cytokines in a dose dependent manner in astrocytes. Further, we assessed the effect of α7 nAchR agonist on activation of NFκB, which is a transcription factor involved in regulating inflammatory responses. We observed that α7 nAChR activation blocked LPS mediated NFκB nuclear translocation in astrocytes indicating that the observed anti-inflammatory effect may be mediated through NFκB pathway. We further tested the antioxidant effect of astroglial α7 nAChR through modulation of nuclear factor erythroid-derived 2-related factor 2 (Nrf2) pathway, which is a member of the NF-E2 family of basic region leucine-zipper transcription factors and responds to oxidative and electrophilic stress by regulating antioxidant responsive genes. We demonstrated that treatment with α7 nAChR agonists upregulates canonical Nrf2 antioxidant genes and proteins suggesting antioxidant properties of α7 nAchR. The anti-inflammatory and antioxidant responses were reversed by α7 nAchR specific antagonist, MLA; which further demonstrates that these effects in astrocytes are specifically mediated by α7 nAchR activation. In conclusion, our results demonstrate that activating astroglial α7 nAChR may have a role in neuroprotection by decreasing inflammation and oxidative stress, and therefore could have therapeutic implication for disease modifying treatments of neurodegenerative diseases.

Title: Stress-induced structural and functional plasticity in Neuron-Glia interactions

Authors: *C. MURPHY-ROYAL, G. R. J. GORDON, J. S. BAINS;
Hotchkiss Brain Inst., Calgary, AB, Canada

Abstract: Astrocytes play key roles in maintaining basal synaptic transmission and synaptic plasticity. They express a wide range of ion channels, transporters, and receptors, which enable them to detect a variety of neuronal and glial signals. Each astrocyte occupies unique volume domain and is associated with hundreds of thousands of synapses in the rodent brain. In spite of this privileged access to synapses, little is known about changes in the functional relationship between astrocytes and neurons in response to physiological challenges.
Stress causes rapid changes in synaptic signaling and alters the threshold for plasticity in a number of brain regions. Here we asked whether acute stress directly impacts astrocytes and whether this has consequenes for neuronal function.
Mice were subjected to acute stress (swim 20 min) and cortical brain slices were prepared. Data obtained from these mice was compared to data from unstressed mice. Structural and functional adaptations by astrocytes were monitored using two-photon microscopy in combination with patch-clamp electrophysiology.
Using morphometric analysis, we measured astrocyte territory size in response to acute stress. There was a 11% increase in astrocyte territories following swim stress (2385±113 μm2 vs 2646±75 μm2). Scholl analysis on these cells revealed an increase in branching of astrocytes following stress (Schoenen Ramification Index: 7.7 vs 10.6). These observations indicate that acute stress results in mild hypertrophy that is accompanied by increased ramification.
Next, we conducted functional assays to investigate the effects of stress on the intrinsic signalling properties of astrocytes. We investigated astrocyte-astrocyte coupling, as observed by dye coupling between cells. After stress, there was a 68% decrease in coupling (256±22 s vs 430±43 s). This suggests a specific impairment or reduction in gap-junction coupling between astrocytes.
Finally, we investigated the effect of stress on astrocyte calcium signalling. We focused on microdomains as changes in calcium in these domains have been linked to intracellular signalling and gliotransmitter release. Stress had no effect on the amplitude (4.2±0.6 dF/F vs 3.7±0.6 dF/F) or frequency (0.52±0.06 events/min vs 0.41±0.07 events/min) of spontaneous astrocytic calcium events. There was, however, a 32% increase in the half-width of these events (3.3±0.2 s vs 4.4±0.4 s).
Our findings are consistent with rapid changes in astrocyte morphology and function following a single episode of stress. These stress-induced alterations in astrocyte structure and function may play a previously unknown role in the central response to stress.

Title: Reduction of Kir4.1 potassium channel expression in diabetic mice: relevance to stroke.

Authors: *D. E. RIVERA-APONTE[1], M. P. MÉNDEZ-GONZÁLEZ[1], L. MIRANDA[2], L. A. CUBANO[3], S. N. SKATCHKOV[4], M. J. EATON[1];
[1]Biochem., [2]Physiol., [3]Anat. and Cell Biol., [4]Physiol. and Biochem., Univ. Central Del Caribe, Bayamon, PR

Abstract: Diabetics are at greater risk for stroke when compared to non-diabetics and elevated blood glucose concentration during stroke is associated with poor outcome. Astrocytes play a critical role in protecting neurons by maintaining extracellular homeostasis and preventing neurotoxicity through glutamate uptake and potassium buffering. These functions are aided by the presence of potassium channels, such as Kir4.1 inwardly rectifying potassium channels, in the membranes of astrocytic glial cells. We have previously shown that Kir4.1 expression and function is down-regulated in cultured astrocytes grown in high glucose compared to astrocytes grown in normal glucose. The purpose of the present study was to extend these findings from cultured astrocytes to brains of diabetic mice. In this study we used the db/db mouse model of Type 2 diabetes and the heterozygous db/+ control mice. The db/+ control mice have mean fasting blood glucose levels of 96.1 ± 4.8 mg/dl, whereas the db/db diabetic mice have mean 230.6 ± 15.9 mg/dl glucose levels. We first evaluated the protein and gene expression of Kir4.1 using Western blot and q-PCR. We found a 40% reduction of Kir4.1 protein levels and a 30% reduction in Kir4.1 mRNA levels in db/db mice as compared to db/+ control mice (n=3 for all groups). We next examined the consequences of ischemic stroke on performance of a sensorimotor task by control and diabetic mice. We performed a focal photothrombosis in the sensorimotor cortex of db/db and db/+ mice via the Rose Bengal method and evaluated sensorimotor function using the rung ladder walk behavioral test. The rung walk measures sensorimotor function particularly after stroke. After obtaining baseline data, db/db mice and

db/+ mice received the focal lesion and 24 hours later their behavioral performance on the rung test was re-evaluated. Limb placement accuracy was rated on a scale from 0 to 6 with 6 being a perfect step and 0 being a total miss of the rung as described by Farr et al., (2006). We found no difference between the ability of control (n=4 for sham; n=5 for control with surgery) or diabetic (n=5) mice to perform on the rung walk prior to the receiving the focal lesion. 24 hours after the surgery, the control (non-diabetic) mice had apparent deficits in placing the right front limb/paw on the rungs. In addition, the diabetic mice had more severe deficits than the control mice in both the right front and right back limb/paw placement 24 hours after surgery. Our results indicate that Kir4.1 channels are down-regulated in brains of Type 2 diabetic mice and this correlates with greater sensorimotor deficits after ischemic stroke.

Title: Mechanisms and effects of remote astrocyte reactivity in response to axotomy

Authors: *G. E. TYZACK[1], R. PATANI[1], A. LAKATOS[2];
[1]Mol. Neurosci., UCL, London, United Kingdom; [2]Clin. Neurosci., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: The role of astrocyte reactivity in response to remote axonal injuries is not fully understood. After such injuries, a complex process of reorganization of synaptic connections is observed on the dendrites of surviving neurons. This process, named adaptive synaptic plasticity, is crucial for the re-establishment of previously lost connections, for neuronal survival and ultimately for functional recovery. Emerging evidence from our laboratory and others suggest that remote astrocyte activation has a fundamental impact on neuron survival and synaptic reorganization after axonal injuries. However, the molecular mechanisms underlying this response are still unresolved. Using a combination of *in vivo* and *in vitro* model systems we investigated (1) the triggers and signaling pathways involved in remote astrocyte activation in

response to peripheral axotomy and (2) the potential effects of astrocyte reactivity on adaptive synaptic plasticity following neuronal injury. We showed that after peripheral nerve axotomy in mouse, perineuronal astrocytes become activated via signal transducer and activator of transcription-3 (STAT3) signaling. Using transgenic approaches, we then evaluated the effects of STAT3-mediated astrocyte reactivity on neuronal integrity and synapse recovery following nerve transection. We showed that after axotomy, STAT3 activation in astrocytes induces process formation, promotes neuronal survival and the recovery of synapses. We then confirmed that astrocytic STAT3 directly controls the re-expression and release of the synaptogenic molecule thrombospondin-1 (TSP-1), which promotes the restoration of excitatory input onto axotomized motor neurons. These data may provide insights for developing novel synapto- or neuro-protective strategies.

Title: Prolactin protects rat cortical astrocytes against oxidative stress

Authors: *E. ARNOLD[1,2], K. G. ORTIZ-GOMEZ[2], R. M. AROÑA[2], C. CLAPP[2], G. MARTÍNEZ DE LA ESCALERA[2];

Abstract: Astrocytes maintain brain homeostasis by protecting synaptic integrity, providing metabolic support for neurons, regulating inflammatory responses, and increasing survival under oxidant conditions. Several types of stress and injury in the brain induce mitochondrial dysfunction and oxidative stress leading to astrocyte death. Prolactin (PRL) is a stress-related hormone limiting gliosis and degeneration of neural retina (Arnold et al. JN 2014). Here, we investigate whether PRL protects brain astrocytes against oxidative stress and cell death. Primary cultures of cortical astrocytes were isolated from the brain of neonatal Wistar rats. The long PRL receptor isoform was detected in cortical astrocytes by qRT-PCR. Astrocytes were treated with increasing concentrations of PRL (1-100 nM) 24 hours after being exposed to oxidative stress

induced with 400 μM hydrogen peroxide (H_2O_2) for 3 hours. Incubation of cortical astrocytes with PRL inhibited H_2O_2-induced cytotoxicity, evaluated by the MTT assay, in a dose-dependent manner. These findings indicate that PRL can act directly on astrocytes to protect them against oxidative stress injury.

Title: Disease-related alteration and recovery of corticostriatal synaptic transmission and astrocytic glutamate transport in Q175 Huntington mice

Authors: A. DVORZHAK[1], T. VAGNER[1], A. M. WÓJTOWICZ[1], I. MELNICK[2], *R. GRANTYN[1];
[1]Exptl. Neurol., Univ. Med. Charité, Berlin, Germany; [2]Bogomoletz Inst. of Physiol., Kiev, Ukraine

Abstract: The excitatory amino acid transporter EAAT2 (GLT1 in rodents) accounts for the major part of glutamate uptake from the extracellular space. Several groups have reported reduced levels of GLT1 expression and striatal glutamate uptake in Huntington's disease (HD), but so far there is little evidence that individual glutamatergic synaptic connections were affected by glutamate uptake insufficiency. Here we show that in 1 year old hypokinetic Q175 homozygotes unitary corticostriatal EPSCs are longer than in their wildtype (WT) littermates. Corticostriatal afferents were visualized by YFP fluorescence after stereotaxic injection of AAV9/CaMKIIa.hChR2(E123T/T159C)-eYFP into the motor cortex. Individual axons were repeatedly activated by a small light spot at 473 nm or by electrical microstimulation. Both methods rendered the same results. The AMPAR- and NMDAR-mediated components of the corticostriatal unitary EPSCs (uEPSCs) were separated by setting the holding potential to - 70 or +40 mV. We found a significant HD-related difference in the time constant of decay of both the

AMPAR and the NMDAR uEPSC components. This alteration is associated with an HD-related decrease in the glutamate uptake activity to 46% of the WT level, as determined in individual SR101-positive astrocytes by photolytic uncaging of 3 mM Rubi-glutamate and recording of the respective Na transients after loading SBFI-AM. Treatment with the beta-lactam antibiotic ceftriaxone is known to promote the transcription of GLT1. In SR101+ astrocytes ceftriaxone restored the glutamate uptake activity to 83% of the WT level. It also reversed the prolongation of the AMPAR but not the NMDAR component. We then aimed at characterizing the ceftriaxone-mediated recovery of GLT1 in the GFAP-expressing subclass of astrocytes (~20% of S100beta+ cells in the striatum). In WT and HD mice GFAP-expressing astrocytes were visualized by Tomato-fluorescence after systemic (intravenous) application of AAV9-gfaABC1D-Tomato. Average GLT1 immunofluorescence was quantified within and outside the domains of solitary Tomato+ astrocytes. To our surprise, in Tomato+ astrocytes GLT1 immunofluorescence was not reduced, but even significantly increased in comparison with WT. In contrast, outside the domains of GFAP+ astrocytes the GLT1 level was lower in HD, consistent with the conclusion that the majority of astrocytes, but not the GFAP-expressing subclass, exhibit insufficiency of GLT1 expression which is responsive to ceftriaxone treatment.

Title: Analyzing post-stroke astrocyte heterogeneity to guide neural repair

Authors: *A. J. GLEICHMAN[1], R. KAWAGUCHI[2], M. V. SOFRONIEW[3], G. COPPOLA[2], S. T. CARMICHAEL[1];
[1]Neurol., [2]Psychiatry and Neurol., [3]Neurobio., UCLA, Los Angeles, CA

Abstract: Stroke is one of the most common causes of long-term disability, yet few treatment options exist. Many patients experience limited stroke recovery, suggesting it may be possible to

determine the mechanisms underlying and limiting this endogenous neural repair in order to induce more complete recovery. Successful neural repair is likely to include numerous elements, including angiogenesis, blood-brain barrier maturation, structural and functional synaptic plasticity, and mitigation of the extensive post-stroke inflammatory response. Astrocytes influence or drive all of these elements, yet very little is known about how astrocytes respond to stroke. Here, we have developed new approaches to investigate how astrocytes respond to stroke as well as how those responses change depending on the type of stroke and the proximity of astrocytes to the infarct.
Astrocytes are increasingly recognized to be heterogeneous, the most obvious level of heterogeneity being the morphologic and phenotypic differences between white matter, or fibrous, and gray matter, or protoplasmic, astrocytes. Using both cortical and white matter stroke models, we have mapped morphologic and phenotypic changes of protoplasmic and fibrous astrocytes in response to region-specific stroke. In order to fully elaborate the detailed astrocytic arbors, we developed lentiviral astrocyte-specific reporters using new proteins called spaghetti monsters, which allow much better resolution of small processes. Phenotypically, we evaluated the staining pattern of a panel of astrocyte markers and proteins thought to be important in astrocytic response to injury. These studies have revealed stereotypic changes in both fibrous and protoplasmic astrocytes after stroke that vary with both stroke type and proximity to injury.
We have used these stereotyped changes in astrocyte morphology and phenotype to define zones of reactive astrocytes after stroke. In order to gain a more comprehensive understanding of the ways in which these zones of astrocytes respond to stroke, we utilized a mouse line in which tagged ribosomal subunits are expressed in a Cre-dependent fashion, in conjunction with an astrocyte-enriched Cre. By laser capturing the distinct reactive astrocyte zones and immunoprecipitating these tagged ribosomes, we selectively isolated and sequenced astrocyte-enriched ribosomally loaded mRNA. These RNAseq results have yielded extensive information as to the precise, diverse functions of post-stroke astrocytes, providing numerous potential intervention points to improve post-stroke neural repair.

Title: Relative role of extracellular and intracellular calcium concentration in MeHg induced cytotoxicity in mouse primary cerebellar and cortical astrocytes

Authors: *R. JAIMAN[1], J. ORTIZ-RODRÍGUEZ[3], W. D. ATCHISON[2];
[1]Neurosci., [2]Michigan State Univ., East Lansing, MI; [3]RISE Program Univ. of Puerto Rico, Cayey, PR

Abstract: Methylmercury (MeHg) is a potent environmental neurotoxicant that preferentially targets granule cells in the cerebellum. Despite the fact that MeHg primarily affects these neurons, astrocytes are also targets of this metal. MeHg-induced neurotoxicity in astrocytes has been studied in the cortical layer. However, effects on cerebellar astrocytes are less studied, and regional differences can occur in astrocytes between these two areas of the brain. The aim of this study was to compare the relative sensitivity of MeHg exposure on cerebellar and cortical astrocytes and the contribution of intracellular and extracellular Ca^{2+} to MeHg-induced astrocyte death. Primary astrocyte cultures from the cerebellum and cortex of 7-8 day old C57BL/6 mice were exposed for 3h to 0, 1, 2, or 5μM MeHg. Cytotoxicity was measured 24h after the 3h of MeHg exposure using ethidium homodimer and calcein-AM. To determine if astrocyte death was due to an increase in intracellular Ca^{2+}, the chelator BAPTA was added to chelate intracellular Ca^{2+}. To test whether extracellular Ca^{2+} contributed to cytotoxicity, the cell--impermeant chelator EGTA was used. The mean percentage of cell death in the cerebellum was: 0 %, 21%, 63%, and 95% at 0, 1, 2, or 5μM MeHg respectively. In the cortical layer it was: 1.1%, 1.3%, 20%, and 73% respectively. When treated with BAPTA+MeHg, incidence of cell death was reduced to 56% in cerebellar astrocytes at both 2 and 5 μM MeHg compared to the MeHg group which did not receive BAPTA. For cortical astrocytes, BAPTA significantly decreased the incidence of cell death to 68% at 5μM MeHg. EGTA significantly reduced incidence of MeHg-induced cell death to 68% and 88% at 2 and 5μM MeHg respectively in cerebellar astrocytes. However, EGTA did not protect cortical astrocytes from MeHg-induced cytotoxicity. Thus while both cortical and cerebellar astrocytes express MeHg-induced cytotoxicity, the sensitivity of the glia in the two regions differs, as does the relative contribution of intra- and extracellular Ca^{2+} to cytotoxicity.

Abstract: Genetic predisposition may be required for adolescent cannabis exposure to produce long-term cognitive abnormalities. Yet, the mechanisms whereby genetic liability interacts with cannabis exposure remain unknown. A major psychoactive ingredient of cannabis, delta-9-tetrahydrocannabinol (Δ9-THC) is mainly responsible for cannabis-induced cognitive deficits. Our pilot study with a mouse model of astrocyte-specific inducible expression of dominant-negative Disrupted in Schizophrenia 1 (DN-DISC1), a neurodevelopmental risk factor, showed that astrocytic DN-DISC1 and adolescent Δ9-THC exposure synergistically impair recognition memory in adult animals. We found that these behavioral changes were accompanied by increased glutamate tissue content that could result in excitotoxicity and neuronal dysfunction. In order to uncover the underlying mechanisms of DN-DISC1-THC interaction, we evaluated if astrocytic DN-DISC1 and Δ9-THC could synergistically alter inflammation signaling cascades which may underlie resulting phenotypes. We found that Δ9-THC treatment of primary mutant DISC1 astrocytes significantly activates NF-kB signaling. Our results suggest that astrocyte DN-DISC1 and Δ9-THC may interact during adolescence by synergistically activating NF-kB signaling, which could lead to neuronal dysfunction and cognitive impairment.

Abstract: Chronic pain, neurodegenerative diseases such as Parkinson´s, and psychiatric disorders, although having different etiologies, share some common molecular and biochemical processes. For example, it has been shown that inflammation plays an important role in the physiopathology of these diseases. Astrocytes, the most abundant cell in the CNS, modulate synaptic activity and provide metabolic and trophic support to neuron. It has been shown that during chronic pain, epilepsy, and neurodegenerative diseases astrocytes produce a set of molecules that can be beneficial or detrimental to neurons. For instance, increases in asynchronous neuronal discharges such as those achieved during status epilepticus lead to an increase in the expression and release of pro-inflammatory molecules, reactive oxygen species, and pro-apoptotic molecules. Release of these molecules can induce neuronal dysfunction and death. Importantly, these results suggest that electrical activity can directly modulate signaling pathways that impact the gene expression in astrocytes. Recent studies have suggested that electrical neuromodulation (ENM) can work by resetting the neuron´s electrical properties which induces changes in the oscillatory circuits involved in the genesis of the disease. However, less is known about how ENM can affect other cells in the CNS. For example, there is no data showing if ENM may work by regulating astrocytes activation and production of inflammatory, oxidative and/or apoptotic molecules. Additionally, it is unknown whether ENM can modulate the production of these molecules depending on the frequency of stimulation and type of electrical stimuli. In the present work, we evaluated the capacity of ENM to regulate the production of pro- and anti-inflammatory cytokines by mice astrocytes in vitro. The obtained results showed that

ENM can indeed regulate the production of cytokines by astrocytes. At low frequency (50Hz; 4V), ENM stimulates the production of IL-6, TNF-α, and CCL-2. At high frequency (185Hz; 4V), ENM highly stimulates the production of CCL-2. However, the production of IL-6 and TNF-α was four times lower than the one achieved a at 50Hz stimulation. Interestingly, the 50Hz-dependent production of cytokines was decreased by the use of microglia-conditioned medium, suggesting that microglia can regulate the action of ENM on astrocytes. In addition, none of the frequencies affected the production of the anti-inflammatory cytokines IL-10 and TGF-beta. All together our results suggest that ENM can regulate the production of pro-inflammatory cytokines by astrocytes and this effect is dependent of the stimulation frequency and microglia.

Title: MeCP2 deficient astrocytes have altered signaling pathway activation and reduced visually-evoked microdomain sizes.

Authors: ***R. GARCIA**, R. V. RIKHYE, J. PETRAVICZ, C. DELÉPINE, M. SUR; Brain & Cognitive Sci., MIT, Cambridge, MA

Abstract: Loss of function mutations in the X-linked gene encoding for MeCP2 are the underlying genetic cause for Rett Syndrome (RTT), a devastating neurodevelopmental disorder that primarily affects girls. Loss of function mutations in this ubiquitously expressed transcriptional regulator leads to imbalances in excitation and inhibition and disruption to neuronal circuit function. While the function of this transcriptional regulator remains elusive and complex, recent focus has turned to downstream signaling pathways as putative targets for novel therapeutics. The complexity of MeCP2 function is compounded by the heterogeneity of cell types in the brain, with recent evidence implicating glia cells in RTT pathophysiology. MeCP2 expression has been detected in astrocytes, and selective deletion or re-introduction of MeCP2 in astrocytes alone has been sufficient to induce or ameliorate pathological symptoms, respectively. Previously, we identified signaling pathways upstream of synaptic function that are impaired in MeCP2 mouse models, yet the downstream molecular and signaling effects resulting from a loss of MeCP2 function in astrocytes remains unknown. Here we measure signaling and astrocyte-specific proteins in a heterogeneous MeCP2-expressing population. We find that activated mTOR and AKT are reduced in astrocytes lacking MeCP2, while levels of cortical glutamate transporter 1 (GLT-1) are upregulated. We have recently shown that astrocytes in layer 2/3 of rodent visual cortex can respond to visual stimuli with robust and reliable microdomain Ca^{2+} elevation and that this effect is influenced by the availability and function of GLT-1. In $MeCP2^{-/+}$ astrocytes, we find that the microdomain areas evoked during visual stimulation are reduced, in line with reduced circuit function. These data identify novel, cell-specific effects in astrocytes lacking MeCP2 and offer insight on their signaling and circuit interactions.

Title: Characterization of glutamate release during cellular edema induced by osmotic stress

Authors: *J. B. HJUKSE;
Univ. of Oslo, Oslo, Norway

Abstract: Accumulation of glutamate in the brain interstitial space - a hallmark of stroke, traumatic brain injury and other conditions with cellular edema - poses a toxic threat to neurons. The molecular mechanisms underlying glutamate release during cellular edema are debated and may vary in different settings. Here, we characterized the mechanisms underlying glutamate release in acute cortical slices exposed to artificial cerebrospinal fluid (ACSF) with 20% reduction in osmolarity, a challenge known to induce cellular edema. Changes in extracellular glutamate levels were detected by two-photon microscopy using the fluorescent glutamate sensor iGluSnFR delivered by recombinant adeno-associated virus 2-4 weeks prior to imaging. We targeted iGluSnFR to the external surface of neurons by using the synapsin (*SYN*) promoter to drive expression of the sensor. In acute cortical slices from wildtype mice exposure to hypo-osmotic ACSF elicited frequent transient localized increases in iGluSnFR fluorescence. These fluorescent transients displayed amplitudes of 1.19 ± 0.02 (peak $\Delta F/F_o$), lasted 0.45 ± 0.02 sec and covered 196 ± 9 μm^2 (maximal area). Slices treated with DCPIB (10 μM), an inhibitor of volume-regulated anion channels, exhibited delayed and reduced frequency of hypo-osmotically evoked iGluSnFR transients. Similar findings were obtained in slices from *Itpr2*$^{-/-}$ mice, which lack the inositol 1,4,5-triphosphate type 2 (IP3R2) receptor that mediates Ca^{2+} release from the endoplasmic reticulum. The hypo-osmotically evoked iGluSnFR transients were also delayed in mice lacking the glial water channel aquaporin-4. We conclude that hypo-osmotic stress elicits glutamate release through volume-regulated anion channels and that astrocytic glutamate release is dependent on aquaporin-4 and IP3R2-mediated Ca^{2+} release from internal stores. The observed brief elevations in extracellular glutamate likely correspond to the events eliciting slow inward currents in cortical neurons.

Title: Recovery from cortical spreading depression by systemic administration of noradrenaline (norepinepherine) blockers

Authors: *H. MONAI[1], Y. IWAI[1], H. HIRASE[1,2];
[1]RIKEN BSI, Wako, Japan; [2]Saitama Univ., Saitama, Japan

Abstract: Brain insults such as traumatic brain injury and ischemia induce cortical spreading depression (CSD), which is a slowly propagated wave of depolarization across the cerebral cortex. CSD induces a severe long-lasting suppression of neural activities due to increased potassium (K^+) in the interstitial fluid. After CSD, neural activities recover as the ionic balance is restored. Astrocytes play a key role in ionic homeostasis in the brain by extracellular K^+ uptake, which is prompted by IP_3/Ca^{2+} signaling in astrocytes. Recently, as an alternative mechanism for the maintenance of the extracellular environment in the brain, the "glymphatic system" has been proposed, which describes astrocytes' involvement in the brain-state-dependent exchange of interstitial fluid under noradrenergic (NA) control. We hypothesized that either astrocytes-mediated K^+ uptake or self-clearance mechanisms are important for the recovery from CSD. Here we show that recovery of neural activity after CSD depends on astrocytic IP_3/Ca^{2+} signaling and negatively related to NA receptor activation. We used the "G7NG817" transgenic mouse, in which astrocytes and a subpopulation of cortical neurons express G-CaMP7, to visualize and characterize the dynamical properties of Ca^{2+} waves during high-K^+-induced CSD under urethane anesthesia. In the double transgenic mouse line "$IP_3R2^{-/-}$;$G7NG817^{+/-}$", in which astrocytic Ca^{2+} surges are absent, we confirmed that CSD-associated Ca^{2+} wave is still observable and the dynamical properties of Ca^{2+} waves are similar. Furthermore, we find that it takes longer time to recover the neural activity to its basal level after CSD in IP_3R2 KO mice, compared with the recovery time of ~60 min in wild-type mice, possibly due to the reduced of ability to uptake extracellular K^+ (Wang et al. 2012, *Sci Signal*). Interestingly, spontaneous astrocytic Ca^{2+} activity increased shortly after CSD in G7NG817 mice. This post-CSD enhancement of astrocytic Ca^{2+} activity was blocked by NA receptor antagonists. Remarkably, NA receptor blockade facilitated the recovery of neural activity to ~30 min. The observations are in line with the glymphatic system proposal that interfering NA signaling promotes interstitial fluid exchange, thereby restoring the healthy ionic balance more efficiently. These results suggest that both astrocytes-mediated K^+ uptake and self-clearance mechanisms are independently important for the recovery from CSD.

Title: Essential role of FE65 phosphorylation in APP metabolism

Authors: *K.-F. LAU[1], W. CHOW[1], W. LI[2], H. CHAN[2], J. NGO[1];
[1]The Chinese Univ. of Hong Kong, Shatin, NT, Hong Kong; [2]The Chinese Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: Aggregation of amyloid-β peptide (Aβ), derived from the aberrant processing of amyloid precursor protein (APP), is believed to be a crucial event in the pathogenesis of Alzheimer's disease. FE65 is a neural enriched adaptor protein has been shown to interact with APP via its PTB1 domain. FE65/APP interaction is reported to stimulate APP processing. Therefore it is essential to understand the mechanism(s) by which FE65/APP interaction is regulated. FE65 is a phospho-protein with several reported phosphorylation sites. However, the biological significance of FE65 phosphorylation is largely unknown. In this study, we showed that serum- and glucocorticoid-induced kinase 1 (SGK1) phosphorylates FE65 on serine-610 (S610)and to attenuate FE65/APP interaction. Importantly, FE65 S610 phosphorylation suppresses the stimulatory effect of FE65 on APP processing. Moreover, the effect of FE65 S610 phosphorylation on APP processing is linked to a role of FE65 in metabolic turnover of APP via the proteasome. Together, our work suggests that FE65 phosphorylation can influence FE65-mediated APP processing.

Title: Direct imaging of APP proteolysis in living cells

Authors: *M. CALAMAI[1], N. PARENTI[2], A. DEL GROSSO[3], M. CECCHINI[4], F. S. PAVONE[2];
[1]LENS, CNR-INO, Sesto Fiorentino, Italy; [2]LENS, Univ. of Florence, Sesto Fiorentino, Italy; [3]NEST, Scuola Normale Superiore, Pisa, Italy; [4]NEST, CNR-NANO, Pisa, Italy

Abstract: It is now widely accepted that oligomers consisting of Aβ peptide are the cytotoxic species contributing mostly to the development of Alzheimer's disease. Aβ peptide production results from the specific proteolytic processing of the amyloid precursor protein (APP). Understanding the factors governing the activity of the secretases responsible for the cleavage of APP is still a critical issue. The standard commercial kits measure the enzymatic activity of secretases from cells lysates, *in vitro*. By contrast, we have developed a rapid bioassay that provides visible information on the proteolytic processing of APP directly in living cells. APP was fused to a monomeric variant of the green fluorescent protein (mTagGFP) and a monomeric variant of the red fluorescent protein (mCherry) at the C-terminal and N-terminal, respectively. Changes in the proteolytic processing rate in transfected neuroblastoma cells were imaged with a confocal microscope as changes in the red/green fluorescence intensity ratio. Once APP is cleaved, the N-term mCherry containing domain is released and the 1:1 fluorescence intensity ratio between the red and green channels is lost. It is thus possible to monitor in living cells a higher or lower processing of APP in function of the ratio shift. We found that the degree of proteolytic processing of APP is not completely homogeneous within the same single cell, and that there is a high degree of variability between cells of the same type. Moreover, we fused a monomeric blue fluorescent protein (mTagBFP2) to the C-terminal of the β secretase BACE1 and co-expressed it with mCherry-APP-mTagGFP. We found a significant decrease in the mean red/green ratio in cells expressing BACE1-mTagBFP2, confirming that the proteolytic site is still accessible. siRNA against α secretase ADAM10 was used to discriminate the individual contribution of BACE1. We also followed with a fluorescence spectrometer the changes in the 610 nm (red) emission intensity of the extracellular medium when BACE1 was overexpressed. This represents a complementary approach to fluorescence microscopy for rapidly detecting changes in the proteolytic processing of APP in real time. Finally, we obtained a quantitatively

robust estimate of the changes in the red/green ratio for the above conditions by using a flow cytometer able to simultaneously excite and measure the fluorescence of mCherry and mTagGFP. Overall, our novel approach allows investigating in an unbiased way the proteolytic processing of APP in single living cells, and might be used to study the effect of drugs or particular conditions, such as high or low cholesterol levels.

Title: Effects of U18666A on APP metabolism in cultured astrocytes

Authors: *H. YANG[1,4], Y. WANG[2], S. KAR[3];
[1]Dept. of Med., [2]Psychiatry, [3]Med. & Psychiatry, Univ. of Alberta, Edmonton, AB, Canada;
[4]Pharm. Sch., Qiqihar Med. Univ., Qiqihar, China

Abstract: Amyloid-β (Aβ) peptides originating from β-amyloid precursor protein (APP) play important roles in the degeneration of neurons and subsequent development of Alzheimer's disease, the prevalent cause of dementia affecting elderly people in our society. Evidence suggests that increased levels/redistribution of cholesterol can influence the Aβ production from APP within neurons. However, it is unclear how cholesterol regulates APP/Aβ metabolism in astrocytes. To address this issue, we treated rat primary astrocytes with U18666A, a class 2 amphiphile, to trigger redistribution of cholesterol to the endosomal-lysosomal (EL) system. First, we assessed cell viability and cellular levels/distribution of cholesterol following U18666A treatment in astrocytes. Subsequently, we evaluated the effects of U18666A on APP level and its metabolism. Our results clearly showed that U18666A treatment increases levels of APP and its cleaved products (i.e. APP-CTFα and APP-CTFβ) in a time- and dose-dependent manner without affecting the steady state levels of β- or γ-secretase components. The secretory levels of $A\beta_{1-40}$ and $A\beta_{1-42}$ in conditioned media showed a trend of decrease. Additionally, U18666A treatment increased levels of microtubule-associated protein 1A/1B-light chain 3-II and lysosomal-associated membrane protein1 indicating that lysosomal-autophagic function may be affected in primary astrocytes. Our results obtained so far suggest that cholesterol redistribution within the

EL system in astrocytes can influence APP processing and Aβ generation and thus may have an important role in AD pathogenesis.

Title: Accumulation of APP-C99 in mitochondria-associated ER membranes causes mitochondrial dysfunction in Alzheimer disease

Authors: *M. PERA[1], D. LARREA[1], C. GUARDIA-LAGUARTA[2], R. B. CHAN[2], M. F. MEHLER[5], G. DI PAOLO[2], K. VELASCO[3], R. ACIN-PEREZ[6], J. ENRIQUEZ[6], E. A. SCHON[4], E. AREA-GOMEZ[1];

Abstract: In the amyloidogenic pathway associated with Alzheimer disease (AD), the amyloid precursor protein (APP) is cleaved by β-secretase to generate a 99-aa C-terminal fragment (C99) that is then cleaved by γ-secretase to generate the β-amyloid (Aβ) found in senile plaques. In previous reports, we and others have shown that γ-secretase activity is enriched in mitochondria-associated endoplasmic reticulum (ER) membranes (MAM), and that ER-mitochondrial connectivity and MAM function are upregulated in AD. We now show that C99 is localized to

MAM, where it is normally processed rapidly. In AD, however C99 accumulates above normal levels in MAM regions, resulting in increased sphingolipid turnover and an altered lipid composition of both MAM and mitochondrial membranes. In turn, this change in mitochondrial membrane composition interferes with the proper assembly and activity of mitochondrial respiratory supercomplexes, thereby likely explaining the bioenergetic defects characteristic of AD.

Title: Effects of age and the expression of wild type human APP (hAPPwt) on synaptic plasticity and spine morphology in transgenic knock-in mice expressing an Alzheimer's disease related mutant Presenilin-1 (PS1(M146V)) gene.

Authors: *H. S. ZANJANI[1], K. KINUGAWA[1,2], M. W. VOGEL[3], J. MARIANI[1,2], C. ROVIRA[1,2];
[1]UMR 8256, Univ. of P. & M. Curie and CNRS, Paris, France; [2]Inst. de la Longévité, Charles Foix Hosp., Ivry sur Seine, France; [3]Lab. of Neurosciences, Columbia, MD

Abstract: Memory impairment, the major and early cognitive symptom of Alzheimer disease (AD), has been linked to synaptic deficits in the hippocampus. Understanding the mechanisms of these synaptic deficits is essential for preventing dementia. The vast majority of familial AD (FAD) cases are related to mutations in presenilin-1 (PS1). As part of the gamma-secretase complex, PS1 is involved in the release of the neurotoxin amyloid Aβ. PS1 variants also activate GSK3β, cause Tau phosphorylation, and influence synaptic function and transmitter release. In PS1(M146V)KI transgenic mice there is an overproduction of Aβ42, but it fails to aggregate and it is much less toxic than human Aβ.
In this study we crossed PS1(M146V)KI transgenic mice with AD mice overexpressing wild

type human APP (hAPPwt) to generate double transgenic hAPPwt/PS1(M146V)KI mice that secrete human Aβ. We tested the effect of the PS1 mutation on neuronal function and synaptic plasticity in the presence of human Aβ expression. As synaptic plasticity is correlated with spine remodeling, we also analyzed spine densities and morphology.
We recorded the early LTP response in the CA1 region from hippocampal slices in 9-month-old mice. We found a clear deficit in the early LTP response in hAPPwt/PS1(M146V)KI mice (0.0997 ± 0.0018, n=11), but no significant differences between control mice: +/+ mice (1.29 ± 0.0027, n=11); +/APP mice (1.242 ± 0.0027, n=10); or PS1 KI/KI mice (1.2563 ± 0.0032, n=10). The analysis of average spine density the stratum radiatum of Golgi-impregnated CA1 pyramidal neurons revealed significant increases in total spine density, particularly mushroom spines in PS1 KI/KI and hAPPwt/PS1(M146V)KI mice (0.9±0.003/μm) compared to WT and +/APP mice (0.8±0.02/μm, $p<0.005$; n=3; Tukey's test). Therefore, these studies revealed early Aβ-dependent synaptic deficits and alteration in spine density caused by the PS1(M146V)KI mutation.
For imunohistopathological analysis, brain sections from young and aged WT and transgenic mice were immunostained with anti- β-amyloid protein and anti-paired helical filament-tau (PHF-tau) antibodies. Intracellular immunoreactivities for PHF-tau staining were observed in the transgenic but not in the wild-type mice brains. We found a deposition of fibrillar β-amyloid within cerebral vessels, indicating the presence of a cerebral amyloid angiopathy (CAA) in the PS1(M146V)KI, hAPPwt and double transgenic mice at the age of 15 and 21 months, but not in the WT mice. An amyloid plaque deposition was observed as well in the 21-month-old double transgenic mice brain indicating age-related progression of PS1-induced pathology in the presence of human Aβ.

Title: Function and processing of the Alzheimer's Disease associated amyloid precursor protein in the endocrine pancreas.

Authors: *J. KULAS, C. K. COMBS;
Biomed. Sci., Univ. of North Dakota, Grand Forks, ND

Abstract: Numerous lines of evidence indicate that the pathophysiology of diabetes and Alzheimer's disease (AD) share molecular mechanisms. This suggests that a common intervention may ultimately apply to either disease. In order to test this idea, we have examined the amyloid precursor protein (APP). It is well-known that APP is highly expressed in neurons and serves as the precursor of the beta amyloid peptide that accumulates as plaques in AD brains. Several mutations in the gene coding for APP result in a rare early-onset form of AD that is characterized by increased proteolysis of APP. Therefore, enzymatic processing of APP and production of its secreted fragments remain an area of intense study related to AD. We have observed that the α/β cells of the endocrine pancreas also abundantly express APP, including expression in both type II diabetic pancreas and pancreatic adenocarcinoma. The endocrine pancreas is the primary site of insulin production in the human body, and dysfunction of this critical organ is a hallmark of both type I and type II diabetes. We demonstrate that APP is present in the endocrine pancreas by both immunohistochemistry and western blots of isolated murine and human islets. Interestingly, similar to what has been demonstrated in neurons, we observed that primary cultures of pancreatic islets shed N-terminal APP fragments (sAPP). Based upon the trophic effects of sAPP described in the brain, we demonstrated that sAPP fragments potentiate glucose stimulated insulin secretion in isolated islets. In addition, we have screened for compounds which block the release of sAPP from endocrine pancreatic cell lines. Our data indicate that these compounds inhibit the growth of endocrine pancreas cell lines, but proliferation can be rescued through the exogenous administration of recombinant sAPP. These data demonstrate that sAPP has a critical role in regulating endocrine pancreas physiology and indicates that APP has functions in both the brain and pancreas. This work suggests an APP related common mechanistic pathway involved in diabetes, Alzheimer's disease, and neuroendocrine tumor biology.

Title: App abeta hsp60 functional interaction. relevance to alzheimer's disease

Authors: *C. MARINO[1,2], F. CAPPELLO[2,3], P. SAN BIAGIO[4], G. TAGLIALATELA[1]; [1]Mitchell Ctr. for Neurodegenerative diseases, Dept. of Neurol., Univ. of Texas Med. Br., Galveston, TX; [2]Exptl. Biomedicine and Clin. Neurosci., Univ. of Palermo, Palermo, Italy; [3]Euro-Mediterranean Inst. of Sci. and Technol., Palermo, Italy; [4]Inst. of Biophysics, Natl. Res. Council, Palermo, Italy

Abstract: Alzheimer's disease (AD) is a devastating neurodegenerative disorder affecting more than 40 million individuals worldwide. The high number of factors triggering the onset of AD justifies the current absence of disease-curing therapies. The involved pathological mechanisms are still elusive and, therefore, the finding of effective therapies requires further elucidation of biomolecular mechanisms controlling AD pathogenesis. Particularly, the aberrant amyloidogenic cleavage of amyloid precursor protein (APP), amyloid beta (Aβ) peptide misfolding and oligomerization, and the impairment of the protein quality control machinery are key hallmarks characterizing the onset of the disease. Moreover, evidence suggests that the age-related impairments of chaperones, a class of modulatory proteins involved in the protein quality control of the cell, contributes to the neurotoxicity induced by Aβ oligomers, but the underlying mechanism remains unresolved. In the present work, we characterized the functional interaction between Aβ and the mitochondrial chaperon Hsp60 using an *in vitro* approach to test if up-regulation of Hsp60 can protect against Aβ toxicity. Specifically, Chinese Hamster Ovary (CHO) cell line overexpressing human APP751 variant of APP (7PA2 cell line), a model of human Aβ oligomer production, were used, along with immunocytochemistry, ELISA and western blotting techniques, to investigate the effect of Hsp60 overexpression on Aβ production in different sub-cellular environments: intracellular, extracellular and mitochondria. Moreover, the effect of Hsp60 on APP-derived fragments was also tested in order to elucidate the effect of Hsp60 on APP cleavage. Our data suggest that up-regulation of Hsp60 interferes with APP processing and the release of Aβ in the extracellular environment, leading to reduced production of toxic Aβ oligomers in cell overexpressing Hsp60. Based on these initial results, we propose that the understanding of Hsp60-APP/Aβ functional interaction might contribute to the design of future effective therapeutic concept for AD centered on reducing the endogenous production of neurotoxic Aβ oligomers.

Title: Role of SorLA in APP trafficking and implications for amyloidogenesis

Authors: *M. C. MICSENYI, R. PANDIT, M. WITTMANN, T. BUSSIERE;
Biogen, Cambridge, MA

Abstract: *SORL1* variants are implicated in both sporadic and familial forms of Alzheimer's disease (AD). Several large-scale genome-wide association studies (GWAS) have shown *SORL1* to be associated with late-onset AD, while exome sequencing studies have shown enrichment of rare, putatively damaging *SORL1* variants in early-onset AD. *SORL1* encodes the neuronal sorting receptor SorLA, which has been implicated in the trafficking of APP. Studies suggest SorLA protein levels are reduced in sporadic AD patient brains and this is associated with increased beta-amyloid load. Reduced levels of SorLA have been reported to inhibit APP recycling between endosomal and trans-Golgi compartments, thereby promoting APP cleavage by BACE1 and driving amyloidogenesis. The majority of beta-amyloid generated through this mechanism is believed to occur within acidic endosomes where secretase activity is optimal. While several reports have confirmed SorLA's role in APP trafficking using over-expression models, this interaction in more physiologically relevant systems remains largely undefined. Additionally, it is unclear how intracellular amyloid generation caused by reduced SorLA levels could ultimately result in extracellular deposition of the pathological protein. Using biochemical and immunocytochemical methods we are evaluating the interaction and subcellular localization of endogenous SorLA and APP. Furthermore, we hypothesize that reduced SorLA levels result in increased beta-amyloid generation, accumulation and oligomerization within endosomal compartments. Of particular interest is whether increased endosomal generated amyloid is efficiently targeted for lysosomal degradation, exocytosed, or if it promotes endosomal membrane permeability and release into the cytosol. These studies have significant implications for further defining SorLA in APP trafficking and the downstream consequences associated with amyloidogenesis in AD.

Title: Rac and Rho GTPases affect production of Alzheimer's disease proteins: APP, Aβ, and Tau

Authors: *R. CHABAYTA[1], J. REDDY[2], D. HYNDS[2];
[2]Biol., [1]Texas Woman's Univ., Denton, TX

Abstract: Alzheimer's disease (AD) is a fatal neurodegenerative disorder that is histopathologically characterized by the formation of amyloid plaques and neurofibrillary tangles in the brain. Aberrant cleavage of the amyloid precursor protein (APP) produces beta amyloid plaques. Hyperphosphorylation of a microtubule associated protein, tau, forms the neurofibrillary tangles. Small Rho GTPases (guanosine triphosphatases) have been implicated in many neurological diseases, including Alzheimer's disease. Rho proteins (Rho, Rac, and Cdc42) regulate a wide variety of cellular functions and play key roles in actin cytoskeletal rearrangements. The purpose of this study was to determine the effects of manipulating Rho GTPases: Rho, Rac, Cdc42, on the production of Alzheimer's disease proteins. For that purpose, B-35 cells were treated with different Rho GTPases inhibitors and activators. The levels of APP, Aβ, and tau were determined. Toxin A, a Rho/Rac/Cdc42 inhibitor, increased the levels of Aβ and tau as expected and decreased the levels of APP. Rho inhibitor I and Rho/Rac/Cdc42 activator treatments significantly decreased APP levels, but increased the levels of tau. Rac I Inhibitor II decreased the levels of APP, suggesting that disruption of Rho GTPases affect APP, Aβ, and tau production. To further investigate the role of Rac and Rho in AD pathology, lysates from cells transfected with EmGFP, EmGFP-RhoA, EmGFP-RhoA^{C190A}, EmGFP-Rac1, and EmGFP-Rac1^{C196A} were used to detect changes in APP and tau levels. High molecular weight APP increased and tau levels decreased when transfected with EmGFP-Rac1 and Rac1^{C196A}, while levels of APP decreased when transfected with EmGFP-Rac1 and EmGFP-RhoA^{C190A}. Our data support a role for Rho GTPases in the classic hallmarks of AD pathology and suggest targeting Rac and Rho as a possible AD therapy.

Title: NEP versus IDE in *In vivo* Aβ metabolism

Authors: *H. SASAGURI, T. SAITO, Y. MATSUBA, T. C. SAIDO;
Lab. for Proteolytic Neurosci., RIKEN Brain Sci. Inst., Wako-Shi, Japan

Abstract: Alzheimer's disease (AD) is the most common cause of dementia, pathologically characterized by senile plaques in the affected brain areas composed of amyloid β peptide (Aβ). In sporadic AD, it is hypothesized that aging-dependent decrease of extracellular Aβ catabolism causes Aβ accumulation. Neprilysin (NEP) and insulin degrading enzyme (IDE) are two major candidates considered to degrade extracellular Aβ. They have, however, never been relevantly compared side by side *in vivo*. In order to achieve objective comparison, we crossbred our single *App* knock-in mice, App^{NL-F} mice (NL-F mice) with NEP- and IDE-KO mice. NEP deficiency significantly increased Aβ deposition in the knock-in mice. In contrast, IDE deficiency actually decreased Aβ deposition presumably due to an increased expression of NEP. Expression of presenilin 1, BACE-1 and C-terminal fragment-β (CTF-β) remained unchanged in NL-F X NEP-KO mice, indicating that the decrease of Aβ in the double mutant mice is not due to alteration of intracellular APP processing. These observations establish NEP as the major Aβ-degrading enzyme *in vivo*. We conclude that NEP can become an ideal therapeutic target for reducing Aβ burdens in preclinical stage of AD patients and that our new generation AD mice are relevant models for AD prevention study. Using a similar strategy, we are now trying to generate a novel non-human primate model of AD.

Title: Endosomal-lysosomal sequestration of cholesterol alters metabolism of Amyloid Precursor Protein (APP) in cultured N2a cells

Authors: J. CHUNG[1], A. MOHAMED[2], M. MAULIK[3], G. THINAKARAN[4], E. POSSE DE CHAVES[2], *S. KAR[5];
[1]Dept. of Psychiatry, [2]Dept. of Pharmacol., [3]Ctr. for Prions and Protein Folding Dis., Univ. of Alberta, Edmonton, AB, Canada; [4]Depts of Neurobiology, Neurology, and Pathology, The Univ. of Chicago, Chicago, IL; [5]Depts Med. and Psychiatry, Univ. Alberta, Edmonton, AB, Canada

Abstract: Multiple studies have shown that elevated levels of cholesterol can influence processing of amyloid precursor protein (APP) leading to increased production of amyloid β (Aβ) peptides, which are believed to play a critical role in Alzheimer's disease (AD) pathogenesis. However, very little is currently known on how sequestration of cholesterol within endosomal-lysosomal (EL) system, the major site of Aβ production, can regulate APP metabolism. In this study we use U18666A, a class II amphiphile that triggers redistribution of cholesterol to the EL system, on cultured N2a cells grown in media containing 0%, 5% or 10% fetal bovine serum (FBS). The N2a cells used in the study includes wild type N2a cells ($N2a_{wt}$), N2a cells transfected with either wild type human APP ($N2aAPP_{wt}$) or human APP carrying Swedish mutation ($N2aAPP_{sw}$). Our results indicate that U18666A treatment in 0% FBS, but not in 5% or 10% FBS, decreases the levels of total and free cholesterol in all categories of N2a cells. This reduction in cholesterol is reflected in increased levels of SREBP2. The levels of APP and APP-CTFs are differentially increased in $N2aAPP_{wt}$ and $N2aAPP_{sw}$ cells but not in $N2a_{wt}$ cells. While intracellular levels of $A\beta_{1\text{-}40/42}$ are increased, the secretory levels of these peptides are found to be decreased in $N2aAPP_{wt}$ and $N2aAPP_{sw}$ cells following treatment with U18666A. The steady state levels of α-secretase ADAM10, β-secretase BACE1 and components of γ-secretase (PS1, Nicastrin, PEN2 and APH1) remain unaltered in all three types of cells. We are currently evaluating if delipidation can reverse the observed changes in APP metabolism. Our results, obtained so far, suggest that redistribution of cholesterol into the EL system can differentially alter the levels/processing of APP depending on the cultured conditions and endogenous levels of APP.

(DZNE) and Neuroproteomics, Klinikum rechts der Isar, TU Munich, Munich, Germany; [7]Heinrich Heine Univ., Duesseldorf, Germany

Abstract: One of the major hallmarks of Alzheimer´s Disease (AD) is the accumulation of soluble and aggregated amyloid β (Aβ) peptides in the brains of AD patients. Aβ peptides are generated from the amyloid precursor protein (APP) in the amyloidogenic pathway through two consecutive cleavage events. Most prominent, BACE 1 (β-site APP cleaving enzyme 1) cleaves APP at the β-secretase cleavage site and generates the N-terminus of Aβ. Second, the γ-secretase complex cleaves the remaining 99 amino acids long C-terminal fragment (CTF/C99) and releases the C-terminus of Aβ. As both secretases are not restricted to a single site, Aβ peptides vary in length. BACE 1 can generate Aβ starting in position p1 or p11 (Aβ1 x/11 x) whereas γ-secretase complex has several cleavage sites and can generate varying C-termini of Aβ. The metalloprotease meprin β cleaves APP as a β-secretase reminiscent of BACE 1, however, predominantly generating N-terminally truncated Aβ2-x variants. We observed increased endogenous sAPPα levels in the brains of meprin β knock-out (ko) mice compared to wild-type controls. We further analyzed the cellular localization of this interaction and found that cleavage of APP by meprin β occurs prior to endocytosis. Additionally we demonstrate that meprin β cleavage of APP occurs prior to the endocytic compartments, as diminished APP endocytosis has no influence on meprin β mediated Aβ generation. Moreover, we are able to demonstrate that meprin β generates N-terminally truncated Aβ2-40/42 peptides that display increased aggregation compared to non-truncated Aβ peptides. This catalytic activity of meprin β is differentially affected by mutated forms of APP and in contrast to wt APP, meprin β is not able to cleave APPswe at position 672 and does not generate N-terminally truncated forms of Aβ from this APP mutant. Furthermore, we are able to demonstrate increased staining of meprin β in brains of Alzheimer disease patients compared to non-demented control subjects. Concluding, we propose that meprin β may be involved in the generation of N-terminally truncated Aβ2-x peptides of APP, but acts independently from BACE-1.

Title: Insulin promotes non-amyloidogenic processing of amyloid precursor protein through PI3K/Akt signaling.

Authors: *O. KWON, Y. CHO, H. OH, S. CHUNG;
Physiol., Sungkyunkwan Univ. Sch. of Med., Suwon-City, Korea, Republic of

Abstract: Alzheimer's disease (AD) is the main form of dementia mostly affecting elderly people. Increased level of amyloid-β peptide (Aβ) is the main pathological feature of AD. Aβ is derived from amyloid precursor protein (APP) by the amyloidogenic pathway. In this pathway, APP in the plasma membrane is internalized through clathrin-dependent endocytosis, and delivered to endosomes, where it is cleaved by β-secretase. Alternatively, APP can be cleaved by α-secretase at the plasma membrane excluding Aβ production (non-amyloidogenic pathway). There are many evidences for the association between AD and diabetes mellitus (DM). Factors related to the pathogenesis of AD include metabolic alterations such as insulin resistance and impairment of insulin signaling, both are also hallmarks of DM. However, the underlying mechanism for the close association between AD and DM is still unknown. To investigate the effect of insulin on APP processing, we tested whether insulin affected the processing of APP and Aβ production from SH-SY5Y cells overexpressing hemagglutinin-tagged wild-type APP. We found that insulin treatment changed APP processing, increasing APP level at the cell surface, and decreasing the rate of endocytosis. Consistent with decreased APP endocytosis, Aβ level was decreased by insulin in a time and concentration dependent manner. We also found that the specific inhibitor for protein kinase B prevented the effects of insulin on APP processing and Aβ level, indicating that the effects of insulin are mediated via PI3K/Akt insulin signaling. Our results show that insulin may affect Aβ generation by regulating APP processing, suggesting a possible link between insulin deficient DM and cerebral amyloidosis in the pathogenesis of AD.

Title: MiR-20b reduces levels of amyloid precursor protein (APP) and beta-amyloid in human cells

Authors: *N. CHOPRA, K. NHO, B. L. BAYON, D. K. LAHIRI;
Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disorder affecting millions of individuals worldwide. The disease is characterized by the post-mortem presentation of senile plaque and neurofibrillary tangles. Neuritic plaque is produced due to oligomerization of monomeric Aβ peptide which is generated from the larger amyloid precursor protein (APP), thereby making APP a potential therapeutic target. One method of targeting APP would be to identify putative microRNA (miRNA) that modulate APP expression. Using predictive algorithms such as TargetScan, we identified miR-20b as a miRNA that may target the APP 3' untranslated region (UTR). We confirmed this interaction by co-transfecting miR-20b with a reporter vector containing the full-length APP 3'UTR and observing a reduction in the reporter's luciferase assay in HeLa cells. On mutating the predicted target site, we observed that miR-20b's luciferase reduction was abrogated, thereby confirming the seed site of interaction. We also confirmed that miR-20b reduces levels of APP protein in HeLa cells. Using a primary human mixed brain culture developed in our laboratory, we showed that miR-20b reduces levels of APP protein, but has no effect on β-APP site-cleaving enzyme-1 (BACE1); the rate-limiting enzyme in the production of Aβ. We also showed that co-transfection of the antagomir to miR-20b reverses the miR-20b-mediated reduction of APP. Given that APP is a synaptic protein, we were interested in the effect miR-20b may have on synaptic integrity. Using the IncuCyte Zoom imaging system, we showed that while APP siRNA reduced neurite length and branch points, miR-20b had no effect on these metrics relevant to neuronal function. We also showed that overexpression of miR-20b results in a reduction in soluble Aβ as measured by sensitive ELISA. In order to look at possible changes in expression of the MIR20B gene in a large cohort of AD and control patients, we looked for SNPs within the gene boundary on Chromosome X. We found SNP rs138397515 which was associated with CSF Aβ as well as CSF phosphorylated tau. Finally, using quantitative RT-PCR, we showed a differential expression of miR-20b in various cell types, but observed no different in levels of miR-20b in a post-mortem brain cohort subdivided across Braak stages. In conclusion, we have identified miR-20b as a novel target for AD therapy.

Title: APP expression in mammary gland secretory epithelium

Authors: *K. L. PUIG, S. A. URQUHART, A. A. REBEL, C. K. COMBS;
Univ. of North Dakota, Grand Forks, ND

Abstract: The amyloid precursor protein (APP) is often characterized as a neuronal protein although myriad cells have demonstrated expression. For example, we and others have reported robust APP expression by intestinal epithelial cells. Moreover, we demonstrated stimulated Aβ secretion and uptake by these cells. To determine whether APP expression and processing to Aβ could be a common behavior of secretory epithelium, we examined murine mammary glands from C57BL/6 wild type littermate controls and APP/PS1 mice. As expected, mammary gland epithelial cells demonstrated robust APP immunoreactivity in particularly the APP/PS1 mice. A similar pattern of immunostaining was observed in human mammary tissue. More importantly, Aβ peptide was quantifiable in expressed milk suggesting that it may be secreted from the mammary gland. Alternatively, milk Aβ may have a relationship with levels of blood or brain Aβ.

Title: Utilizing strain-specific Toxoplasma gondii infection to investigate APP processing pathways

Authors: *J. B. FRANCO, C. M. CABRAL, W. R. MCDONALD, A. A. KOSHY;
BIO5 Inst., Univ. of Arizona, Tucson, AZ

Abstract: Alzheimer's Disease (AD) is a neurological disorder affecting millions of people worldwide. AD is characterized by progressive neurodegeneration and the presence of amyloid-beta (Aβ) plaques which are protein aggregates that derive from differential processing of the amyloid precursor protein (APP) by the β-secretase enzyme. Aβ peptides are thought to play a central role in the development and potentiation of AD; yet, treatments targeting Aβ have failed to change disease progression. Taking novel approaches to understand Aβ dynamics may offer new, more successful therapeutic options. One such approach would be to leverage the co-evolution between the obligate intracellular parasite *Toxoplasma gondii* and the mammalian brain. *Toxoplasma* is a ubiquitous parasite that naturally establishes a life-long, asymptomatic CNS infection in both mice and humans. A previous study demonstrated that in a human APP (hAPP) AD mouse model, chronic infection with *Toxoplasma* led to a >80% reduction in Aβ plaque burden compared to uninfected controls. To determine if all strains of *Toxoplasma* offered protection against Aβ, and if this protection could be induced by acute infection only, we infected a different hAPP mouse model with the 3 genetically distinct, canonical strains of *Toxoplasma* (type I, II, or III). We found that the type I strain (acute infection only) mirrored uninfected controls in all tested parameters. Conversely, both the type II and III strains (acute and chronic infection) established a CNS infection and provoked neuroinflammatory changes, but only the type II infection was protective against Aβ. Having established these *Toxoplasma* strain-specific effects on Aβ, we hypothesized that by comparing the CNS effects of type II and type III infection we would be able to identify changes linked to protection rather than those simply associated with infection. To establish the baseline effect of type II and III infection on proteins relevant to Aβ generation and processing, we measured protein levels of APP, ADAM10, PEN2, BACE1, neprilysin, and IDE in C56BL/6 mice at 3 weeks post infection (wpi). We found that type II infection was associated with a ~2-fold increase in ADAM10, a marker for α-secretase. None of the other protein levels significantly differed between type II and III infection. This finding suggests that type II infection protects against Aβ by increasing the activity in the non-amyloidogenic APP processing pathway. Current work is focused on confirming these results in infected hAPP mice.

Title: Ciliary receptors modulate neuronal autophagy: impact of amyloid beta

Authors: *O. PAMPLIEGA[1,2], E. BEZARD[3,2];
[1]Inst. des Maladies Neurodégénératives, Univ. De Bordeaux, Bordeaux Cedex, France; [2]Inst. des Maladies Neurodégénératives, UMR5293, CNRS, Bordeaux, France; [3]Inst. des Maladies Neurodégénératives, UMR5293, Univ. de Bordeaux, Bordeaux, France

Abstract: Autophagy is an intracellular catabolic pathway that contributes to cell homeostasis and maintenance of the cellular energetic balance. Neurodegenerative diseases like Alzheimer's disease (AD) are characterized by the accumulation of neuropathogenic proteins that compromise autophagic function at different steps, perpetuating the accumulation of toxic aggregates and amplifying the deleterious effects of neuronal activity. In AD, both the endocytic and autophagy pathways contribute to APP processing and amyloid beta (Aβ) generation by mutant presenilin-1 (PS1).
In the search of new ways to upregulate autophagy with therapeutic purposes, we have previously described that signaling pathways clustered in the primary cilium (PC) activate autophagy. The PC is a solitary organelle sited on the surface of almost all cell types that compartmentalizes several signaling pathways. Neurons and glia in the CNS possess a cilium that responds to neurotrophins, growth factors, hormones and other extracellular signaling elements, whereas neurons in the hippocampus require the PC for neuronal regeneration. Interestingly, it has been reported that Aβ binds selectively the $p75^{NTR}$ receptor, which localizes in the PC of hippocampal neurons. Moreover, AD animal models have a decreased PC length immunostained for $p75^{NTR}$ receptor. However, despite the increasing description of signaling pathways that require the PC for their effector mechanisms, the cellular mechanisms that govern these pathways are poorly understood in the adult brain.
Using pharmacological and genetic approaches, we investigated the role of the ciliary $p75^{NTR}$ receptor over autophagy function in primary hippocampal neurons and neuronal cellular models. Moreover, we studied the effect of recombinant Aβ on PC morphology and structure, as well as its effect on cilia-dependent autophagy *in vitro*. Our results will help characterizing the ciliary signaling pathways that modulate autophagy in the hippocampus in physiological conditions as well as during Aβ pathology. Overall, we aim to define through the PC new ways to burst

autophagy for developing new therapeutic strategies against neurodegeneration.

Title: Hindlimb locomotion deficits are related to spinal cord beta amyloid levels in both intact and spinal Alzheimer's disease model J20 mice

Authors: *R. HUANG[1,2,3], M. S. JOSEPH[4], H. ZHONG[4], Y. SEO[4], X. LIU[4], W. GUO[5], S. SHAHRESTANI[1], R. R. ROY[2,4], E. KOO[5], V. R. EDGERTON[1,2,4], D. C. LU[1,2,3];

Abstract: Although often overlooked, impairments of gait and postural stability are common features of Alzheimer's Disease (AD). These deficits generally are considered secondary impairments attributable to cerebral degeneration and dementia, but detailed studies of spinal cord function in AD are lacking.
To study the potential role of spinal cord involvement in motor deficits associated with AD we used an APP mouse model (PDGF- APPswe/Ind mice (J20)) to determine changes in stepping behavior, spinal learning, and the levels of spinal amyloid-precursor protein (APP) and beta-amyloid peptide (Aβ) expression in intact and spinal cord transected mice.J20 mice exhibited deficits in treadmill stepping and hindlimb clasp tests when compared to their wild type (WT) littermates at both the 3-4 and 10-13 month time points (n=16-24 mice/group). ELISA and Western Blot analyses showed higher levels of APP and Aβ in J20 compared to WT mice in all spinal cord segments (cervical, thoracic, lumbar and sacral) at both time points. These results indicate that motor deficits in J20 mice can be related to deficits in spinal as well as supraspinal networks.
To further investigate how the spinal circuitry might contribute to the motor deficits observed in J20 mice, a complete mid-thoracic spinal cord transection was performed in J20 and WT mice to eliminate supraspinal input to the lumbosacral cord. Treadmill bipedal stepping ability

(n=14/group) and paw withdrawal spinal learning (PaWL) performance (n=12/group) were assessed at 3-4 and 10-13 month time points. Spinal J20 mice showed slower hindlimb stepping recovery and impaired spinal learning of the simple PaWL motor task compared to the spinal WT mice. Moreover, the motor outcomes for the spinal J20 mice were negatively related with Aβ levels in the lumbar cord.
The results from both the behavioral tests and the molecular analyses suggest that early and local changes in the spinal cord circuitry are present in J20 mice. The negative correlation between motor function and Aβ levels in the lumbar cord in spinal J20 mice are consistent with the hypothesis that AD pathological changes in the spinal cord may be associated with motor deficits in AD human subjects.

Abstract: Cerebrovascular accumulation of the amyloid β-protein (Aβ), a condition known as Cerebral Amyloid Angiopathy (CAA), is a small vessel disease that is prevalent in the elderly, an important driver of vascular cognitive impairment and dementia (VCID) and a prominent comorbidity of patients with Alzheimer's disease (AD). Additionally, familial CAA disorders result from mutations that reside within the Aß peptide sequence. Previously, we generated the unique Tg-SwDI transgenic mouse that produces Dutch/Iowa CAA mutant human Aß in brain

and develops early-onset fibrillar cerebral microvascular Aß deposition, associated neuroinflammation, and behavioral deficits. However, relative to rats, mice are limited in terms of exploring specific cognitive deficits using a broad range of sophisticated and well-validated tests. Therefore, we have generated a new rat model, rTg-SwDI, with the same familial Dutch and Iowa CAA mutations in the Aß peptide. Initial analyses of histopathology of the rTg-SwDI rats show a progressive and robust accumulation of small vessel fibrillar amyloid accumulation starting at 3 months of age. Preliminary behavioral analyses from 3 and 6 months aged rTg-SwDI rats in the Radial Arm Maze and the Novel Object task reveal a form of perceptual slowing, a characteristic impairment in CAA in humans, which we have termed stimulus encounter rate slowing (SERS). This occurs in the absence of changes in measures of general activity, motor ability or balance in the Open Field task. These findings introduce the rTg-SwDI model as a promising tool for furthering our understanding of the contribution of CAA to VCID. *This work was supported by NIH R21 NS091969

Title: Fate of hippocampal neural stem cells in human amyloid precursor protein transgenic mice

Authors: *C.-H. FU, D. M. IASCONE, A. HAZRA, M. S. PYFER, X. ZHANG, J. CHIN; Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Alzheimer’s disease is associated with hippocampal dysfunction in both human patients and in transgenic mouse models of disease. Adult hippocampal neural stem cells, which contribute to normal hippocampal function via neurogenesis, appear to have finite neurogenic potential in normal aging. However, epileptiform activity, exhibited by both AD patients and transgenic mice, appears to accelerate and prematurely exhaust the neural stem cell pool, which may contribute to hippocampal dysfunction. We found that the aberrant dynamics of neurogenesis in amyloid precursor protein (APP) transgenic mice throughout disease progression are associated with epileptiform activity, corresponds with the development of dentate

dysfunction, and is normalized by treatment with an antiepileptic drug. However, the fate of the neural stem cells that exit the stem cell pool in disease conditions is not clear. Previous studies demonstrated that in normal aging, division-coupled exhaustion of the neural stem cell pool results from terminal differentiation of neural stem cells into astrocytes, and a coincident increase the number of astrocytes in the dentate gyrus with age. To assess whether a similar process occurs in disease conditions such as in AD, we examined whether the number of astrocytes increased as neural stem cells decreased in the dentate gyrus of APP mice over time. Our results suggest that there are both similarities and differences in neural stem cell pool dynamics between normal aging and in AD.

Title: The 1-42 isoform of amyloid beta reduces cell viability of Salmonella enterica

Authors: A. O'MEARA[1], B. ELLSWORTH[1], *G. D. GRIFFIN[2];
[1]Biol., [2]Departments of Biol. and Psychology, Hope Col., Holland, MI

Abstract: Alzheimer's disease (AD) is the sixth-leading cause of death in the United States. In fact, one out of every eight Americans aged sixty-five and older will develop the disease. One pathological hallmark associated with AD and other forms of dementia is the over-accumulation of the peptide amyloid beta. While amyloid beta is present at low levels in all humans, its function is a source of great debate. The peptide has been shown to reduce the viability of microbes that have invaded the central nervous system. However, this finding has only been demonstrated once so far. The present work tested the hypothesis that amyloid beta exerts antimicrobial activity against *Salmonella enterica* (*S. enterica*), a leading cause of meningitis. After treating *S. enterica* with a range of concentrations (1pM-1microM) of both major isoforms of amyloid beta (1-40 and 1-42), we measured bacterial cell viability with the alamar blue assay. Our results revealed that the 1-42 isoform, but not the 1-40 isoform of amyloid beta, had an

effect on bacterial growth. More specifically, administration of 10pM of amyloid beta (1-42 isoform) reduced cell viability over 20 percent (compared to vehicle control; $F=32.91$, $p<0.0001$). This result extends the finding that amyloid beta has an anti-microbial function. Moreover, our results indicate that the 1-42 isoform, enriched in amyloid beta plaques associated with dementia, has unique properties that allow it to reduce the growth of *S. enterica*. Lastly, our data suggest that the peptide can exert antimicrobial effects at a concentration (10pM) lower than that associated with protein misfolding and the plaque formation associated dementia. While ongoing work is being performed to dissect the mechanisms underlying these findings, our data supports the hypothesis that amyloid beta release *in vivo* is prompted by microbial infection of the central nervous system.

Title: Amyloid beta levels are influenced by the circadian system

Authors: *G. J. KRESS, F. LIAO, D. M. HOLTZMAN, E. S. MUSIEK;
Dept of Neurol., Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Alzheimer's Disease (AD) is the most common age-related neurodegenerative disease and the most common cause of dementia. Pathogenic amyloid-β (Aβ) plaques accumulate prior to the onset of cognitive impairments in AD. Thus, it is important to identify mechanisms that influence Aβ levels which may be useful for the prevention of cognitive decline in AD. Circadian dysfunction is also a common symptom of AD, which is thought to occur as a consequence of AD pathogenesis. More recently, it has been suggested that there is a possible causative role for circadian dysfunction in AD pathogenesis. Therefore, we sought to investigate whether the circadian system could influence brain Aβ levels in a mouse model of AD. Our overall study aim is to disrupt circadian clock function without perturbing the sleep-wake cycle in order to isolate roles of the circadian system in the regulation of brain Aβ levels. We therefore

genetically disrupted hippocampal circadian clock function via viral mediated deletion of a core circadian clock gene, *Bmal1* within the hippocampus of ~1.5 month old APP/PS1-21 mice, prior to Aβ plaque deposition. Using *in vivo* microdialysis in awake behaving mice, in 12:12 light:dark conditions, we collected hourly interstitial fluid from the ipsilateral virally injected hippocampus and measured soluble Aβ levels over 24 hours. We found no change in the diurnal Aβ oscillation when hippocampal clock function was disrupted, supporting the idea that local clock function within the hippocampus does not acutely mediate Aβ levels. Next we asked if disrupting circadian clock function within the whole brain, while sparing the master circadian pacemaker--the suprachiasmatic nucleus (SCN) and leaving the sleep-wake cycle intact, would influence Aβ levels. To our surprise, we found that diurnal oscillation of Aβ levels persisted in the hippocampus, though with a change in the waveform. Next we investigated if global circadian dysfunction resulting in fragmented sleep patterns acutely impacts Aβ levels. We found with whole brain circadian dysfunction, including the SCN, Aβ oscillations were dramatically blunted. Furthermore, chronic long-term whole brain circadian dysfunction accelerated Aβ plaque deposition. In summary, our present study shows that Aβ levels are dependent upon whole brain circadian clock function implicating SCN function and sleep-wake dynamics as key regulators of Aβ oscillation and plaque deposition. The insight gained from this work should create a cellular framework within which the dynamics of Aβ levels can be better understood and therapeutically modulated.

Title: Regulation of neurotrophins and GSK-3/CREB signal transduction pathways by Amyloid beta oligomers in human hippocampal neural precursor cells (hHippNPCs).

Authors: *G. LOPEZ-TOLEDO[1,2], L. GOMEZ-VIRGILIO[3], U. GARCIA[2], M. CARDENAS-AGUAYO[4];
[1]Physiol. Biophysics and Neurosci., CINVESTAV, Mexico City, Mexico; [2]1Department of Physiology, Biophysics and Neurosci., [3]Dept. of Mol. Biomedicine, Ctr. for Res. and Advanced Studies of the Natl. Polytechnic Inst., Mexico City, Mexico; [4]Dept. of Physiology, Sch. of Med., Natl. Autonomous Univ. of Mexico, Mexico City, Mexico

Abstract: Background: Amyloid Beta (Aβ) is a peptide derived from amyloidogenic APP processing. Extracellular deposit of Aβ constitute one of the histopathological hallmarks of Alzheimer's Disease. The role of Aβ in non-pathological conditions remains elusive. Aβ forms low molecular weight oligomers (dimer/trimer), that can give rise to high molecular aggregates that progress to protofibrils and insoluble fibrils. At high concentrations (micromolar to millimolar) Aβ causes neurotoxicity and cell death. However, it has been proposed that low concentrations (picomolar to nanomolar) of Aβ could act as trophic signal modulating synaptic activity, with implications in memory and learning (Cardenas-Aguayo et al., 2014). It is known that Aβ42 stimulates neurogenesis in the SVZ of adult mice. It is possible that Aβ could act through the neurotrophins receptors, since neurotrophins promote survival, differentiation and synaptogenesis. Understanding the physiological functions of Aβ, could help to elucidate its role during health vs disease. **Methods**: By western blot, immunofluorescent studies and survival assays, we characterize our oligomeric sample incubated in different defined medium and had investigated the role of physiological concentrations of Aβ42 and Aβ40 oligomers on neurotrophins and GSK-3/CREB signal transduction pathways, as well as on major proteolytic systems in hHippNPCs. We prepared Aβ42 and Aβ40 Oligomers (Klein 2002) and characterize the sample by AFM. **Results:** We characterize our oligomeric sample in vitro and in cultures of hHippNPCs, in different FBS free culture medium compared to PBS and at different incubation times, by Western blotting and AF microscopy. Defined Medium supplemented with 0.001% Insulin, transferrin and selenium (ITS), was the optimal condition to evaluate the effects of Aβ oligomers. By Immunofluorecence studies we found that at 6h Aβ oligomers (fluorescein labeled) colocalize with vesicular structures such as endosomes, autophagosomes and lysosomes, suggesting that Aβ oligomers are first endocytosed and then processed by autophagy. Our results show no toxic effects of either Aβ42 or Aβ40 oligomers in hHippNPCs. Aβ42 induce TrkB activation, CREB phosphorylation and modulates GSKα/β. We analyze its implications in tau phosphorylation. **Conclusions**: We conclude that different defined culture medium had differential effects on Aβ aggregation. hHippNPCs internalize Aβ oligomers in endosomes and autophagic vesicles as early as 6h. Aβ42 at physiological concentrations its able to modulate the neurotrophins pathway thus having a neurotrophic function possible linked to neuronal survival and synaptic function.

Title: A common mechanism of proteasome impairment by neurodegenerative disease-associated oligomers

Authors: *R. T. ANDERSON[1], T. A. THIBAUDEAU[2], D. M. SMITH[2];
[1]Neurosci., Howard Hughes Med. Inst. - West Virginia Un, Morgantown, WV; [2]Biochem., West Virginia Univ., Morgantown, WV

Abstract: Despite their diverse pathologies, the vast majority of neurodegenerative diseases are characterized by protein aggregation and loss of proteostasis. As a key regulator of proteostasis, the ubiquitin proteasome system (UPS) degrades soluble cellular proteins, and its function is critical for synaptic maintenance and remodeling as well as general cell viability. Past studies have shown that the UPS is impaired in virtually all neurodegenerative diseases. However, we do not understand how misfolded proteins impair the UPS or if there is a common mechanism. Here, we show that three different proteins from Alzheimer's, Parkinson's, and Huntington's disease misfold and oligomerize into a similar three-dimensional structure. This shared structure, irrespective of the misfolded proteins sequence, binds to the 20S proteasome core particle with low nM affinity and allosterically inhibits opening of the substrate channel. Challenging oligomer inhibition with different allosteric activators demonstrates that the oligomers inhibit conformational changes in the 20S that are required for the 19S regulatory particle to induce gate-opening. By fractionation, we identified that only oligomers that contain the A11 antibody epitope could bind to and inhibit the 20S and 26S proteasomes. Therefore, the accumulation of A11+ oligomers in neurons, irrespective of the type of misfolded protein, would be expected to directly and potently impair proteasome function in any neurodegenerative disease, thus promoting further protein accumulation and the dysregulation of proteostasis.

Abstract: Cholesterol levels are elevated in the brains of Alzheimer's disease (AD) patients. We previously showed that an increase of cholesterol at the plasma membrane promotes endocytosis of the amyloid precursor protein (APP) leading to an increase of Aβ production (Marquer *et al*. 2011, 2014). Moreover, an interaction between C99, the protein fragment resulting from the cleavage of APP by the β-secretase BACE1, and cholesterol has been described in vitro (Barrett *et al*, 2012). In the present work, we studied the involvement of this cholesterol-binding site (CBS) on the production of amyloid-β peptides (Aβ) in HEK293 cells. First, Surface Plasmon Resonance was used to quantify the interaction between 25aa synthetic peptides corresponding to wild-type (wt) or mutated APP CBS and liposomes containing cholesterol. Cholesterol enriched liposomes and wt peptides showed a significant interaction whereas mutant peptides did not. Starting from an APP751-mCherry plasmid, we generated single and double mutants of the CBS using site-directed mutagenesis, namely E693K, S697A, K699A, K699E, G700A, G704A, V710A, S697A/K699A and G700A/G704A (numbering APP770). The amount of Aβ peptides secreted by HEK293T cells transiently expressing the CBS mutants was measured. All mutants, except S697A, produced 1.4 to 10 fold less Aβ40 and Aβ42 than the wt but had no effect on β and γ-secretase activity (levels of C99 and APP intracellular domain unchanged), suggesting that CBS mutants produced Aβ peptides of shorter length as shown previsouly (Kukar *et al*, 2011; Joo In Jung *et al*, 2014). Since APP processing occurs in the endosomal compartment, we analyzed the morphology of early endosomes using immunocytochemistry with an anti-Early Endosome Antigen1 antibody. Early endosomes were categorized in three classes (small, medium and large) according to their mean endosomal volume. HEK293 cells expressing mutants E693K, K699A, G700A and S697/K699A showed an increased number of endosomes of larger volume. We also quantified the subcellular localization of CBS mutants and found less colocalization of APP-E693K in enlarged endosomes as compared to wt. Finally, as BACE1 and APP are in close interaction in lipid rafts (Marquer *et al*, 2011); we studied the distribution of the CBS APP mutants in these micro-domains particularly enriched in cholesterol using biochemical methods. In conclusion our results suggest that a specific interaction between APP and cholesterol controls the level of Aβ40 and Aβ42. We will discuss how this CBS could be targeted in order to diminish the production of toxic amyloid peptides in sporadic AD.

Title: New modeling to find the co-relation between Alzheimer’s disease and Metabolic diseases

Authors: ***M.-H. JO**, A. ASFAQ, F. UL AMIN, M.-O. KIM;
Gyeongsang Natl. Univ., Jin-ju, Korea, Republic of

Abstract: The blood-brain barrier (BBB) represents the interface between the peripheral circulation and the brain, and plays a fundamental role in the cross-talk between these two compartments. The homeostatic function of the BBB is the protection of the brain from peripheral insult/inflammation. Alterations in the function of the BBB lead to pathologies of the central nervous system. Recently, metabolic imbalance has been shown to be an important risk factor associated with the decline of BBB integrity and function. And it has been reported that high-fat diet induced breakage of the BBB. Thus BBB is major link between metabolic disorder and Alzheimer’s disease. In sharp contrast with epidemiological studies and clinical needs, little is known about the mechanisms that link metabolic syndrome to BBB functionality and cognitive disorders. Therefore, it is little known about the making in-vivo and in-vitro models for studying these mechanisms. Here, We study the modeling by specially focusing the Blood-brain barrier.

Title: Role of vascular amylin receptors in the development of amyloid pathology in Alzheimer's disease

Authors: *W. FU, R. SOUDY, A. PATEL, D. WESTAWAY, J. JHAMANDAS;
Med. (Neurology), Univ. of Alberta, Edmonton, AB, Canada

Abstract: Alzheimer's disease (AD) and vascular dementia are the two most common forms of dementia that share a similar pathological feature of cerebral amyloid angiopathy, although the mechanistic link between the two conditions has not yet been identified. Recent, amylin receptor antagonist, AC253 or a synthetic amylin analog, pramlintide have been shown to improve cognitive impairment in different AD mouse models. We hypothesized that amylin receptors could also serve as a pathogenetic factor for the vasculopathic component of AD. To establish this link, we first identified the presence of amylin receptors on the endothelium in two endothelial cell lines, HUVEC and HMEC-1. We determined uptake of $A\beta_{1\text{-}42}$ by these two types of endothelial cells and the resultant formation of amyloid plaques on their membranes. Amylin receptor-3 subtype (AMY3) appears to be mostly involved in the Aβ plaque formation, although the amylin receptor-1 (AMY1) is also found to be present on these cells. Next, we sought to confirm whether mouse brain blood vessels also express amylin receptors. These receptors are not only present on mouse brain vasculature but are also functional because the hydrophilic amylin receptor antagonist, AC253, is easily to penetrate into the brain after a single intraperitoneal (ip) injection in both AD transgenic (TgCRND8) or wild-type control mice. Since amylin receptors are up-regulated in TgCRND8 mice, there is more brain uptake of ip injected AC253 in TgCRND8 mice compared to wild type mice. As chronic ip injections of AC253 have been shown to improve cognitive impairment in TgCRND8 mice, we were also further able to demonstrate that AC253 also reduced cerebral amyloid angiopathy and Aβ plaque burden in these mice using a CLARITY technique. Our data indicate that the amylin receptors on brain vasculature could play a key role in Aβ clearance, plaque formation, and cerebral amyloid angiopathy.

Title: Abnormal axonal transport in tau 45-230-transfected hippocampal neurons

Authors: *A. B. FERREIRA, N. D. RIHERD-METHNER, S. AFREEN, A. E. RUBINO; Cell & Mol. Biol., Northwestern Univ., Chicago, IL

Abstract: We have previously shown that beta-amyloid-induced calpain activation leads to tau cleavage and the generation of the tau_{45-230} fragment in Alzheimer's disease (AD) and related disorders. In addition, the expression of this fragment in otherwise healthy hippocampal neurons induces neurodegeneration followed by cell death. To get insight into the mechanisms underlying the neurotoxicity of tau_{45-230}, we have assessed its effects on organelle transport in hippocampal neurons. For these studies, neurons transfected with GFP-conjugated constructs (p-eGFP-N1 empty vector, hTau40-GFP or Tau_{45-230}-GFP) were identified using a 460-500 nm bandpass filter, and non-transfected neurons were used as controls. Time-lapse recordings of fluorescent-labeled axonal mitochondria and lysosomes were acquired by scanning a single focal plane every 2 sec for a total of 100 sec. Our results showed that the expression of tau_{45-230} in hippocampal neurons significantly reduced the number of organelles transported along their axons. This altered axonal transport did not correlate with changes in the total number of organelles present in these cells or in motor protein levels. No specific changes on anterograde vs. retrograde movements were detected. To determine if this tau fragment could cause a mechanical disruption or blockade of transport, we investigated its subcellular localization. Our results showed that ~30 % of tau_{45-230} was localized in membrane-bound organelle- and cytoskeletal fractions. Together these results suggest that tau_{45-230} could exert its toxic effects by partially blocking axonal transport along microtubules thus contributing to the early pathology of AD. *This work was supported by NIH grant NS090993 to AF.*

Abstract: Tauopathies are neurodegenerative disorders characterized by the accumulation of aggregated Tau proteins. The aggregation of this protein causes formation of histopathological lesions called neurofibrillary degeneration (NFD). In Alzheimer's disease, NFD is able to progress, along existing neural networks, in a hierarchical pattern. The propagation mechanisms are still unclear and our team previously showed that Tau is transferred from primary to secondary connected neurons at least thanks to extracellular vesicles and especially microparticles. Nevertheless, other pathways, such as nanotubes (TNTs), have been described in the transfer of pathogens (ie prion or HIV). The objective of this study is to determine if TNTs might be involved in the inter-cellular passage of Tau. Two cell models have been used; the neuronal lineage CAD and rat primary neuronal cultures. Lentiviral vectors (LVs) were generated to encode: 1) actin or tubulin fused to fluorescent proteins to visualize TNTs and 2) the wild type human protein Tau to follow its transfer. Acquisitions were made after immunocytochemistry or in real-time imaging. We characterized TNTs in both models using specific markers (actin, tubulin and MYO10) and showed that the microtubule-associated Tau protein is physiologically found in TNTs and may be one of its constitutive components. Furthermore, extracellular Tau aggregates induce TNTs formation in primary neuronal cultures, which in turn facilitate the intercellular spread of Tau fibrils. In conclusion, Tau possibly contributes to TNTs formation and function that appear involved in prion-like propagation of Tau assemblies involved in tauopathies. Now, we would like to investigate how Tau is shuttle in TNTs and especially, the contribution of Tau to formation, stabilization and function of TNTs.

Title: The role of selective autophagy in neurofibrillary tangle pathology

Authors: *Y. XU, A. COLE, H. ZHENG;
Baylor Col. of Med., Houston, TX

Abstract: Tauopathies consist of a group of diseases, including frontotemporal dementias and the most common form Alzheimer's disease, and are characterized by the accumulation of intracellular neurofibrillary tangles (NFTs) composed of aggregates of hyperphosphorylated Tau protein and extensive neurodegeneration. Tau is normally localized to the neuronal axons where it binds and stabilizes the microtubules. Aberrant Tau phosphorylation leads to its dissociation from the microtubules followed by aggregation and redistribution to cell bodies and dendrites. Accumulating evidence has implicated impaired autophagy-lysosome pathway in neurodegenerative diseases including diseases of tauopathies. In this study, we examined the role of the autophagy receptor protein p62/SQSTM1 in three tauopathy models: seeding based cellular model and mouse model, showing the prion-like replication and spreading of tau, and tau transgenic moue model, rTg4510. We found that p62 was significantly increased in three models. And further, we found that overexpression of p62 specifically decreased pathological tau. These results suggest that p62-dependent selective autophagy counteracts tangle pathology.

Abstract: There is growing evidence that tau aggregates, a key neuropathological feature of Alzheimer's disease and other neurodegenerative diseases collectively named tauopathies, would be responsible for synaptic loss and cognitive deficits. Although it has been postulated that amyloid beta oligomers are responsible for the onset of Alzheimer's disease, progression of the disease is thought to be dependent on soluble tau oligomers. A number of drug discovery projects are targeting tau related neurotoxicity and neurodegeneration, but current models are inadequate due to their artificial overexpression of mutated or truncated human tau protein. Here, we report the progress in our development of a novel tauopathy model, solely based on a single acute stimulus by misfolded human tau oligomers (hTO) to trigger neurodegeneration and disease progression. Highly reproducible hTO were prepared from wild-type human 4R2N tau monomers and induced neuronal cell death in rodent primary neurons from different brain areas, proven by various and complementary read-outs. Similar properties were measured in human neuronal cultures derived from iPS cells and in human neuroblastoma cell lines. hTO-induced neurodegeneration was associated with loss of synaptic markers and neuro-inflammatory processes, including increased production of pro-inflammatory cytokines. In contrast to highly effective hTO, human tau monomers or fibrils did not induce neuronal death in our hands. This work strongly supports the hypothesis that hTO are toxic species and promising targets for therapeutic interventions.

Abstract: The pathological aggregation of Tau protein is strongly implicated in the pathogenesis of AD and other tauopathies. Previously we generated a conditional expression (Tet-on) cell model of Tau pathology based on N2a cells expressing the 4-repeat domain of Tau with the FTDP-17 mutation ΔK280 (termed $Tau^{4RD\Delta K}$). The deletion variant ΔK280 of Tau is highly amyloidogenic and forms fibrous aggregates in the cells within few days staining brightly with the reporter dye Thioflavin S. The aggregation of Tau protein in cells is toxic but the mechanisms and Tau species responsible for toxicity are still not well understood. We have studied the correlation between stages and intermediate species of Tau aggregation correlated with parameters of cellular toxicity, using a combination of microscopic analysis, fluorescence-activated cell sorting (*FACS*) and biochemical analysis. The pathway of aggregation includes initial dimerization (day 2), low-n oligomerization (days 2-3) and higher aggregation (>day 3). This correlates with early apoptosis (days 1-2), rapid induction and continuous increase of ROS (days 1-4), finally leading to cell damaging, membranes leakiness and cell death (days 3-4). Tau aggregation and cell toxicity can be suppressed by Tau aggregation inhibitors which reduce the aggregation of Tau, and as a consequence the toxicity, as demonstrated by the parameters of apoptosis, viability, and cell death.

Title: Characterization of neurofibrillary tangles and hyperphosphorylated tau in olfactory neural precursors obtained from living Alzheimer's disease patients

Authors: *M. VALDES-TOVAR[1], A. RIQUELME[1], V. MAYA-AMPUDIA[1], L. MENDOZA-DURÁN[1], J. ARGUETA[1], A. LORA-CASTELLANOS[1], O. UGALDE[2], G. BENÍTEZ-KING[1]; [1]Neuropharm. Lab., [2]Psychogeriatric Clin., Inst. Nacional De Psiquiatría Ramón De La Fuen, Mexico City, Mexico

Abstract: Neurofibrillary tangles (NTs) are one of the cytopathological changes found in neurons of Alzheimer's disease (AD) patients. NTs are formed of hyperphosphorylated tau protein, which in this phosphorylated state, dissociates from the microtubules causing cytoskeletal collapse and apoptosis with the subsequent loss of neural connections. NTs have been demonstrated in brain tissue and nasal mucosa samples obtained postmortem from AD patients. In this study we characterized the NTs and hyperphosphorylated tau in neural precursors from olfactory neuroepithelium of living patients with AD stage I diagnosis recruited from the Psychogeriatric Clinic of the National Institute of Psychiatry. Research protocols were approved by the Institutional Research and Bioethics Committee and conducted strictly according to international bioethical policies. Olfactory neural precursors (ONPs) were obtained by nasal exfoliation at the middle turbinate, the nasal septum opposite to the middle turbinate and the olfactory cleft from 4 female patients with AD and from 4 female healthy control subjects (HCS) paired by age. Tau immunofluorescent staining of cultured ONPs showed an increased number of cells with pretangle-like NTs in AD patients regarding the HCS. Nuclear tau1-immunostaining was evident in all preparations after alkaline phosphatase treatment, indicating the presence of phosphorylated tau in the nuclei of ONPs. Immunodetection of the tau protein after 2D-electrophoresis revealed the presence of three isoforms in ONP-extracts of the HCS, whereas AD patients presented five isoforms with higher molecular weight and more basic isoelectric point than those found in HCS. Also, increased levels of hyperphosphorylated tau at either Ser199-202 or Ser396-404 were observed in AD subjects. Results indicate that ONPs obtained by exfoliation are useful to detect pretangle-like NTs and to evaluate tau hyperphosphorylation in AD patients. Further research would define if these findings can be correlated with an early diagnosis, disease stage or progression, and treatment outcome evaluation. Moreover, ONPs may be useful to evaluate novel therapeutic alternatives for AD patients.

Title: Determining the half-life of tau in rat serum.

Authors: *F. D. TINGLEY, III, N. C. REISING, M. L. HAYASHI;
Eli Lilly and Co., Indianapolis, IN

Abstract: Hyperphosphorylated Tau protein is a key component of the neurofibrillary tangles, a pathological hallmark of Alzheimer's Disease (AD). Tau protein is primarily present in the neurons of the brain; however, recent findings demonstrate the presence of Tau in the plasma of AD patients--levels significantly higher than those of normal individuals. The aim of this study is to determine the half-life of Tau in the periphery, specifically that of rat serum.
We used dual cannulated JVC/FVC rats for the infusion of recombinant human Tau protein with a BSAi syringe pump apparatus. Confirmation of the perfusion setup was completed with 0.1% BSA solution as a carrier protein and 5 ug/ml recombinant human Tau yielding 2% variability over a 40 minute interval (total Tau ELISA, 2.9--3.6 ug/ml measured). For half-life estimate, a 2.5-hour infusion of 1 ug/ml Tau via a femoral vein cannula was performed and then the pump was turned off. Using a Phoenix WinNonLin platform software (Pharsight Co.), calculation of half-life eliminations for recombinant human Tau was estimated to be 14 minutes in rat serum. Furthermore, when a Tau antibody (DA9) was co-infused with Tau at a 100 minute time point, the total Tau levels increased and there was a noticeable prolongation of Tau half-life estimates; whereas the addition of a control antibody in the same paradigm gave no exaggeration of these effects(total Tau ELISA, AT120 or Tau5 with BT2 and HT7).
Our results indicate that the half-life of peripheral Tau is short and can be modulated by binding to anti-Tau antibodies.

Title: Pro-aggregant chaperone complexes regulate tau neurotoxicity

Authors: *L. B. SHELTON, J. D. BAKER, D. ZHENG, L. J. BLAIR, J. J. SABBAGH, A. SUNTHARALINGAM, B. NORDHUES, C. A. DICKEY;
Neurosci., Univ. of South Florida, Tampa, FL

Abstract: Pathogenic tau is one of the major hallmarks associated with Alzheimer's disease. Recent work has shown that the Hsp90 system and its co-factors can differentially regulate tau aggregation. For example, one of these co-factors, FKBP52, while being well known for its role in steroid hormone receptor control can also directly affect pathological tau oligomer and fibril formation *in vitro* and in fish. This is important because oligomeric tau is now considered to be the more toxic species of tau, while tau densely packed fibrils may be more inert. We hypothesized that distinct Hsp90 co-factors could exacerbate oligomeric tau pathology in a mammalian model of tau accumulation, the rTg4510 mouse line, leading to greater neurotoxicity. Four-month-old rTg4510 mice received bilateral hippocampal injections of adeno-associated virus (AAV) serotype 9 tagged with either Hsp90 co-chaperones or mCherry as a control. The over-expression of some of these co-factors caused massive neuronal loss in the hippocampus leading to frank deficits in long-term potentiation (LTP). We also performed immunohistological staining and biochemical analysis, as well as cell based studies to better understand this phenomenon. Overall, these findings suggest that increased Hsp90 co-factors can promote neurotoxicity in the mammalian system by regulating tau aggregation, making these proteins excellent therapeutic target for Alzheimer's disease and other tauopathies.

Title: Supplemented zinc on learning and memory in tau mice (P301L/CaMKII) using contextual and cued fear extinction

Authors: *C. M. HERNANDEZ, C. L. C. NEELY, W. R. KOCHEN, K. M. CRAVEN, M. L. SMITH, A. B. BOOTH, J. M. FLINN;
Cognitive & Behavioral Neurosci., George Mason Univ., Fairfax, VA

Abstract: Neurofibrillary tangles (NFTs) are associated with behavioral disorders in Alzheimer's disease, Parkinson's disease, and also in chronic traumatic encephalopathy (CTE), and can lead to memory deterioration and learning impairments. Biometals such as zinc (Zn) can exacerbate these behavioral disorders. Previous studies have shown that excessive Zn led to increased freezing levels in animals during cued fear extinction (Railey et al., 2010). In another study that used tau mice, mice showed impaired retention in contextual fear conditioning (Hunsbergera et al., 2014). Therefore to observe the effects of both NFTs and Zn, the current study conducted contextual and cued fear extinction with the tau mouse model raised on 10ppm supplemented Zn water. Four experimental groups were used for this study: WT mice (C57BL/6J) on lab or Zn water and tau mice on lab or Zn water. Mice underwent contextual and cued fear conditioning and extinction at six months of age. A 20 second 75-decibel tone was used as the cue, and a two second 0.5 mA mild foot shock was administered. All animals, regardless of genotype and water, learned and retained the association between the cue and the aversive stimulus. During extinction, 25 tones were presented. All animals showed similar extinction rates to the tone. Thus preliminary data shows that there were no significant differences between groups. Additionally open field test was conducted to assess motor differences. Results showed that duration of movement, distance traveled, and speed in tau mice was significantly greater than mice ($p < .05$). These results are consistent with other studies that indicate tau mice are hyperactive (Hunsbergera et al., 2014). Aside from the behavioral tests included here, these mice underwent other behavioral tests and significant differences between groups were observed; see Kochen SfN poster. These results in combination with the other behavioral measures may indicate that affects in Zn on tau mice are behaviorally specific at 6 months.

Title: The effects of zinc on expression of phosphorylated tau and zinc fluorescence

Authors: *K. M. CRAVEN, W. R. KOCHEN, M. R. HARBOUR, C. M. HERNANDEZ, J. M. FLINN;
George Mason Univ., Fairfax, VA

Abstract: Tau is a microtubule associated protein that normally binds to and stabilizes microtubules and therefore is vital for cellular communication. However, when it becomes hyperphosphorylated it no longer binds to microtubules and forms neurofibrillary tangles (NFTs) which occur in various neurodegenerative disorders such as Alzheimer's disease, Parkinson's, and Huntington's. Increasing evidence supports the interaction of tau with the essential trace element zinc. Zinc can affect the regulation of proteins and is important for memory and neuronal communication. The effect of zinc and tau on brain pathology were determined in this experiment. Transgenic tau (P301L/CamKII) and wildtype (C57BL/6J) mice were given either standard lab water or lab water supplemented with 10ppm zinc starting at 8 weeks of age. Mice were sacrificed at 7 months of age. NFT staining was completed followed by western blot analyses and fluorescent staining for zinc. The amount of tau protein within the brain was semi quantified using PHF-1, an antibody specific for phosphorylated tau at Ser396 and Ser404, and Tau-5, an antibody for total tau. Furthermore, Zinpyr-1 fluorescence staining was used to assess and semi quantify the amount of free zinc within the hippocampal and infralimbic regions. A difference in tau levels as well as zinc fluorescence between groups is expected. These data will be compared with results from morris water maze (MWM), novel object recognition (NOR), cued and contextual fear conditioning, and circadian rhythm and nesting assays. Preliminary behavioral results show an interaction between genotype and water type for circadian rhythm as well as a main effect for genotype in MWM and NOR.

Title: Zinc exacerbates tauopathy deficits in measures of daily living in mice.

Authors: *W. R. KOCHEN, K. M. CRAVEN, J. M. FLINN;
Cognitive and Behavioral Neurosci., George Mason Univ., Fairfax, VA

Abstract: Microtubules are a part of the cells cytoskeleton that are crucial for axonal transport of organelles and vesicles. Tau is a protein that provides support for the Microtubule transport system. When tau is hyperphosphorylated, it ceases to provide support for microtubules and the cellular transport system fails, eventually causing neurons to die. Diseases where tau is hyperphosphorylated include Alzheimer's disease, Picks disease, Parkinson's disease and Huntington's disease. The location of the deficits seen in these disorders correlates with the location of neurofibrillary tangles that result from this hyperphosphorylation. One common behavioral symptom seen in Tauopathies is deficits in daily living activities and circadian rhythm disruptions. Zinc is a biometal whose homeostasis is very important for neuronal functioning. Excess Zinc levels have been found to increase Tauopathy even in the absence of hyperphosphorylation. This experiment used P301L/CamKII mice (Jax) that display Tauopathy in both behavior and pathology. Half of these mice had their drinking water supplemented with 10ppm Zinc for four months prior to behavioral testing. At 6 months of age, mice were tested for nest building behavior and for circadian rhythm. Preliminary results indicate that tau mice consuming supplemental zinc from 8 weeks of age showed significantly enhanced behavioral deficits. These mice performed significantly worse than all other groups in nest building behavior ($p < .05$), as well as having significantly different times for onset of nocturnal wheel-running activity ($p < .05$)

Title: The stress granule protein TIA1 regulates tau pathophysiology and toxicity

Authors: *D. APICCO[1], P. ASH[1], B. MAZIUK[2], B. WOLOZIN[1];
[1]Pharmacol. & Exptl. Therapeut., Boston Univ. Sch. of Med., Boston, MA; [2]Boston Univ., Boston, MA

Abstract: Increasing evidence links neurodegenerative disease processes to dysfunction of RNA metabolism and RNA-binding proteins. Here, we show that the progressive accumulation of stress granules is a novel component of Alzheimer's disease (AD) and frontotemporal dementia (FTLD-tau) neuropathology. TIA1, an RNA-binding protein required for stress granule nucleation, co-localizes with hyperphosphorylated tau in the cortex of AD and FTLD-tau patients, and progressively co-accumulates with tau in mouse models of tauopathy. In primary cultured neurons, TIA1 overexpression promotes the formation of tau-positive stress granules that reduce tau turnover and stimulate neurodegeneration. Conversely, reduction of TIA1 by shRNA knockdown or genetic knockout decreases levels of misfolded tau and prevents P301L mutant tau toxicity. In vivo, hemizygous deletion of TIA1 delays disease onset in PS19 transgenic tau mice, as evident by reduced levels of phosphorylated tau, sarkosyl-insoluble tau, and microgliosis in the hippocampus at 2.5 months. Our results highlight an important role for TIA1 and RNA-binding proteins in the pathogenesis of tauopathies and identify modulation of stress granule formation as a novel therapeutic strategy for the treatment of AD and FTLD-tau.

Title: A meta-analysis assessing the influence of tau and amyloid-beta on cognitive decline in a preclinical model of alzheimer's disease

Authors: *C. HUBER, T. MAY, G. COAN, C. S. MITCHELL;
Biomed. Engin., Georgia Inst. of Technol., Atlanta, GA

Abstract: The hallmarks of Alzheimer's disease pathology comprise the onset of disease with accumulation of extracellular amyloid-beta (Aβ) plaques in the brain followed by intracellular neurofibrillary tangle (NFT) growth. Aβ upregulates the generation of NFTs by increasing glycogen synthase kinase-3 (GSK3) activity, leading to the phosphorylation of tau (pTau). Phosphorylated tau begins to self-assemble to form NFTs. Both Aβ plaques and NFTs interfere with normal neuronal cell function by disrupting proper synapse function at neural junctions, in addition to inflicting damage to neurons, eliciting cognitive decline. Based on previous literature, the presence of Aβ causes only a qualitative decrease in cognitive performance. We hypothesize that tau accumulation and phosphorylated tau contribution may more strongly correlate with cognitive decline and Alzheimer's disease progression. We perform a meta-analysis in order to evaluate this hypothesis by combining and analyzing experimental findings extracted from a database of more than 3,000 peer-reviewed articles. Inclusion criteria encompass: use of 3xTg-AD mouse model, quantification of cognitive performance by Morris water maze (MWM) escape latency, and quantify Aβ and/or tau levels. 3xTg-AD mice express both Aβ and tau pathologies, making it one of the most complex mouse models and allowing assessment of both proteins' effects together in one animal. Cognitive ability of mice are compared with Aβ and tau levels to test for significance of any correlation. Phosphorylated tau, tau, and amyloid-beta levels are compared for largest impact on cognitive performance by correlative assessment of escape latency. Aβ and tau are linked by GSK3, but it is not known whether the relative protein levels affect disease progression. To assess this possibility, combination levels of Aβ and tau are assessed for significant interactions. It is likely that these two proteins may interact to cause more rapid cognitive decline.

Title: The effect of chronic excess zinc on memory tasks in tauopathic mice.

Authors: *M. HARBOUR, W. R. KOCHEN, K. M. CRAVEN, J. M. FLINN;
George Mason Univ., Fairfax, VA

Abstract: Tauopathies are disorders characterized by dysfunction in the tau protein. Examples of Tauopathies include Alzheimer's disease, Parkinson's disease, Huntington's disease and Picks disease. These diseases form when the tau protein, a protein integral for intracellular communication, is hyperphosphorylated causing neurofibrillary tangles. Tauopathies possess many similar behavioral deficits including deficits in memory. Zinc is a biometal whose homeostasis is very important for neuronal functioning. Excess Zinc levels have been found to increase Tauopathy and exacerbate Alzheimers Disease even in the absence of hyperphosphorylation. This experiment used P301L/CamKII mice (Jax) that display Tauopathy in both behavior and pathology. Half of these mice had their drinking water supplemented with 10ppm Zinc for four months prior to behavioral testing. At the age of 7 months old, these four groups were tested on both Novel Object Recognition and Morris Water Maze. Preliminary results of Morris Water Maze show a main effect of genotype on latency to find the platform as well as a main effect of genotype on thigmotaxicity ($p < .05$). Earlier experiments completed with these mice (Kochen et al, SFN 2016) showed zinc exacerbated Tauopathic deficits in two measures of daily living: nest building, and circadian rhythm.

Abstract: Aggregation of neurotoxic proteins is the pathological hallmark of several neurodegenerative diseases. Pathogenic proteins spread to distant brain regions in a stereotypical pattern through synaptic networks. Recent studies showed that these protein aggregates recruit the endogenous protein and induce pathology in healthy neurons, suggesting that interneuronal transmission of these proteins contributes to progressive spread of disease in a 'prion-like' manner.
The Microfluidic culture device platform was used as neuron-based in vitro model to study neuron-to-neuron transmission of pathogenic tau proteins, and also as an assay platform to evaluate the efficacy of therapeutic tau antibodies in preventing or reducing propagation of pathological proteins.
We demonstrated the trans-synaptic transmission of pathogenic tau proteins in cultured neurons using the Microfluidic culture device. In addition, antibodies against tau significantly reduced the transmission of these proteins, suggesting that these antibodies may be a viable therapeutic strategy for the treatment of neurodegenerative diseases. The Microfluidic neuron device is a useful platform for testing molecules capable of abrogating transneuronal spreading of pathological proteins.

Title: Evaluation of the propagation properites of tau species from different disease states in multiple cellular models

Authors: *A. M. JABLONSKI, B. CONNOLLY, M. USENOVIC, R. GENTZEL, S. PARMENTIER-BATTEUR, B. VOLETI;
Merck and Co., West Point, PA

Abstract: Tauopathies are a group of neurodegenerative diseases classified by the accumulation of tau aggregates in diverse brain areas leading to distinct clinical manifestations. Evidence suggests that the propagation and transmission of tau throughout the brain occurs when tau "seeds" spread from an affected cell to a previously unaffected cell. Previous evaluations of brain homogenates from different tauopathies *in vitro* and *in vivo* suggest distinct biochemical and morphological tau species are present in different tauopathies. The goal of our study was to characterize the tau species present in these diseases and and to identify the differences in the propensity of these tau species to propagate within i*n vitro* cellular models. Brain samples were obtained from patients diagnosed with Alzheimer's disease (AD), Corticobasal degeneration (CBD), Pick's disease (PiD) and Progressive Supranuclear Palsy (PSP). Brain specimens were sectioned and catalogued for immunohistochemical and biochemical analyses which included the characterization of tau isoforms, phosphorylation states, and aggregates present. In order to investigate the differences in tau seeding properties between different tauopathies, homogenates from tau-affected and tau non-affected brain areas were added to three different cellular models - a stable HEK293 cell line expressing a fluorescently-tagged tau repeat domain; rat primary hippocampal cultures; and human iPSC-derived neurons. The effects of these treatments were evaluated for their effects on tau aggregation, conformational status, and post-translational modifications, as well as overall cellular dysfunction. Results gave evidence for distinct characteristics among the tauopathies which are able to be recapitulated in *in vitro* cellular system models. These cellular models will enable studying tau seeding in a tauopathy-specific manner and provide a new understanding of tauopathies.

Title: Disrupted nuclear export in presence of tau protein in neurodegenerative diseases

Authors: *B. EFTEKHARZADEH[1,2], S. WEGMANN[1,2], J. MERTENS[3], F. H. GAGE[3], B. T. HYMAN[2,1];

Abstract: Trafficking of transcription factors and other regulatory proteins between the cytoplasm and the nucleus is essential for signal transduction. There is growing evidence that the disruption of efficient nucleocytoplasmic transport can significantly impair neuronal function, and thus may be involved in toxicity mechanisms in neurodegenerative diseases. Previous studies demonstrated nuclear transport irregularities in cells that accumulate misfolded protein aggregates. These observations suggested an impairment of nuclear pore complex (NPC) components - such as Nups, which are critical for nucleocytoplasmic transport in neurons - in AD. In our study, we use a fluorescence-based reporter to monitor the integrity of nuclear export and import in mammalian cells in the presence of different tau species. The reporter comprises two GFP with nuclear export signal (NES), IRES sequence, and two RFP with nuclear import signal (NIS); this results in a clear separation of cytoplasmic GFP and nuclear RFP. In cells with impaired nuclear transport, the intracellular localization of GFP and RFP start to overlap in cytoplasm and/or in nucleus, depending on the disruption of nuclear import or export. Our results suggest that the presence of aggregated tau as well as the overexpression of tau disrupt nuclear export, while the nuclear import is less compromised. Further investigations, particularly towards the identification of specific NPC elements involved in tau-dependent nuclear export disruption, will help identify the pathophysiological significance of this observation.

Title: The interplay between brain circuit oscillations during an attentional task in a transgenic mouse model of tau pathology: assessment of Alzheimer’s disease as a neuronal disconnection disorder

Authors: J. JOYES[1], S. JACOB[2,1], A. AHNAOU[1], K. TAHON[1], L. RAEYMAEKERS[1], K. VAN KOLEN[1], *W. H. DRINKENBURG[1];

Abstract: Abnormal hyper-phosphorylated and misfolded Tau in the brain are pathological signs associated with Alzheimer's disease (AD). Electroencephalographic (EEG) alterations in the spectral contents and connectivity have been associated with cognitive decline in AD. Difficulties in attentional processing have been noted as one of the earliest clinical signs of AD, therefore investigating neuronal networks associated with attention can lead towards a better understanding of AD pathology and the identification of functional markers of early disease progression. The present study used a tau seed injection model[1] to investigate changes in neuronal connectivity associated with tau pathology during attentional performance. K18 - a synthetic preformed tau fibril- or buffer control was administered via a cannula into the hippocampal (HPC) CA1 region of 12 weeks old P301L transgenic male mice. These mice express human 2N4R Tau with a P301L mutation. P301L model carries a transgene encoding human tau, causing tauopathy after 6 months. We investigated how the spread of K18 affects attentional processes and EEG. Network oscillations in the frontal association area, anterior cingulate cortex and the left and right HPC CA1 regions were monitored for 20 weeks, post HPC CA1 injection, while the animals performed in the 5 Choice Serial Reaction Time Task (5CSRTT), a validated test for assessing attention in rodents. In the immediate weeks post injection, no major difference was found in behavioral performance between K18 and buffer mice. Cross-Frequency Phase-Amplitude Coupling (CF-PAC: when the phase of a lower frequency oscillation modulates the amplitude a higher frequency oscillation) has been suggested to be instrumental in cognitive processes, including attentional selection. Freely moving P301L tau seed model mice have shown a decrease in CF-PAC at the site of K18 injection, while a compensatory increase in CF-PAC was noted contralaterally[2]. For K18 animals, changes in neuronal connectivity were visible as early as 2 weeks after tau seeding. It is hypothesized that PAC compensation may prevent behavioral differences between K18 and buffer injected mice during the 5CSRTT in the first weeks following injection. The attentional performance-related oscillations further help to understand the tau-pathology induced disconnection symptoms as seen in AD. Looking at AD as a disconnection disorder allows for a focus on markers and intervention therapies related to the earliest signs of pathology, and well before clinical cognitive symptoms become apparent.1- Peeraer et al. Title: Hypothermia causes Tau hyperphosphorylation in the brain of diabetic ob/ob mice: importance of thermoregulation in linking diabetes and Alzheimer's disease

Authors: *M. GRATUZE[1], N. EL KHOURY[2], F. MORIN[2], C. JULIEN[2], A. MARETTE[3], F. CALON[2], E. PLANEL[2];
[1]CRCHUL, Quebec, QC, Canada; [2]CRCHUL, Québec, QC, Canada; [3]Ctr. de Recherche de l'Institut Universitaire de Cardiologie et de Pneumologie de Québec, Québec, QC, Canada

Abstract: Hyperphosphorylated tau is the major component of paired helical filaments in neurofibrillary tangles found in Alzheimer's disease (AD) brains, and tau hyperphosphorylation is thought to be a critical event in the pathogenesis of the disease since it correlates with the degree of cognitive impairment in AD. Only a small proportion of AD is due to genetic variants, the large majority of cases is late onset and sporadic in origin. The cause of sporadic AD is likely to be multifactorial, with external factors interacting with biological or genetic susceptibilities to accelerate the manifestation of the disease. Type 2 diabetes (T2D) might be such factor, as there is accumulating evidence from epidemiological studies suggesting that T2D is linked to an increased risk of AD. The consequences of T2D on AD pathologies, such as tau hyperphosphorylation, are thus not well understood. Therefore, we evaluated the impact of T2D on tau phosphorylation in ob/ob diabetic mice, aged 4 and 26 weeks. These mice lack leptin, are hyperphagic and obese, and mimic major human T2D features, including hyperglycemia, hyperinsulinemia and insulin resistance. We found increased tau phosphorylation at the AT8 epitope in 4-week-old ob/ob mice while 26-week-old ob/ob mice displayed tau hyperphosphorylation at multiple tau phospho-epitopes (Tau1, CP13, AT8, AT180, PHF1). We then examined the mechanism of tau hyperphosphorylation, and demonstrated that it is mostly due to hypothermia, since ob/ob mice were hypothermic and normothermia rescued tau phosphorylation to control levels. Because caffeine has been shown to be beneficial for diabetes, obesity and tau phosphorylation, we used it as therapeutic treatment. Unexpectedly, chronic caffeine intake exacerbated tau hyperphosphorylation while promoting deeper hypothermia. Our results suggest that tau hyperphosphorylation is mostly a consequence of hypothermia due to

impaired thermoregulation in ob/ob mice. These results provide a novel link between diabetes and tau pathology, and underline the importance of investigating thermoregulation mechanisms to better understand the relationship between diabetes and AD.

Title: Tau pathology is required for significant stress granule and RNA binding protein pathology in mouse models of Alzheimer's disease

Authors: *B. MAZIUK[1], D. APICCO[1], K. DUFF[3], H. YU[3], W. QIU[1], N. AYTAN[2], A. DEDEOGLU[2], M.-H. OU-YANG[4], R. VASSAR[4], B. WOLOZIN[1];
[1]Pharmacol., [2]Neurol., Boston Univ., Boston, MA; [3]Columbia Univ., New York, NY; [4]Northwestern Univ., Chicago, IL

Abstract: Alzheimer's disease (AD) is a neurodegenerative disease characterized by severe deficits in memory, thinking and behavior. At the molecular level, AD is characterized by two major pathologies: the development of extracellular amyloid plaques and intracellular neurofibrillary tangles (NFTs). In particular, NFTs are formed from tau, which is a microtubule binding protein expressed in all neurons throughout the brain. During AD pathogenesis, hyper-phosphorylated tau forms pathological aggregates. However, the molecular mechanisms which

drive the development of tau pathology remain elusive. Recently, the Wolozin lab has identified stress granules (SG) as a major component of AD pathology which coincides with the development of tau pathology. T-cell intracellular antigen 1 (TIA-1) is a primary SG nucleating protein which co-localizes with neuropathology in Amyotropic Lateral Schlerosis (ALS), AD, and frontotemporal dementia (FTD). In addition, recent evidence from our lab also implicates a large number of other RNA binding proteins in the development of tauopathy and AD.
Our results indicate that tau pathology must be present to observed significant accumulation of SG pathology. Brain tissues from transgenic mice expressing human tau, including rTg4510, PS19 and 3xTgAD, all exhibit strong SG pathology that co-localizes to varying degrees with tau pathology. However, brain sections from 5xFAD mice, which don't express human tau, do not exhibit significant SG pathology, despite strongly accumulating beta-amyloid pathology.
Improved detection of pathological SGs represents an additional outcome from our study. Antibody-mediated detection of SG pathology in human tissue is challenging because aggregation of the RNA binding proteins frequently masks key antigen epitopes. The current work optimized the methods for antibody mediated visualization of SG and RNA binding protein pathologies in AD. We characterized and verified a number of antibodies useful for immunohistochemical staining, as well as fixation and staining methods for these antibodies in mouse and human tissue. From our immunohistochemical analysis, we demonstrated that previously described TIA-1 positive SG pathologies co-localize with phospho-tau pathology in the Tg4510 and PS19 tauopathy mouse models but not the 5xFAD amyloid mouse model of AD. Furthermore, we also demonstrated co-localization of tau pathology with numerous RNA binding proteins that biochemically interact with tau, using both mouse tauopathy and human AD tissue. The proteins examined include Taf15, EWSR1, which also co-localize with tau pathology, and HNRNPA0, which becomes localized to the cytoplasm in AD.

Title: Alternative splicing of tau exon 10 is directly regulated by temperature

Authors: *F. PETRY[1], L. MORANT[2], I. POITRAS[1], F. MORIN[1], L. BUÉE[2], V. VINGTDEUX[2], N. SERGEANT[2], E. PLANEL[1];

Abstract: Tau is microtubule-associated protein abundant in neurons. Its main function, bind and stabilize the MTs, is mediated by its MT binding domain. Alternative splicing (AS) of tau exon 10 results in the presence or the absence of a MT-binding repeat, leading to the expression of tau with four (4R-tau) or three (3R-tau) MT-binding repeats. In human brain development, 3R-tau are expressed from the embryonic while 4R-tau expression begins after birth. An equal ratio of 3R-tau and 4R-tau is maintained in adult brain. Interestingly, a different pattern of tau isoforms is reported in mice development, since adult mice only express 4R-tau. Preliminary data on pups temperature show that pups are hypothermic during the first post-embryonic stages, which correspond to the period of 3R-tau expression. We thus hypothesized that temperature might be able to regulate tau splicing with hypothermia promoting 3R-tau and normothermia or hyperthermia promoting 4R-tau. To test this hypothesis, we studied a complete range of development points in mice from embryonic to adult. We changed the environmental temperature of the room housing the mother and the pups to prevent the hypothermia found in the first developmental stages. We also used N2a cells, a mouse cell line expressing both isoforms, that we directly exposed to different temperatures from hypothermia to hyperthermia. We also used mouse primary neuronal cell culture that recapitulate the pattern of expression of tau isoforms found during mouse brain development. We designed a kinetics of differentiation from day in vitro 1 to 20 at 3 different temperatures: 37°C, 32°C and 40°C. During mouse brain development, we confirmed a specific pattern of expression of tau isoforms with a shift from 3R-tau to 4R-tau between P9/P14 and hypothermia from birth until P9/P14, significantly correlating with 3R-tau. Our results on N2a cells indicate that hypothermia increases the exclusion of tau exon 10, whereas hyperthermia increases its inclusion. Our results on primary cell culture show that both hypothermia and hyperthermia are able to modify the specific pattern of tau exon 10 isoforms compared to 37°C. Our results demonstrate for the first time that temperature is a powerful regulator of exon 10 alternative splicing, with hypothermia leads to exon 10 exclusion whereas hyperthermia to exon 10 inclusion, which is reversible in N2a cells.

Title: Effects of fractalkine on tau pathology in a mouse model of tau deposition

Authors: *D. J. FINNERAN[1], A. DAWDY[2], J. COLEY[2], K. MALE[3], M. N. GORDON[2], D. MORGAN[2], K. R. NASH[2];

Abstract: Alzheimer's disease is a progressive neurodegenerative disorder and the most common form of dementia. Microglial activation and inflammation have been suggested to be significant contributing factors to the neurodegeneration. It has been demonstrated that increasing inflammation exacerbates tau pathology while reducing inflammation ameliorates it. Fractalkine (CX3CL1; FKN) is an endogenous chemokine expressed throughout the body. In the CNS, FKN is expressed solely by neurons and binds its unique receptor, CX3CR1, which is expressed only on microglia. FKN signaling leads to decreased expression of pro-inflammatory cytokines such as IL-1β and TNF-α. Recent studies have shown that disrupting FKN signaling in hTau mice exacerbates pathology and hastens the onset of pathology. Furthermore, AAV-mediated overexpression of a soluble FKN in Tg4510 mice reduced tau pathology and ameliorated neuron loss. However, this overexpression did not rescue behavioral deficits, perhaps due to the limited over expression only in the hippocampus. In this study, our aim was to increase soluble FKN signaling globally throughout the CNS with limited invasiveness. Therefore, we chose to inject animals bilaterally in the lateral ventricles, thus secreting FKN into the CSF and exposing the entire CNS to increased FKN agonism. Five month-old Tg4510s were injected either in the lateral ventricles with AAV4 FKN or in the anterior cortex and hippocampus with AAV9 GFP. Behavioral assessment was performed and mice were euthanized 3 months later for biochemical analysis of pathology. Animals injected with AAV4 FKN showed significant improvement in the radial arm water maze task of hippocampal-dependent learning and memory. Furthermore, nesting behavior significantly improved in these animals. AAV4-FKN successfully transduced ependymal cells, FKN was secreted into the CSF, and FKN levels were increased in the hippocampus of treated mice by ELISA. We are in the process of assessing changes in tauopathy and microglial activation in these mice. Since FKN signaling is generally anti-inflammatory in the CNS, we anticipate a reduction in microglial activation in the animals treated with FKN.

Title: Leptin regulation of tau phosphorylation in both *In vitro* and *In vivo* models of Alzheimer's disease

Authors: *J. GRIZZANTI[1], S. PATRICK[1], G. CASADESUS[1,2];
[1]Sch. of Biomed. Sci., [2]Dept. of Biol. Sci., Kent State Univ., Kent, OH

Abstract: Evidence suggests that leptin signaling within the brain is both neurotrophic and neuroprotective and leptin signaling is known to be impaired in AD brains. To address the role of leptin signaling in AD we determined the effects of leptin treatment on tau pathology in the APP/PS1 mouse. Our preliminary data indicates that 3 month continuous leptin treatment reduces tau phosphorylation within the hippocampus. However, this decrease in tau phosphorylation is coupled with decreases in total Ob-R expression and subsequent STAT3 signaling. In vitro leptin treatment is able to regulate tau phosphorylation levels in a neuroblastoma cell line transfected with the Tau40 mutation. These modifications to tau phosphorylation levels are associated with Ob-R expression, regulation, and signaling in a dose-specific manner. Together, these data suggests that the benefits derived from leptin treatment may stem from inhibition rather than upregulation of leptin signaling.

Title: Targeting the tau-fyn interaction for ameliorating Aβ-induced neurotoxicity

Authors: *T. RUSH[1], S. J. THOMPSON[2], J. N. COCHRAN[3], P. V. DIGGS[2], E. D. ROBERSON[2];

Abstract: Tau is widely considered a prime therapeutic target for Alzheimer's disease (AD), in part because tau reduction is protective in cell and mouse models of AD. Despite wide support, strategies to target tau have proven difficult to develop. Much like tau, the Src-family tyrosine kinase, fyn, is also a requisite mediator of Aβ-driven neuropathology. Indeed, reducing fyn levels is protective in AD mouse models and overexpressing fyn results in behavioral abnormalities not otherwise present in a mouse line expressing low levels of APP. Inhibiting fyn kinase activity has been reported to be protective, but this approach also leads to learning and memory deficits and impaired synaptic plasticity in non-transgenic mice. Importantly, tau and fyn interact via their respective proline-rich and SH3 domains. In addition, recent evidence suggests that Aβ-driven behavioral abnormalities and neuropathology involve the tau-fyn interaction. We recently completed a high-throughput screen to identify small molecule inhibitors of the tau-fyn interaction. We also developed a cell-permeable TAT-peptide that spans full-length tau's 5th and 6th proline-rich, PxxP motifs and competitively inhibits the tau-fyn interaction. We used rat primary neuron cultures to test whether this tau-fyn interaction peptide inhibitor could ameliorate Aβ-induced neurotoxicity. Exposing primary neurons to $A\beta_{1\text{-}42}$ oligomers (Aβo) for 48 hours resulted in neurotoxicity that was precluded by tau knock-down (using antisense oligonucleotides) and was blocked by pre-treatment with the TAT-PxxP peptide. These data suggest that the tau-fyn interaction is an important mediator of Aβ-driven neuropathology and represents a promising therapeutic approach to translate the mechanisms of tau-reduction for the treatment of AD.

Title: IL-10 deficiency enhances tau phosphorylation in a mouse model of LPS-induced systemic inflammation

Authors: *L. WESTON, S. JIANG, N. MAPHIS, K. BHASKAR;
Mol. Genet. and Microbiology, Univ. of New Mexico, Albuquerque, NM

Abstract: Tauopathies include a number of neurodegenerative diseases associated with accumulation of hyperphosphorylated microtubule associated protein tau (MAPT or tau) as neurofibrillary tangles (NFTs). The presence of hyperphosphorylated tau (pathological tau or p-tau) has been shown to strongly correlate with cognitive decline. Furthermore, neuroinflammation is a common feature of tauopathies and studies from our lab have suggested that microglia-mediated neuroinflammation promotes tau phosphorylation in a mouse model of tauopathy in a manner dependent upon the activation of pro-inflammatory cytokine interleukin-1β (IL-1β). Given that anti-inflammatory cytokines are also key players in regulating immune responses in the brain, the direct effects of certain prominent anti-inflammatory cytokines in tau pathology is still unclear. One of the most established anti-inflammatory cytokines is interleukin-10 (IL-10), which plays a role in downregulating pathways involved in inflammation and activation of kinases that may be involved in tau phosphorylation. To determine if IL-10 has a role in regulating pathological tau phosphorylation, here we compared the effects of lipopolysaccharide (LPS) administration in 5-6 month old C57BL/6 (WT) and IL-10 knockout (KO) mice. First, consistent with our previously published results, LPS administration (10mg/kg b.w; i.p; single dose) increased tau phosphorylation (on AT8, AT180 sites) within 24 h in the hippocampus of WT mice compared to vehicle injected WT mice. Second, IL-10 KO mice injected with the same dose of LPS showed significantly enhanced AT8 and AT180 site tau phosphorylation compared to LPS injected WT mice. Third, levels of total tau were significantly reduced in LPS-injected IL-10 KO mice compared to vehicle injected IL-10 KO and WT control mice (with or without LPS). Fourth, LPS injected IL-10 KO mice show significantly elevated levels of activated (pT180/pY182) p38 mitogen activated protein kinase (p38 MAPK) compared to LPS injected WT mice. Finally, basal levels of IL-1β are elevated in IL-10 KO mice compared to WT mice. Together, our results suggest that IL-10 plays an anticipated anti-inflammatory role

to prevent neuroinflammation and reduces inflammation-induced tau pathology relevant to tauopathy.

Title: Tau oligomeric strains spread from the eye to the brain, inducing diverse phenotypes

Authors: *J. GERSON[1], U. SENGUPTA[1], Y. HA[2], K. FARMER[1], W. ZHANG[2], R. KAYED[1]; [1]Neurosci. and Cell Biol., [2]Opthamology, UTMB, Galveston, TX

Abstract: While tau aggregation is a common feature in a number of neurodegenerative diseases termed tauopathies, the symptoms and patterns of pathology are highly diverse. A growing number of studies have shown that the fibrillar forms of tau, neurofibrillary tangles (NFTs), considered the hallmarks of these disorders are actually not the most toxic form of the protein. Rather, soluble aggregates formed en route or independently of NFTs—tau oligomers—are the toxic tau species. A large body of research suggests that oligomeric tau exhibits prion-like properties similar to other amyloid proteins, including the ability to seed tau monomer and spread from affected to unaffected brain regions. Recent studies suggest that tau also forms conformationally distinct strains that may impact the disease phenotype similarly to prions. A lack of understanding of the conformational diversity of tau aggregates in disease may hinder progress in the field of therapeutics against tau toxicity. Moreover, inability to effectively diagnose tauopathies early in disease progression may also make treatment difficult. Evidence suggests that protein aggregation and heightened inflammation may occur in the eyes of affected patients, suggesting that the eye may be a possible window to toxicity in the brain. However, the ability of oligomeric tau to travel between the eye-brain axis has not been well-defined. Therefore, we isolated and characterized tau oligomeric strains from Alzheimer’s disease,

Progressive supranuclear palsy and Lewy body dementia. We injected brain-derived tau oligomeric strains intravitreally in Human tau mice and showed for the first time that tau oligomers can induce inflammation and toxicity in the eye and spread from the eye to the brain. Moreover, we discovered that disease-specific tau strains led to diverse behavioral effects and seeding *in vivo*, providing support for the hypothesis that strain differences defined *in vitro* may induce different disease phenotypes. Differences in regional and cell-specificity of tau oligomeric strains were also seen in human disease brains using tau oligomer-specific monoclonal antibody (TOMA) clones. These findings suggest that differences in tau conformation may differentiate disease phenotypes. Further insight into tau oligomer conformation in different diseases may be critical for the understanding of mechanisms for the onset of disease and improved therapeutic and diagnostic strategies.

Title: ROCK inhibitors for modulation of tau phosphorylation, targeting Alzheimer's disease pathology and enhancing memory.

Authors: *M. TURK[1,3,4,5], A. L. SINIARD[3,4,5], M. DE BOTH[3,4,5], T. WANG[3], T. DUNKLEY[3], P. PIRROTTE[3], S. ODDO[2], M. J. HUENTELMAN[3,4,5];

Abstract: Rho-associated, coiled-coil-containing protein kinase 1 (ROCK) is an enzyme that plays important roles in neuronal cells including mediating actin organization and dendritic spine morphogenesis. The ROCK inhibitor (ROCK-i) Fasudil has been shown to increase learning and working memory in aged rats, but another ROCK-i, Y27632, was shown to impair learning and memory. We are interested in exploring how these, and other ROCK-i, may be acting mechanistically to result in very different outcomes in treated animals.
We have previously tested thirteen different ROCK-i to treat human neuroglioma cells overexpressing 4-repeat tau (H4-tau) across a 96-hour time course at the IC-10 dosage. The ratio of Serine 396 phosphorylated tau (p-tau) to total tau was measured using ELISA at each of 8

time points. Phosphorylation of tau at Serine 396 decreases tau mobility and the ability of tau to bind microtubules, possibly contributing to the tauopathy of AD. The measurement of this ratio was chosen as our in vitro bench mark for the action of ROCK inhibitors. Tau protein is a putative anti-Alzheimer's disease (AD) therapeutic target and we have shown previously that Fasudil can inhibit tau phosphorylation in addition to its effect on learning and memory. We showed that Fasudil and a novel ROCK-i, T343, significantly decreased the p-tau to total tau ratio. We also showed that Y27632 and a novel ROCK-i, T299, did not display a change in the ratio. However, at the IC-50 dosage, while Fasudil, T343, and Y27632 showed the same effects, T299 in contrast significantly increased the p-tau to total tau ratio.
Using these drugs, another study was conducted, treating H4-tau cells across a 36-hour time course at the IC-50 dosage. RNA was collected at 6 different time points and prepared for sequencing using the TruSeq RNA Sample Preparation Kit (Illumina Inc) and sequenced by 100bp paired-end sequencing on a HiSeq2000 (Illumina Inc). Of note, BDNF expression was shown to decrease at 24 hours for Fasudil, T299, and Y27632 (p adj. =0.01; <0.01; <0.01). However, BDNF expression was only significant at another time point for Fasudil, at 48 hours, when it increased (p adj.=0.01). No significant changes were found for BDNF expression in cells treated with T299 at any time point. Interestingly, there was a significant decrease in Fasudil expression across time points from 24 to 36 hours (p adj. < 0.01), and Y27632 only at 24 hours (p adj.<0.05).
The results from the RNA study show that effects on RNA expression are different for each drug, which indicates that changes in p-tau to total tau ratio could be due to off-target effects of the drugs. These could also be responsible for the effects of Fasudil on learning and memory.

Abstract: <Objective> The presence of misfolded proteins such as tau and alpha-synuclein, key players in the pathogenesis of dementia with Lewy bodies (DLB), can lead to activation of microglia in the brain. Indeed, microglia activation or neuroinflammation is reported to relate to the neuronal degeneration in DLB. Activated microglia develop an increased number of receptor known as a translocator protein (TSPO), which can be depicted in vivo by a 2nd-generation TSPO tracer [11C]-DPA713. In addition, a recently developed tracer [11C]-PBB3 has succeeded in imaging of tau deposition in humans. No study has been reported about in vivo relationship between tau deposition and neuroinflammation in the DLB brain so far. Here, we investigated this issue using positron emission tomography (PET) with [11C]-DPA713 and [11C]-PBB3.<Methods> Six probable DLB patients (mean age 72.5±4.2 years, Mini Mental State Examination 19.8±5.1, Clinical Dementia Rating 0.92±0.52) and age-matched healthy adults underwent [11C]-DPA713 and [11C]-PBB3 PET measurements. The non-displaceable binding potential (BP_{ND}) was estimated on the simplified reference tissue model (SRTM). Statistical Parametric Mapping (SPM) was used to compare BP_{ND} level between the DLB and control group. In addition, regional BP_{ND} was also evaluated using region of interest (ROI) analysis.<Results> The DLB patients showed a significantly increase in [11C]-DPA713 BP_{ND} in the brainstem, limbic, frontal, temporo-parietal, and occipital cortical regions compared with healthy adults. [11C]-PBB3 BP_{ND} in DLB patients increased mainly in the limbic and temporo-parietal regions, resembling fibrillar tau deposition at Braak stage III-IV.<Conclusions> In the early stages of DLB, increased microglial activation in the brainstem, limbic and neocortex area was found. Tau deposition was also found in the limbic and temporo-parietal regions, which suggests the presence of the pathological processes similar to those in Alzheimer disease. Microglial activation and tau deposition are pathophysiologically important in the progression of DLB.

Title: Abeta pathology drives Tau toxicity in a new mouse model of Alzheimer’s disease

Authors: *S. DUJARDIN, S. L. DEVOS, R. E. BENNETT, S. WEGMANN, B. T. HYMAN; neurology, Massachusetts Gen. Hospital, Harvard Med. Sc, Charlestown, MA

Abstract: The neuropathological hallmarks of Alzheimer's disease (AD) are aggregated amyloid-beta (Aβ) in extracellular plaques and tau protein in neurofibrillary tangles (NFTs). The relationship between these pathological changes is not understood, in part because plaques and tangles occur in different brain regions, with different spatiotemporal evolution, and they trigger diverse secondary pathological effects in the brain, such as inflammation and neurotoxicity. It is also unclear whether the aggregation of one protein causes the deposition of the other. Indeed, Aβ is not *per se* necessary to trigger tau aggregation, but it appears throughout the cortical mantle of AD patients even earlier than NFTs. In this work, we developed a novel mouse model to study the interaction of tau and Aβ in the brain, and to analyse the toxicity and synergy of both pathologies. We crossed two well-characterized mouse models: rTg4510 mice, that overexpress human mutant P301L tau and develop strong cortical and hippocampal NFT pathology, and APP/PS1 mice, which overexpress a mutated form of the amyloid precursor protein and of presenilin-1 and show dramatic Aβ deposition in the cortex and hippocampus. By histology we found a 2-fold increase of NFTs in rTg4510xAPP/PS1 compared to rTg4510 mice at 6 months of age; this increase in NFTs in presence of APP/PS1 is detected even prior to overt plaque deposition at 4 months of age. Interestingly, the plaque load decreased in rTg4510xAPP/PS1 compared to APP/PS1 mice at 12 months of age. The seeding capacity of tau from brain homogenates was analyzed using a FRET-based cell assay and also showed a significant 2-fold increase in rTg4510xAPP/PS1 compared to rTg4510 mice. The amount of soluble tau in the CSF analyzed by ELISA was similar between rTg4510 and rTg4510xAPP/PS1 mice. Together, these results show that Aβ enhances tau aggregation and tau seeding activity, and, presumably, increases tau toxicity. In the reverse direction, the presence of mutant tau appears to inhibit Aβ plaque deposition, maybe due to a secondary effect. Our model recapitulating the two main hallmarks of AD will be useful to further explore the crosstalk and synergy between tau and Aβ pathology and toxicity, and it will enable us to explore the influence of both proteins on neurodegenerative processes such as synaptic loss, neuronal death, and neuroinflammation.

Title: CYFIP2: A potential link between Aβ and tau pathologies in Alzheimer's disease

Authors: *A. GHOSH[1], S. S. TIWARI[1], K. MIZUNO[1], C. TROAKES[1], T. HORTOBAGYI[1,2], K. P. GIESE[1];
[1]Basic & Clin. Neurosci., King's Col. London, London, United Kingdom; [2]Dept. of Neuropathology, Univ. of Debrecen, Debrecen, Hungary

Abstract: Alzheimer's disease (AD) is histopathologically characterised by the presence of plaques made of amyloid-β (Aβ) peptide and tangles comprising hyperphosphorylated tau. However it is in fact synaptic degeneration that best correlates with impaired memory in both AD and its prodrome Mild Cognitive Impairment (MCI), and precedes neuronal loss. Therefore early changes in the AD brain may involve alterations at synaptic sites. These localised changes require rapid access to specific macromolecules and an attractive hypothesis is that several proteins required for synaptic function are locally synthesised within dendrites or spines, and are regulated by RNA-binding proteins and related molecules. A likely candidate for such modulation of local protein synthesis is the *Cy*toplasmic *F*MRP-*I*nteracting *P*rotein 2 (CYFIP2), a highly conserved protein that is abundant in synapses, developmentally expressed and may itself be locally translated. While not much is known about the precise physiological role of CYFIP2 in the brain, it has been proposed to have functions in regulating protein synthesis of FMRP-regulated mRNAs, as well as in modulating cytoskeletal dynamics via a Rac-dependent pathway. We have previously found that CYFIP2 is reduced by about 50% in severe AD post mortem hippocampus when normalised for the number of synapses, suggesting it is an early event that precedes synaptic loss. Adult CYFIP2 heterozygous knockout mice have been used to model the condition. At the biochemical level, $CYFIP2^{+/-}$ mice have increased expression of FMRP-regulated proteins such as Amyloid Precursor Protein (APP) and the α subunit of the calcium/calmodulin-dependent kinase II (αCaMKII) at hippocampal synapses. These changes occur post-transcriptionally as corresponding mRNA expression is not altered. $CYFIP2^{+/-}$ mice also have increased levels of the APP-cleaving enzyme Beta-secretase 1 (BACE1) in hippocampal synapses, and elevated $A\beta_{1-42}$ in whole hippocampi. Additionally there is increased tau phosphorylation in hippocampal synapses at Ser214, a site that is phosphorylated by αCaMKII in the AD brain and known to result in dissociation of tau from microtubules in vitro. Taken together, reducing CYFIP2 in the mouse brain is sufficient to increase amyloid production and tau phosphorylation, recapitulating two key aspects of the disease. Therefore reduced CYFIP2 expression may be a key mediator of early changes in the AD brain and a potential link between Aβ and tau pathologies. Further studies will be done on aged $CYFIP2^{+/-}$ mice to assess whether this molecular change can contribute to further AD-like phenotypes.

Title: Differences in synaptic dysfunction between rTg4510 and APP_PS1 mouse models of Alzheimer's disease

Authors: S. GELMAN, J. SANCHEZ-PADILLA, J. PALMA, P. KABITZKE, G. TOMBAUGH, *A. GHAVAMI;
PsychoGenics, Montvale, NJ

Abstract: Neurofibrillary tangles with accelerated amyloidosis and plaque formation are widely thought to play a major role in development of Alzheimer's disease pathology. The rTg4510 mouse, a model of tauopathy, overexpresses P301L mutant human Tau in the forebrain. The APP/PS1 transgenic mouse overexpresses mutated forms of the genes for human amyloid precursor protein (APPsw) and presenilin 1 (m146L) and is used to study amyloid deposition. Generally, these lines of mice exhibit an age-dependent and region-specific progression of neuropathology. Additionally, synaptic dysfunction is evident in early development of pathology. However, there is no consensus about the extent to which basal synaptic transmission (BST) and synaptic plasticity are affected in these models. We used extracellular field potential recordings to study BST, short-term plasticity (PTP, post-tetanic potentiation; PPF, paired-pulse facilitation) and long-term potentiation (LTP) at the Schaffer collateral-CA1 pyramidal cell synapses in young and old rTg4510 (2-3 and 6-7 month old) and old APP/PS1 mice (8-10 month old). We find that old but not young rTg4510 mice exhibit a correlated reduction in pre-synaptic fiber volley (FV) amplitude (~50%) and field excitatory post-synaptic potential (fEPSP) slope (~40%) compared to WT, consistent with hippocampal neurodegeneration. We also find that BST per se is not altered in this model, since fEPSP slope, controlled for FV amplitude, remained unchanged. In contrast, old APP/PS1 mice did not show reduced FV amplitude compared to WT, while fEPSP slope was reduced by ~34%, suggesting a deficit in BST. PTP was reduced in old APP/PS1 mice compared to WT, but not in old rTg4510 mice. PPF was unchanged in old APP/PS1 compared to WT, but was reduced in old rTg4510 mice. LTP, induced with high-frequency stimulation, was reduced in old rTg4510 and APP/PS1 mice. Our data suggest that APP/PS1 mice show reduced BST. In rTg4510 mice, early onset of neurodegeneration may mask BST dysfunction. However, PPF was reduced in rTg4510 mice suggesting some pre-synaptic alteration in remaining neurons. In APP/PS1 mice LTP reduction may be due to induction deficits, since they exhibit both reduced BST and PTP. The basis of the LTP deficit in rTg4510 mice remains unclear.

Title: Late phase LTD in transgenic mouse models of AD and tauopathies as a synaptic readout of imbalanced tau phosphorylation.

Authors: *T. AHMED[1], H. DEVIJVER[2], P. BORGHGRAEF[2], B. LECHAT[2], F. VAN LEUVEN[2], D. BALSCHUN[3];
[2]Dept. of Human Genet., [3]Psychology and Educational Sci., [1]KU Leuven, Leuven, Belgium

Abstract: In several neurodegenerative disorders including Alzheimer's disease (AD) and Tauopathies, synapse loss precedes neuronal death. A very sensitive readout of synaptic deficits in murine models of these diseases is monitoring alterations in activity-dependent synaptic plasticity, e.g., long-term potentiation (LTP) or long-term depression (LTD). In the past, LTP was mostly employed to detect functional disturbances during the progression of pathology, but LTD was hardly considered. We have recently introduced LTD as a complementary sensitive read-out. This is in line with several reports that link LTD with cognitive flexibility, which is deteriorated in many AD patients. Here we examined the consequences of Tau and GSK3β pathology on hippocampal synaptic plasticity using LTD in the hippocampal CA1-region of 10-12 month-old mice as a model. We compared the following mouse models: (i) Tau.P301L that express the human familial tauopathy mutant; (ii) biAT that are bigenic mice carrying human mutant APP.V717I and Tau.P301L; (iii) GSK3β$^{n-/-}$ mice in which GSK3β is specifically knocked-out in neurons; (iv) GSK3β.S9A with a constitutive overactive GSK3β by replacing the wild-type serine at position 9 by alanine and; (iv) biGT mice that are bigenic mice that combine mutant Tau.P301L and GSK3β.S9A (Terwel et al., 2005, 2008; Dewachter et al., 2009; Jaworski et al., 2011). While basal synaptic transmission and paired pulse facilitation were unaffected in all but biGT mice, late-phase LTD (>2 h) was impaired in Tau.P301L, biAT, GSK3β$^{n-/-}$ and biGT mice. Application of the GSK3 antagonist SB216783 rescued this deficit only in Tau.P301L and biAT mice, but not in biGT animals. In GSK3β.S9A, SB216783 blocked the

robust LTD to the same extent as in WT mice. Interestingly, a similar rescue of impaired LTD was obtained with the PP2A agonist sodium selenate in Tau.P301L, biAT and biGT mice. Noteworthy, selenate had no effect on LTD in WT control mice. The combined data-sets further strengthen our hypothesis that a fine-tuned balance between PP2A and GSK3 activity is essential for proper neuronal functions and synaptic plasticity (Ahmed et al., 2015).

Title: Activation of astrocytes in the early stage ameliorated synaptic deficits without affecting amyloid plaque loads in an animal model of Alzheimer's disease

Authors: *X. ZHANG;
Inst. of Neurosci., Zhejiang Univ., Zhejiang, China

Abstract: Astrocytes were closely associated with Alzheimer's disease (AD). However, the precise roles of astrocytes in AD pathogenesis were still controversial. One of the reasons behind the different results reported by different groups might be due to the fact that astrocytes were targeted at different stages of disease progress. Here we found that astrocytes could be activated specifically at the early stage of AD before amyloid plaques appeared by crossing hAPP-J20 with a line of GFAP-TK mice, while microglia were not affected by this crossing. Activation of astrocytes at the age between 3-5 months old did not affect the proleolytic processing of hAPP and amyloid plaque loads in the brain of hAPP-J20 mice. However, deficits of synaptic plasticity in the hippocampus of hAPP-J20 mice were significantly ameliorated after the activation of astrocytes. Further studies showed that the recovery of synaptic plasticity might be associated

with increased expression of PSD-95 induced by astrocytes activation. Our data suggested that early activation of astrocytes were beneficial but not harmful in AD pathogenesis.

Title: Spread of tau down neural circuits precedes synapse and neuronal loss in the rTgTauEC model of early Alzheimer's disease

Authors: *E. PICKETT[1], C. M. HENSTRIDGE[1], R. PITSTICK[2], A. M. POOLER[3], S. WEGMANN[3], B. T. HYMAN[3], G. A. CARLSON[2], T. L. SPIRES-JONES[1];

Abstract: Neuropathological tau protein has been implicated in synaptic loss, which is believed to underlie the cognitive decline observed in Alzheimer's disease (AD). Tau pathology initiates in the entorhinal cortex and spreads in a characteristic pattern to the hippocampus and neocortex with evident neuronal loss within these brain regions at later stages of disease progression. Using array tomography, a high-resolution imaging technique, we examined an ECrTgTau,Tom mouse model expressing a P301L human tau transgene and a transgene labelling cytoplasm red (tdTomato) and presynaptic terminals green (Synaptophysin-EGFP). Expression of all transgenes is under the control of sequences that restrict expression primarily to the entorhinal cortex (Pooler et al 2013 J Comp Neurol). In these red-green-rTgTauEC mice, we observed the density of GFP-expressing and total presynapses, and the spread of tau into the postsynapse in the middle molecular layer (MML) of the dentate gyrus of 9 and 18 month old animals. It has previously been shown that rTgTauEC mice exhibit neuronal loss in the entorhinal cortex and synapse density loss in the MML at 24 months of age. Here we tested the hypothesis that synapse loss of the terminals that express mutant tau would precede the global synapse loss in the MML. We did not observe changes in synapse density in rTgTauEC GFP-positive synaptic terminals

compared to control densities at 9 or 18 months, but further studies are needed to determine whether there is atrophy of the MML, which would indicate synapse loss. Interestingly, we observe human tau in postsynaptic densities in these mice at ages before synapse loss occurs. Our results indicate that the spread of tau through neural circuits is not due to the degeneration of axon terminals and is an early feature of the disease process.

Title: Expression of pathological forms of tau affects synaptic function in cultured neurons

Authors: C. JARA[1], *R. A. QUINTANILLA[1,2];
[1]Inst. de Ciencias Biomédicas, Univ. Autónoma de Chile, Ctr. de Investigación Biomédica, Univ. Aut, Santiago, Chile; [2]Ctr. de Investigación y Estudio del Consumo de Alcohol en Adolescentes (CIAA), Santiago, Chile

Abstract: Alzheimer´s disease (AD) is a common age-related neurodegenerative dementia characterized by memory loss and cognitive impairment. AD brains are characterized by the presence of aggregates of tau in where tau truncated by caspase 3 (D421) and tau hyperphosphorylated at Ser396 and S404 (PHF-1 epitope) could play a role in the pathogenesis of AD. Recent research showed that truncated tau is highly fibrillogenic and plays a role in the oligomerization and formation of pathological tau species in AD. Furthermore, studies from our group showed that the expression of pathological forms of tau, including truncated and phosphorylated tau, affect mitochondrial transport and bioenergetics and it is likely that these alterations could lead to a synaptic and neuronal degeneration. Therefore, we evaluated the effects of pathological forms of tau (GFP-truncated tau (T4C3) and GFP-pseudo phosphorylated tau (T42EC)) on synaptic function using live cell imaging and immunofluorescence assays. Our findings showed that expression of pathological forms of tau affected synaptic architecture in mature neurons. For example, expression of truncated tau reduced dendritic spine density

compared to neurons expressing full-length tau and GFP. Additionally, truncated tau affected the expression and distribution of the presynaptic marker synaptophysin. Interestingly, no differences in expression and distribution of the postsynaptic marker PSD 95 were observed in neurons expressing truncated and full-length tau, supporting the idea that truncated tau apparently affects presynaptic function in cultured neurons. These studies contribute to understand how the expression of truncated tau affects neuronal function through the synaptic impairment present in AD.

Title: Rescue of synaptic depotentiation in the tau22 mouse model of Alzheimer's disease by sodium selenate

Authors: E. FALDINI[1], T. AHMED[1], D. BLUM[3], L. BUEE[3], *D. K. BALSCHUN[2]; [1]Lab. of Biol. Psychology, [2]Katholieke Univ. Leuven, Leuven, Belgium; [3]UDSL, Univ. Lille-Nord de France, Lille, France

Abstract: Synaptic loss is the most consistent correlate of cognitive decline in Alzheimer's disease (AD), and AD is considered to be primary a disease of synaptic failure (Selkoe, 2002). Accordingly, several studies with mouse models of AD reported an impairment of long-term-potentiation (LTP), the main candidate mechanism for the formation of memories at the synaptic level. However, in other AD mouse models, LTP was unaffected, notwithstanding the severity of behavioral learning and memory deficits. In an effort to characterize the putative 'synaptic failure' in such mouse models more comprehensively, we focused on depotentiation (DP), a reversal of long-term potentiation (LTP) briefly after its induction. Here we employed the hippocampal slice preparation and performed extracellular recordings from the hippocampal CA1-region of THY-Tau22 mice. These mice overexpress human 4-repeat tau mutated at sites G272V and P301S under the control of Thy1.2 promoter. LTP is unchanged in THY-Tau22 mice despite of a progressive tau pathology (Schindowski et al., 2006) and severe learning and

memory deficits with an early onset (Van der Jeugd 2011). DP was induced by applying 5Hz for 8 min. When THY-Tau22 mice were inspected at an age of 12 months when tau-pathology is fully developed, DP was found to be significantly stronger compared to WT littermates. Since tau-hyperphosphorylation by GSK-3ß is considered a major mechanism of tau-pathology we applied the selective GSK3 antagonist SB216763 but could not reverse the overshoot of DP which is in contrast to the rescue of LTD by this compound (Ahmed et al. 2015). However, the opposite approach, activation of protein phosphatase 2A, the major tau phosphorylating enzyme, by sodium selenate normalized DP to WT level which is in agreement with the efficiency of sodium selenate in rescuing impaired LTD in these mice (Ahmed et al. 2015.
Our results are indicative of a difference in the pathological mechanisms that underlie the changes in DP and LTD in tau22 mice. Furthermore, they point to a higher sensitivity of DP than LTP for detecting tau-mediated deficits in synaptic function.

Title: Effects of tau reduction in excitatory and inhibitory neurons on seizure susceptibility

Authors: *Y. VOSKOBIYNYK, J. N. COCHRAN, E. D. ROBERSON;
Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Considerable evidence indicates that tau is required for the toxic effects of amyloid beta (Aβ). Tau reduction prevents Aβ-induced deficits in multiple AD mouse models and other degenerative diseases. This seems to involve a strong effect of tau reduction decreasing hyperexcitability; global tau reduction ameliorates Aβ-induced epileptiform activity and seizure susceptibility in multiple mouse models of AD. However, it is still unclear how tau reduction manifests its positive effects, and specifically the contributions of excitatory and inhibitory neurons. We hypothesize that tau reduction decreases neuronal excitability in both excitatory and inhibitory neurons, which results in opposite effects on the network level since these neurons

have opposite electrical drives. To test this hypothesis, we generated excitatory and inhibitory neuron–specific tau knockout mice by crossing mice with a floxed tau allele with mice expressing Cre recombinase under the CaMKII and Viaat promoters, respectively. Tau was reduced by about 70% in the excitatory knockout line and by about 30% in the inhibitory knockout line. We used a model of pharmacologically induced seizures with pentylenetetrazole (PTZ), a GABAergic antagonist, to assess seizure susceptibility as a direct measure of network excitability. We also characterized behavioral differences in both excitatory and inhibitory tau knockout models. Excitatory tau knockout mice had lower clinical seizure scores, decreased latencies to reach a given seizure stage, and reduced number of deaths due to seizures after PTZ injections. Meanwhile, inhibitory tau knockout mice had the opposite effects. Our findings contribute to understanding the role of tau on cellular and network levels, as well as its contribution to AD pathogenesis, and may facilitate the development of new therapeutic approaches targeting tau-related processes.

Title: Diabetes induces tau dependent synaptic and cognitive impairments.

Authors: *D. BAGLIETTO-VARGAS, L. TRUJILLO-ESTRADA, J. SHI, A. C. MARTINI, L. CAI, C. DA CUNHA, S. FORNER, F. M. LAFERLA;

Abstract: Despite intensive research efforts over the past few decades, the mechanisms underlying the etiology in Alzheimer's disease (AD) remain unknown, especially in the sporadic form of the disease. This fact is of major concern because the number of patients affected by this medical condition is increasing exponentially and the existing treatments are only palliative in nature and offer no disease modifying affects. Interestingly, recent epidemiological studies indicate that diabetes significantly increases the risk of developing AD, suggesting that diabetes may play a causative real in the development of AD pathogenesis. Here, we investigated whether diabetes impairs synaptic and cognitive function via tau dependent mechanism. Our study shows that tau is a fundamental mediator for T1D-like disease to induce cognitive impairment and its dysregulation causes reduction in synaptic proteins levels and cognitive decline. Moreover, we demonstrate the novel finding that depletion of endogenous tau mitigates behavioral impairment and synaptic deficits induced in T1D-like mice. These data are relevant because elucidating the molecular interactions between diabetes and AD, it might offer a novel approach to identifying mechanisms that may modulate the onset and progression of sporadic AD cases.

Title: Analysis of network dysfunction in hTau-A152T transgenic mice identifies potential new biomarker and opportunity for therapeutic intervention

Authors: *S. MAEDA[1,2], B. HU[1], G.-Q. YU[1], E. MASLIAH[3], L. MUCKE[1,2];

Abstract: Tau aggregation is a pathological hallmark of various neurodegenerative disorders, including frontotemporal dementia spectrum disorders (FTD-s) and Alzheimer’s disease (AD).

Recently, an amino acid substitution in tau (A152T) was reported to increase the risk of both FTD-s and AD. To investigate the effects of A152T-variant human tau (hTau-A152T) *in vivo*, we generated transgenic mice with regulatable expression of hTau-A152T or wildtype human tau (hTau-WT). Our comparative analysis of these models suggests that the A152T substitution augments the risk for neurodegenerative diseases by increasing neuronal levels of soluble hTau, promoting network hyperexcitability, and synergizing with the adverse effects of other pathogenic factors.
In contrast to hTau-WT mice, hTau-A152T mice developed age-dependent neuronal loss and behavioral abnormalities that were preceded by spontaneous epileptiform activity on electroencephalography (EEG). Neuronal expression of hTau-A152T increased epileptiform activity and early mortality in human amyloid precursor protein (hAPP) transgenic mice. Treatment with the anti-epileptic drug levetiracetam (LEV), which reduces synaptic, behavioral and network dysfunction in hAPP mice, acutely suppressed epileptiform activity in hTau-A152T mice. Experiments are in progress to determine whether prolonged treatment with LEV can also reduce other abnormalities in this model.
Analysis of EEG recordings also revealed that neuronal overexpression of hTau-A152T or hTau-WT increased the power of theta oscillations, a spectral alteration that has previously been reported in AD and FTD-s patients. In contrast, neuronal overexpression of hAPP/Abeta did not change theta power in mice with or without hTau-A152T expression. Additional studies are needed to evaluate theta power as a potential biomarker of tau accumulation and for the assessment of treatments aimed at tau.

Abstract: Tau is recently considered an executor of neuronal damage and cognitive dysfunction in Alzheimer's disease (AD). Aβ oligomers are suggested to induce phosphorylated tau, however, the relationship between Aβ oligomers and tau is not obvious. Aβ oligomers, phosphorylated tau, and fyn signaling are supposed to cause synaptic dysfunction in AD brain. We have shown that phosphorylated tau is induced in lipid rafts of Tg2576 mouse brain, and that Aβ oligomers/PrP^c complex and activated Fyn signaling are found in lipid rafts of Tg2576 mouse brain. We examined if Aβ oligomers induce phosphorylated tau and fyn-NMDA cascade in synapse. Tg2576 mice and nontransgenic littermates (6-23 month old, n=12 in each group) were used. Synaptosome fractions and lipid rafts fraction from synaptosomes were extracted, and analyzed by western blotting. Phosphorylated tau and fyn increased in synaptosome with accumulation of Aβ oligomers, and also in lipid rafts of synaptosome. The increase began when Aβ oligomers first accumulated in synaptosomes. Aβ oligomers may induce phosphorylated tau and Fyn-NMDA receptor signal transduction pathways in lipid rafts of synapse.

Abstract: One of the main neuropathological hallmarks of Alzheimer's disease (AD) is the altered proteolytic processing of the amyloid precursor protein (APP), leading to the production and extracellular aggregation of neurotoxic forms of amyloid β-peptide (Aβ). Recent studies indicate that the presence of intracellular Aβ is correlated with neurodegeneration, impaired synaptic plasticity, and memory loss in early AD, but the fundamental cellular mechanism is still largely unknown. In the CNS, neurons relay information by responding to presynaptic input, and generating action potentials to facilitate vesicle release onto their own postsynaptic neurons. In the present study, we directly address whether intracellular Aβ impairs neuronal sensitivity to the presynaptically released vesicles, and its action potential firing capability. 1 μM Aβ was incubated at 37 º C for 24 hours, and was delivered into CA1 pyramidal neurons of mouse hippocampi by the patch pipette during whole-cell patch clamp recording. We monitored the spontaneous neuronal transmissions recorded from the Aβ-challenged, postsynaptic CA1 neurons, while the presynaptic neurons remained unaffected. The intracellular Aβ challenge eliminated any postsynaptic response to the spontaneously released vesicles from the presynaptic neurons. The CA1 neurons also demonstrated significant membrane depolarization, decreased input membrane resistance and impaired action potential firing capability. These detrimental effects of intracellular Aβ could be prevented by an anti-oligomeric monoclonal antibody (A11), which was delivered together with Aβ inside the cell. Targeting intracellular Aβ prior to extracellular Aβ plaque formation could potentially preserve neuronal functions and synaptic transmission in early AD.

Title: Monomeric amyloid beta influences neuronal excitability in immature cortical neurons

Authors: *E. PIZZI[1], G. SERRATTO[2], C. ARZUFFI[1], M. MAZZANTI[1];
[1]Univ. of Milan, Milano, Italy; [2]CNR, Milano, Italy

Abstract: Accumulation of Amyloid-Beta (Aβ) in human brain is commonly associated with Alzheimer's disease (AD). Oligomeric Aβ, the most toxic species of the peptide, is correlated to changes in synaptic function and plasticity resulting in a synaptotoxic activity. For this reason, high levels of Aβ are considered a hallmark of AD even if the peptide exerts different functions at synaptic level in a concentration and configuration-dependent manner. Indeed, monomers aggregation and the consequent damaging effect of Aβ on neuronal circuits rely on its concentration that is one of the factors promoting oligomers formation over time. However, monomeric Aβ is physiologically produced in the healthy brain at picomolar concentrations and it is regulated by spontaneous neuronal activity. It has been reported that monomeric Aβ preparations can play a role on synaptic functions and memory, but its biological relevance is still debated. Moreover, the ability of oligomeric species to cause neuronal damages is linked to the presence of glia cells. While monomers are often harmless in culture, the interaction between Aβ oligomers and glia is necessary to trigger the neurodegenerative process. In light of this, both monomers and oligomers may cause changes in the intrinsic excitability of neurons resulting in different outcomes. Our working hypothesis aims to demonstrate that monomeric Aβ is instrumental to neuronal development and excitability stabilization. To achieve this goal we treated primary cortical neurons at early stage of in vitro development with nanomolar concentration of $A\beta_{1-42}$ peptide. The result is a modulation of neuronal excitability promoted by physiological levels of monomeric Aβ on immature neurons.

Title: *In vivo* characterization of epilepsy-associated short discharges in mice modeling Alzheimer's disease

Authors: I. ISHCHENKO[1,2], I. GUREVICIENE[1,3], K. GUREVICIUS[1], *H. TANILA[1]; [1]Univ. Eastern Finland, Kuopio, Finland; [2]A.B. Kogan Res. Inst. for Neurocybernetics, Southern Fedederal Univ., Rostov-on-Don, Russian Federation; [3]Dept. of Psychology, Univ. of Jyväskylä, Jyväskylä, Finland

Abstract: Background: All widespread amyloid precursor protein (APP) transgenic mice, which are the primary model of Alzheimer-related brain amyloidosis, have been reported to display some form of epileptic activity, including generalized seizures. However, the exact seizure focus awaits to be identified. In addition, a number of various discharges of short duration have been used as surrogate markers for their epilepsy in anti-epileptic treatment trials, but so far these have been poorly characterized and highly variable between studies. We aimed at characterizing these short discharges in APPswe/PS1dE9 mice with well-documented seizure occurrence (Minkeviciene R et al., J. Neurosci. 2009). **Methods**: We have implanted 9 APPswe/PS1dE9 male mice and 7 wild-type littermates (C57Bl/6J background) with multiple chronic electrodes to record local field potentials: bilateral frontal and parietal screw electrodes, as well as double or triple wire electrodes in the medial frontal cortex, reticular thalamic nucleus, CA1 and CA3 layers of hippocampus and retrospenial cortex. The ground and reference electrodes were placed above the cerebellum. Two 3-h video-EEG recordings were conducted during the light period at the age of 5-6 months. **Results**: In the preliminary analysis we have verified the presence of two common EEG patterns that are widely considered epileptic, local cortical spikes and thalamo-cortical spike-and-wave discharges lasting 1-2 s. However, these were present in both TG and WT mice. In addition, we found a new type of discharge complex that spreads to all recordings channels and shows an amplitude maximum in the CA3. The complex is usually followed by EEG suppression. These complexes have been found so far only in TG mice, but only in a subset of them. We are currently testing the effect of levetiracetam and etosuximide on these various discharges. **Conclusion**: We expect to identify short-duration discharge patterns that can be used as surrogate markers to *per se* rare spontaneous seizures in APP transgenic mice to augment the development of optimal anti-epileptic treatment in Alzheimer-related epilepsy. *Supported by Sigrid Juselius Foundation, Finland and Center for International Mobility, Finland.*

Title: Neuronal activity regulates Aß precursor protein processing through NMDA receptor signaling

Authors: *Y. GENG, X. NIU, Y. CHEN;
IRCBC, SIOC, Chinese Acad. of Sci., Shanghai, China

Abstract: Alzheimer's disease (AD) is the most common neurodegenerative disorder with more than 5.7 million patients in China alone. Unfortunately no disease modifying or preventive therapy is available up to date. Overwhelming amount of evidence supports that the abnormal excessive brain deposition of amyloid ß (Aß) is the major cause. Mutants of amyloid ß precursor protein or its key processing enzymes could lead to enhanced Aß deposition and early onset familial AD. However, majority of AD patients are sporadic without these mutations. It is unclear why Aß also accumulates in their brains but not in the age-matched healthy controls. This implicates novel mechanisms that impact Aß metabolism besides mutations led to familial AD. Recent studies have found brain activity controls Aß metabolism, suggesting unique unknown mechanisms exist in nerve system. Using high resolution confocal microscopy and other molecular cellular methods, we found neuronal activity regulates Aß production and APP co-localization with its key enzyme BACE1 in dissociated neuronal cultures through NMDA receptor signaling. We also investigated the potential signaling molecules critical in this process, which shed light to uncover the cause of the Aß mis-regulation in sporadic AD.

Title: Levetiracetam inhibits oligomeric A beta-induced glutamate release from human astrocytes

Authors: J. PINA CRESPO[1], S. SANZ-BLASCO[1], X. ZHANG[1], S. MCKERCHER[2], *M. V. TALANTOVA[3], S. A. LIPTON[2];
[1]Ctr. for Neurosci. and Aging, Sanford Burnham Prebys Med. Discovery Inst., La Jolla, CA; [2]Neurodegenerative Dis. Ctr., [3]Neurosci., Scintillon Inst., San Diego, CA

Abstract: A recently identified mechanism for oligomeric Aβ-induced glutamate release from astrocytes involves intracellular Ca2+ elevation, potentially via Ca2+ dependent vesicular release. Evidence suggests that levetiracetam (LEV, Keppra®), an antiepileptic drug, can improve cognitive performance in both humans suffering mild cognitive impairment and animal models of Alzheimer disease (AD). Because LEV acts by modulating neurotransmitter release from neurons via interaction with synaptic vesicles, we tested the effect of LEV on Aβ-induced astrocytic release of glutamate. We used a FRET-based glutamate sensor (termed SuperGluSnFR), whose structure is based on the ligand-binding site of glutamate receptors, to monitor glutamate release from primary cultures of human astrocytes exposed to oligomeric amyloid-β peptide 1-42 (Aβ42). We found that LEV (10 μM) inhibited oligomeric Aβ-induced astrocytic glutamate release. Additionally, we show that this Aβ-induced glutamate release from astrocytes is sensitive to tetanus neurotoxin (TeNT), an inhibitor of the vesicle release machinery. Taken together, our evidence suggests that LEV inhibits Aβ-induced vesicular glutamate release from astrocytes and thus may underlie, at least in part, the ability of LEV to reduce hyperexcitability in AD.

Abstract: Key histopathological features of Alzheimer's disease (AD) are aggregates of amyloid β-peptide (Aβ), which form extracellular plaques, and intracellular accumulation of hyperphosphorylated protein tau, designated as neurofibrillary tangles (NFT). Deficits in executive functions, which indicate prefrontal (PFC) and hippocampal (HC) dysfunction, could serve as potential early indicators of neurodegenerative diseases. Mouse models of AD have been powerful resources to elucidate the neurobiological mechanisms underlying the disease. In this study, we used a novel knock-in mouse model where endogenous APP is replaced by human APP (NLGF). APPNLGF mice develop robust Aβ amyloidosis without APP overexpression, which allow the identification of potential artifacts caused by unphysiological high levels of APP found in previous APP transgenic mice.
We investigated the pathogenic mechanisms that affect the functional integrity of the PFC and HC by combining biochemical, behavioral, electrophysiological and in vivo neuroimaging techniques. Executive (dys)functioning was reliably assed in the reversal paradigm of the touchscreen boxes, which depends on nearly identical features as in human studies. In addition, other high-order cognitive functions were evaluated in a complex behavioral test battery: Morris Water Maze, Contextual fear response and emotional response and Elevated plus maze, that also depend on these brain structures. Since AD is predominantly a synaptopathy, measures of synaptic plasticity, such as long-term potentiation (LTP) and depression (LTD) are expected to be highly sensitive in detecting early signs of synaptic deficits in PFC and HC slices. Finally, the temporal correlation of blood-oxygenation-level-dependent (BOLD) fluctuations between spatially distinct areas allowed us to study impairments in functional connectivity (FC) that can be associated to the disease progression.
Our results indicate that early plaque deposition at 3 months coincides with mild decreases in anxiety-related behavior and extinction learning. As the pathology progresses at 6 months, cognitive decline becomes more evident in the behavioral tests that strongly require normal PFC and HC function. Interestingly, while CA1-LTP in APPNLGF mice was severely impaired in its magnitude, LTP recorded in mPFC had a deficit in the maintenance of potentiation as compared to APPNL. Our imaging data has been acquired and is being currently analyzed. This study provides potential insights into the role of Aβ pathology for PFC and HC functions in a crucial APP knock-in mouse model that will influence drastically future therapeutical approaches.

Title: Enhancing inhibitory interneuron function improves neuronal network activity and cognitive function in multiple mouse models of Alzheimer's disease

Authors: *K. MA, S. SAILLET, A. GUTIÉRREZ, Z. CHOU, J. J. PALOP;
Gladstone Inst., San Francisco, CA

Abstract: Alzheimer's disease (AD) results in deterioration of cognitive functions and abnormal patterns of brain activity, and is pathologically characterized by beta-amyloid (Aβ) plaques, neurofibrillary tangles of hyperphosphorylated tau, neuroinflammation, synaptic loss, and neuronal degeneration. Mouse models of AD overexpressing familial AD (FAD) mutant forms of human amyloid precursor protein (APP) or presenilin (PS1) develop cognitive deficits and abnormal patterns of neuronal network activity with an increased incidence of seizures and premature mortality. Previously work in the laboratory identified that decreased levels of the interneuron-specific voltage-gated sodium channel Nav1.1 subunit contributes to network and cognitive alterations in FAD-mutant APP-J20 mice. Here, we extend these original findings to three APP transgenic mouse models of AD with varying ratios of APP versus Aβ overexpression, including mice expressing APPswe/PS1dE9, APPswe/ind and wildtype APP (APPwt). Nav1.1 levels were enhanced in the interneurons by Nav1.1-BAC overexpression and interneurons were identified by expressing eGFP under the control of Lhx6 promoter. We found that increasing Nav1.1 expression similarly reduced premature mortality in both APPswe/PS1dE9 and APPswe/ind mice. Importantly, APPwt mice did not have premature mortality, suggesting that premature mortality in APP mice depends on FAD mutations and Nav1.1 expression levels. In FAD mouse models APPswe/PS1dE9 and APPswe/ind, enhancing Nav1.1 levels also improved spatial reference memory in the Morris water maze as indicated by decreased latency and distance to reach the hidden platform and increased time spent in the hidden platform quadrant of the probe trial. APPwt mice did not have probe trial deficits in the Morris water maze. In addition, enhancing Nav1.1 expression rescued deficits in other

behavioral domains including habituation to novel environment, anxiety and nest building. In order to mechanistically link cognitive improvements to neuronal network function, EEG recordings and anatomical data of GFP-interneurons were performed in these three APP transgenic lines. Our data suggest that FAD-dependent functional alterations in multiple APP overexpressing mouse models are modulated by Nav1.1 expression in interneurons.

Title: Optogenetic modulation of interneuron-dependent oscillatory activity in a mouse model of Alzheimer’s disease

Authors: S. SAILLET, A. GUTIERREZ-LERMA, Z. CHOU, K. MA, J. PAZ, *J. J. PALOP; Gladstone Inst. and UCSF, San Francisco, CA

Abstract: Alterations in inhibitory neurons and oscillatory activity are commonly associated with neurological disorders, including Alzheimer’s disease, schizophrenia, and epilepsy. Previous studies in the laboratory suggested that interneuron dysfunction results in abnormal oscillatory activity, network hypersynchrony, and cognitive impairment in the hAPP-J20 mouse model of Alzheimer’s disease. Here, we mechanistically assessed the specific contributions of different cell-types of inhibitory interneurons on cortical oscillatory rhythms and network synchrony in wildtype and hAPP-J20 mice by optogenetic approaches *in vivo* and *in vitro*. Multi-unit and local field potential recordings were performed in freely behaving mice expressing channelrhodopsin-2 (ChR2) in Lhx6- and parvalbumin (PV)-positive interneurons. We found that blue light stimulation (2-7.5 mW) of Lhx6- or PV-interneurons increased their action potential firing rates and gamma oscillatory power in an intensity-dependent manner.

Interestingly, activation of Lhx6-interneurons resulted in bigger increases of gamma power than activation of PV-interneurons, suggesting that non-PV- but Lhx6-positive interneurons facilitate gamma oscillations. The control green light at the same intensities (2-7.5 mW) did not enhance gamma oscillations. In brain slices, blue, but not green, light stimulation of Lhx6-interneurons increased the power of gamma oscillatory activity in an intensity-dependent manner. Using these methods, we will explore the effects of optogenetic modulation of Lhx6- or PV-interneurons on oscillatory activity and network hypersynchrony in the hAPP-J20 mouse models of Alzheimer's disease.

Title: Peptides of amyloid precursor protein alpha mimic the parent molecule's enhancement of hippocampal LTP

Authors: *J. MORRISSEY[1], B. G. MOCKETT[2], K. PEPPERCORN[3], W. P. TATE[3], S. M. HUGHES[3], W. C. ABRAHAM[2];

Abstract: Amyloid precursor protein (APP) is a transmembrane protein that is cleaved by specific proteases to produce a variety of peptides and larger protein products that contribute to the development, maintenance and plasticity of the brain. One of the produced proteins, secreted APP-alpha (sAPPα), is neurotrophic and neuroprotective, while also facilitating hippocampal long-term potentiation (LTP). To address whether small peptide domains are sufficient to mediate some of sAPPα's effects, we studied a 16 amino acid peptide from the C-terminus region (16mer), and a tri-peptide (trimer) from within sAPPα. The N terminal amino acid of each peptide was acetylated to enhance stability. The ability of these peptides to affect the induction and persistence of LTP at Schaffer collateral/commissural synapses in area CA1 of rat hippocampal slices was assessed using field potential methodologies. After establishing a stable baseline of field EPSP's, either sAPPα or a peptide was superfused for 30 min, at which time a brief theta-burst stimulation protocol was delivered to induce LTP. After a further 5 min, the

protein or peptide was washed out and recordings continued for 1 h post tetanus. The results demonstrated that each peptide, as well as sAPPα, enhanced LTP compared to untreated control slices (15.2% LTP). The trimer, at both 1 nM (41.0%) and 10 nM (46.3%) concentrations gave as strong LTP facilitation as full-length sAPPα (1 nM, 39.0%). The 16mer at 1 nM produced an equivalent level of facilitation (39.3%). The 16mer effect was dose-dependent as the degree of facilitation declined at the higher concentrations of 10 nM and 1 μM. These results indicate that small peptide sequences within APP may have potential for improving the impaired neural plasticity and memory seen in neurodegenerative diseases.

Title: Conditional deletion of Prnp rescues synaptic and behavioral deficits in mouse model of Alzheimer's disease

Authors: *S. V. SALAZAR[1], A. C. KAUFMAN[2], S. M. STRITTMATTER[2];
[2]Neurosci., [1]Yale Univ., New Haven, CT

Abstract: A growing amount of genetic and biochemical evidence suggests soluble oligomeric amyloid-beta (Aβo) as the key toxic species in triggering Alzheimer's disease (AD) pathophysiology. Previously, we reported constitutive deletion of *Prnp* rescued memory impairment in APP_{swe}/PS1ΔE9 transgenic mice, a mouse model of familial AD. We hypothesized that conditional deletion of *Prnp* after onset of AD-related phenotypes might reverse these deficits. Here we report temporally controlled deletion of *Prnp* is able to reverse learning and memory deficits at the age of onset in APP_{swe}/PS1ΔE9 mice. Moreover, *Prnp* deletion at both 12 and 16 months of age was able to reverse synapse loss and behavioral deficits in these mice. These results underscore the therapeutic potential of targeting PrP^C for the treatment Aβo related phenotypes in Alzheimer's disease.

Title: Cholinergic modulation of LTP depends on the activity of glutamatergic neuron and protects synaptic plasticity from synthesized amyloid beta oligomers in hippocampus of adult mice

Authors: *T. SATO[1], Y. OHI[2], D. KATO[1], M. MIZUNO[1], A. HAJI[2], N. MATSUKAWA[1]; [1]Nagoya City Univ., Nagoya-Shi, Japan; [2]Aichi Gakuin Univ., Nagoya-shi, Japan

Abstract: The modulating neural systems play a crucial role for the synaptic plasticity of glutamatergic neurons in hippocampus. Especially, the cholinergic neuronal network from basal forebrain has been well investigated as the therapeutic target for Alzheimer disease. Previously, it was reported that the adrenergic stimulation could protect the synaptic plasticity from amyloid oligomers not only enhance the long-term potentiation (LTP) in hippocampus (S. Li and D. J. Selkoe *et al*, 2013). Therefore, in this study, we assessed protective activity of cholinergic stimuli against amyloid oligomers. We performed electrophysiological analysis by extracellular recording with the acute slices of hippocampus. LTP was induced by tetanus stimuli (TS, 100Hz 1sec) on Schaffer collateral in the CA3 and field excitatory postsynaptic potential was recorded from stratum radiatum in the CA1. The cholinergic modulation on LTP in wild type mice (WT) were achieved pharmacologically by using charbachol (CCh, 50 nM). Moreover, we also investigated LTP with the model mice, hippocampal cholinergic neurostimulating peptide precursor protein transgenic mice (HCNP-pp Tg) which has shown LTP enhancement via muscarinic modulation, as the model of endogenous cholinergic stimuli (Y. Ohi and N. Matsukawa *et al*, 2015). The Amyloid oligomers were assembled from synthesized amyloid peptide and perfused with ACSF preceding by LTP induction. As the results, the synthesized amyloid peptide formed dimers with disulfide bands and aggregated into the protofibril-like oligomers as reported (B. O'Nuallain and D. M. Walsh *et al*, 2010). In WT, the amyloid oligomers could suppress LTP with dose dependent, indicating the toxic effect against glutamatergic neural LTP. In contrast, LTP was maintained in WT with preconditioned by CCh and in HCNP-pp Tg, in spite of the existence of sufficient dose of the amyloid oligomers for LTP

suppression in WT. This result may imply that both of exogenous and exogenous cholinergic stimuli could exert protective activity on glutamatergic neuronal plasticity against the synaptic toxicity of the amyloid oligomers. It was considered that the inhibition of NMDA receptors was one of the mechanisms of acute toxicity of the amyloid oligomers. Therefore, it was speculated that cholinergic modulation of LTP which achieved by elevation of intracellular Ca^{2+} concentration via non-NMDA receptors pathway may be compatible for protecting LTP from the synthesized amyloid oligomers.

Abstract: Alzheimer’s disease (AD) is the most prevalent neurodegenerative disorder among the elderly. Amyloid β is thought to be one of the causative factors for AD, which is produced by BACE1 (Beta-secretase) initiated sequential proteolytic cleavage of APP. BACE1 inhibition is one of the promising therapeutic approaches for AD. Currently, several BACE1 inhibitors are undergoing phase 2/3 clinical trials. However prolonged BACE1 inhibition interfere structural

and functional synaptic plasticity in mice, most likely due to disturbing the metabolism of BACE1 substrates. Sez6 (Seizure protein 6) is predominantly cleaved by BACE1 and *Sez6* null mice share some phenotype with BACE1-inhibited mice including reduced dendritic spine density in cortex and diminished performance in hippocampal-dependent behavioral tests. In order to discover if Sez6 is involved in BACE1-inhibition-induced synaptic alteration, we applied constitutive (*Sez6*$^{-/-}$:GFP) and conditional (*Sez6*$^{cKO/cKO}$:SlickV) *Sez6* KO mice a diet mixed with NB-360, a novel blood-brain barrier penetrant BACE1 inhibitor. Immunoblotting analysis showed that NB-360 strongly suppressed Sez6 and APP cleavage similar to *BACE1* knockout mice. To study the impact of long-term pharmacological inhibition of BACE1 in *Sez6*$^{-/-}$:GFP mice, we repeatedly imaged the apical tufts of layer V pyramidal neurons in the cerebral cortex for 7 weeks by intravital two-photon microscopy. Although NB-360 treatment for 3 week caused a significant but reversible reduction of density of total dendritic spines, persistent spines (persisted $\geqslant$ 7 days) and new gained spines in control mice, the same treatment did not affect dendritic spine dynamics in *Sez6*$^{-/-}$ mice. To rule out developmental deficits and identify which Sez6 proteolytic fragments are involved, we monitored spine dynamics upon NB-360 treatment in Sez6$^{cKO/cKO}$:SlickV mice. The tamoxifen-inducible recombinase CreER^{T2} and eYFP are co-expressed in a small subset of neurons in SlickV mice. By applying tamoxifen, *Sez6* was knockout specifically in YFP positive neurons in adulthood. It caused a small but significant spine density reduction; however chronic NB-360 treatment did not alter spine plasticity in the absence of cell-autonomous Sez6. Finally, electrophysiological field recordings in hippocampus CA1 region showed that LTP reduced in chronic NB-360 treated WT mice and vehicle treated Sez6$^{-/-}$ mice, but NB-360 treatment did not interfere LTP in Sez6$^{-/-}$ mice. Our data suggest that Sez6 has a pivotal role in maintaining normal dendritic spine dynamics. Furthermore, cell autonomous Sez6 is involved in BACE1-inhibitor-induced structural and functional synaptic alterations.

Abstract: Recent studies show that amyloid-β peptide (Aβ) can be produced in an activity-dependent manner locally at synapses. While the role of Aβ accumulation in synaptic dysfunction and AD pathogenesis is well established, molecular mechanisms modulating synaptic Aβ generation remain poorly understood. Aβ is generated via sequential cleavage of amyloid precursor protein (APP) by β-secretase and γ-secretase. It has been previously demonstrated that activity and expression level of BACE1, a major neuronal β-secretase, were significantly increased in mild cognitive impairment brains as well as AD brains, suggesting that abnormal activation of BACE1 may play an important role at an earlier stage of the disease. Recently, BACE1 has been found to preferentially localize to presynaptic terminals including synaptic vesicles. However, whether BACE1 activity affects activity-dependent Aβ production at the synapse remains unknown. To identify activity-dependent BACE1 interacting protein at the synapse, we performed a mass spectrometry-based proteomics of wild-type rat brain synaptoneurosome lysates in the presence or absence of calcium, using anti-BACE1 antibody to pull down BACE1 interacting proteins. Interestingly we identified synaptic vesicle protein 2B (SV2B) as a novel BACE1 interacting protein. SV2B is involved in synaptic vesicle fusion with the presynaptic membrane. We confirmed endogenous BACE1-SV2B interaction with a Ca^{2+}-dependent manner by co-immunoprecipitaiton in synaptoneurosomal preparations. To test potential effects of SV2B on BACE1 activity and Aβ levels, we employed SV2B knockout (KO) and overexpression approaches. Intriguingly, the levels of soluble Aβ40 and Aβ42 in the hippocampal lysates from SV2B KO mice were significantly increased compared to controls. Further, the level of sAPPβ was increased in SV2B KO mice as well, while protein expression level of BACE1 was similar to that of control mice. Conversely, transient overexpression of SV2B in HEK293 cells led to decreased levels of Aβ40 and Aβ42 as well as sAPPβ. Taken together, we suggest that SV2B can regulate presynaptic Aβ generation via the interaction with BACE1. A deeper understanding of the mechanisms by which the interaction between BACE1 and SV2B may affect presynaptic Aβ generation would provide new therapeutic strategies to prevent the onset of AD.

Title: Basal forebrain epigenetic, neurotrophic, and synaptic dysregulation during the progression of Alzheimer's disease

Authors: *L. MAHADY[1,2], M. NADEEM[1], B. HE[1], S. PEREZ[1], E. MUFSON[1];
[1]Barrow Neurolog. Inst., Phoenix, AZ; [2]Interdisciplinary Grad. Program in Neurosci., Arizona State Univ., Phoenix, AZ

Abstract: The region of the basal forebrain containing cholinergic neurons displays neuronal, synaptic, and neurotrophic dysregulation during the progression of Alzheimer's disease (AD). However, it has not been determined if basal forebrain cellular dysfunction is associated with alterations of the epigenome in this region. Several epigenetic proteins including histone deacetylases (HDAC2, HDAC 6, and SIRT1), DNA (cytosine-5-)-methyltransferase 1 (DNMT1), and methyl-CpG-binding domain protein 2 (MBD2) are implicated in the pathogenesis of AD. HDACs form corepressor complexes with MBD2 to regulate transcription of genes including brain-derived neurotrophic factor (BDNF), synaptophysin (SYP), and synaptotagmin (SYT). Whether changes in neurotrophic, synaptic and epigenetic proteins co-occur or precede each other in the basal forebrain during the onset of AD remain unknown. Here we performed quantitative western blotting to determine the relationship between changes in the neurotrophic receptors trkA and $p75^{NTR}$, synaptic proteins SYT, SYP, and drebrin (DRB) as well as the epigenetic proteins HDAC1, HDAC2, HDAC3, HDAC6, SIRT1, DNMT1, and MBD2 in frozen basal forebrain tissue obtained from subjects who died with a premortem clinical diagnosis of no cognitive impairment (NCI, n=17; MMSE=28), mild cognitive impairment (MCI, n=7; MMSE=24), mild/moderate AD (n=9; MMSE=20) and severe AD (n=8; MMSE=9) from the Rush Religious Orders Study (RROS) and the Rush ADC, respectively. Groups were matched by age, gender, and postmortem interval (mean PMI=5 hr). The RROS cases underwent a more detailed premortem clinical and postmortem neuropathologic evaluation than the RADC cases. Western blot analysis revealed increased levels of HDAC2 in severe AD compared to NCI, MCI and mild/moderate AD ($p=0.03$). By contrast, levels of HDAC1, HDAC3, HDAC6, DNMT1, SIRT1 and MBD2 remained stable across the four clinical groups examined. Decreased

levels of trkA were found in mild and severe AD compared to NCI and MCI (p=0.001), while $p75^{NTR}$ levels remained stable. Of the synaptic proteins examined, there was a non-significant trend for a reduction in DRB levels across the clinical groups. There were no significant correlations between protein levels and the neuropathological criteria or cognitive tests examined. These results indicate that basal forebrain synaptic and $p75^{NTR}$ levels are preserved, whereas trkA and select epigenetic protein levels are reduced in the later stages of AD, which may contribute to neuronal selective vulnerability and cognitive impairment as AD progresses.

Abstract: In early stages of Alzheimer's disease (AD), synaptic dysfunction induced by toxic amyloid-β (Aβ) leads to impaired functioning of neuronal networks, altered patterns of synchronous activity and severe functional and behavioral deficits mainly due to hyperexcitability of hippocampal networks. The molecular mechanisms underlying these alterations remain unclear but functional evidences point to the involvement of receptors/channels which modulate neuronal excitability, playing a pivotal role in early Aβ-induced AD pathogenesis. Recently we have shown that Aβ modifies septohippocampal

GABAergic neurotransmission by decreasing the conductance and expression of G protein-gated inwardly rectifying potassium (GirK/Kir3) channels which control neuronal excitability. In this regard, we have proposed a novel A*β*-mediated mechanism of *loss-of-function* of GirK/Kir3 channels contributing to the disruption of hippocampal inhibitory GABAergic neurotransmission, and subsequent network hyperactivity and hypersynchrony in AD. Here, we have further studied the relationship between GirK channels and the effects of A*β* at neural network and behavioral levels, in an *in vivo* non-transgenic model of AD. Mice were *icv* injected with A*β* or GirK modulators and trained in hippocampal-dependent memory tasks such as new object recognition. Synaptic plasticity (LTP) and oscillatory properties of the hippocampus were also studied *in vivo*. Behavioral and electrophysiological data showed significant differences between controls and A*β* groups or animals treated with GirK modulators suggesting that A*β* impairs important hippocampal functions related to learning and memory processes. Importantly, GirK channels seem to be involved in these processes.Taken together, our results indicate that GirK channels could contribute to the imbalance of excitatory/inhibitory neurotransmission in the hippocampus that causes aberrant network activity and early cognitive impairment in AD models and emerge as an interesting potential therapeutic target to be studied in AD preclinical stages.

Title: The pathological role of isomerase ptpa at synapse in alzheimer's disease

Authors: *Y. GONG[1], F. CHOW[2], C. LIPPA[2];
[1]Nanjing Univ. Chinese Med., Jingsu, China; [2]Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Alzheimer’s disease (AD) is a progressive neurodegenerative disorder associated with aging. Synaptic loss correlates strongly with disease severity. The role of aging remains elusive. It has been proposed that oligomers of β-amyloid peptide (Aβ) disrupt the activity of glutamate receptors organized by Shank proteins in the postsynaptic density (PSD). Shank proteins organize the structure and function of the PSD. Oligomers of Aβ and the single shank3 gene mutation lead to Shank protein loss in AD and in the autism spectrum disorders (ASD)

respectively. Both disorders involve impaired cognition. The homeostasis of Shank proteins at the synapse is also regulated by the mammalian target of rapamycin (mTOR). mTOR maintains the homeostasis of synaptic proteins, regulates glutamate receptor trafficking and induces synaptic formation. The phosphotyrosyl phosphatase activator (PTPA), a novel peptidyl-prolyl cis/trans-isomerase (PPIase), is the part of down-pathway of mTOR. PTPA was identified to synaptic rafts and postsynaptic density (PSD), and colocalized with NMDR receptors and Shank proteins in neurons. PTPA was also first identified in quantities 10 times greater than normal at the PSD ($p<0.001$), and the soluble PTPA protein was dramatically reduced to 70% at the synapse in AD ($P<0.05$), compared with that in control human brains. Oligomers of Aβ can induce the soluble PTPA lost to 40% in synapse ($p<0.05$) and insoluble PTPA increase to 80% in PSD ($p<0.01$), compared with that in control neuron in vitro. These findings suggest that abnormal activity of PTPA may lead to the dysfunction of synapse in AD development.

Title: Rapid memory dissipation in Alzheimer’s diease can be ameliorated by reducing Rac1 activity

Authors: *W. SHI, S. DU, Y. ZHONG;
Tsinghua Univ., Beijing City, China

Abstract: Memory loss that disrupts daily life is a major symptom of Alzheimer's disease (AD), especially for new-formed memory. There is mounting evidence that Aβ42 could active Rac1, a small G protein, through several cascades *in vitro* and *in vivo* test, however the function of activation is still obscure. Shuai (2010) reported in Drosophila, Rac1 could regulate forgetting of short-term memory. We speculate the activation of Rac1 in AD may mediate abnormal forgetting that is the reason of why memory loss. Here, we first detected the changes of activation of Rac1 in AD fly and mice model as well as lysis from AD patient’s hippocampus. Significant higher level of Rac1-GTP were observed as previous studies. Then we manipulated Rac1 activity by pharmaceutical and genetic approaches in AD fly and mice model and found the defect of memory and synaptic plasticity could be ameliorated. Furthermore, according the study from

Wang (2012), Aβ42 may initiate EGFR/PI3K/Akt axis which is upstream of Rac1 to exert its pathological function. We found Gefitinib, an inhibitor of EGFR, could rescue synaptic defect *in vitro* and memory loss *in vivo*. Finally, to explain the forgetting is accelerated in AD, we detected spatial working memory in AD models and found more rapid memory decay after couple of minutes in mice model compared with control. Together, we found Aβ42 could accelerate forgetting by evoking Rac1 through EGFR pathway and impair LTP maintenance. We provide a new angle to study the pathological mechanism of AD, and inhibition of forgetting via Rac1 may be a new therapeutic intervention in AD treatment.

Title: Modeling calcium signaling in human induced neurons from Alzheimer's and non-Alzheimer's patients

Authors: *R. A. MARR, C. BRIGGS, J. MCDAID, M. HOSHIZAKI, V. BOTTERO, G. E. STUTZMANN;
Neurosci., Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: New methods for modeling Alzheimer’s disease (AD) are needed as the limitations of current animal models have become apparent. The advent of induced pluripotent stem cell (iPSC) technology has provided the opportunity to develop cell culture models for the study of disease. Furthermore, the ability to re-differentiate these iPSC into neurons allows for the study of neurodegenerative disease mechanisms and potential therapeutics in human neurons. We have derived iPSC from patient’s fibroblasts that carry familial AD mutations in the presenillin-1 (PS1) gene or are wild-type for PS1. In previous work our group has described the early effects of PS1 mutations on calcium homeostasis in pyramidal neurons from transgenic AD mouse models, demonstrating exaggerated ryanodine receptor (RyR) calcium signaling that is linked to a host of AD features, including amyloid and tau pathology, synaptic signaling and plasticity deficits, and increased expression of the RyR2 isoform. In this study, we have set out to describe this process in human induced neurons (iN) derived from patient iPSC using neurogenin-2 (Ngn-2) gene transfer to drive the reprogramming into iN. Using whole cell patch clamp recordings

from iN 2-3 weeks in culture, we have detailed the properties of sodium and potassium currents, action potentials, and spontaneous EPSCs typical of mature neurons. Additionally, calcium responses generated by VGCC entry via depolarizing current injection, or from ER sources by applying the RyR agonist, caffeine (10 or 20 mM), were detected using the fluorescent probe bis-fura-2 and 2-photon microscopy. In further studies the iN system will be used to evaluate calcium signaling in human AD derived cells and to develop a screening tool for novel therapeutics aimed at normalizing aberrant calcium signaling.

Title: Amyloid-beta-mediated disruption of calcium signaling in Alzheimer’s disease and its role in neuronal cell cycle re-entry

Authors: E. J. KODIS, *G. S. BLOOM;
Univ. of Virginia, Charlottesville, VA

Abstract: Alzheimer’s disease (AD) is a devastating neurological disorder characterized by progressive memory loss and cognitive decline. Histopathologically, AD is characterized by two types of protein aggregates in brain, amyloid-β (Aβ) plaques and tau-containing neurofibrillary tangles, as well as by massive synaptic loss and neuron death. Aβ peptides act upstream of tau in AD pathogenesis, and it has been demonstrated that Aβ interacts with multiple proteins at the cell surface. In particular, Aβ oligomers (AβOs) have been shown to bind the N-methyl-D-aspartate (NMDA) receptor. Neurons in adult brain are normally in a permanently post-mitotic state, but in AD they exhibit ectopic cell cycle re-entry (CCR), which leads to their eventual

death. Our lab has previously demonstrated that neuronal CCR is initiated by AβOs and requires tau. When primary neuron cultures are treated with AβOs, they progress through G1, as evidenced by expression of nuclear cyclin D1, and into S-phase, as indicated by BrdU incorporation into nuclear DNA, but not when tau expression is prevented (Seward, et al. J Cell Sci 126: 1278-1276). Many other labs have demonstrated AβO-stimulated calcium influx through the NMDA receptor and resultant excitotoxicity, prompting us to investigate a possible role for an AβO-stimulated calcium rise in neuronal CCR. We now report that exposing AβO-treated neurons to BAPTA-AM to chelate intracellular calcium or to MK-801 to block calcium influx specifically through the NMDA receptor prevents CCR. In addition, we show that CaMKII, a calcium-dependent protein kinase that must phosphorylate tau at S416 for AβO-induced neuronal CCR to occur (Seward, et al. J Cell Sci 126: 1278-1276), is activated within 15 minutes of AβO treatment, and that this increase in CaMKII activity, as well as CCR, are inhibited by MK-801 or knockdown of the NMDA receptor subunit, NR1. Together, these results indicate that excess calcium influx via the NMDA receptor is an essential early step in AβO-induced neuronal CCR. Furthermore, the collective data imply that this specific type of calcium dysregulation triggers the two cell biological responses that together account for the behavioral deficits in AD: neuron death (via CCR), and synaptic dysfunction and loss.

Title: Functional connectivity differences across Parkinson disease subtypes

Authors: *M. C. CAMPBELL[1], C. GRATTON[2], J. KOLLER[2], W. SHANNON[3], C. LESSOV-SCHLAGGAR[2], S. PETERSEN[2], J. PERLMUTTER[2];
[1]Neurol., Washington Univ. Sch. of Med., Saint Louis, MO; [2]Washington Univ. Sch. of Med., St. Louis, MO; [3]Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: **Introduction:** Phenotypic variability in Parkinson disease (PD) may represent distinct subtypes with unique patterns of neuropathology. Therefore, the goal of this project was to 1) identify putative PD clinical subtypes and 2) investigate resting-state functional connectivity differences between these PD subtypes.
Methods: Latent class analyses, controlling for age, sex, and education, identified PD subtypes based on the pattern of motor, cognitive, and psychiatric features from 152 non-demented PD participants. Advanced graph-based object-oriented data analyses compared resting-state functional connectivity data from the entire connectome between 95 PD and 40 age-matched controls as well as across PD subtypes.
Results: The latent class model identified three distinct clinical subtypes: 1) "mild motor/tremor" - prominent tremor with normal cognition and psychiatric function; 2) "psychiatric" - elevated psychiatric symptoms, with intermediate motor deficits and normal cognition; 3) "motor & cognition" - prominent postural instability and gait difficulty, impaired cognition, but normal psychiatric function. Functional connectivity connectomes significantly differed between the control group and both the "mild motor/tremor" ($p = .04$) and "motor & cognition" ($p < .01$) PD subtypes. Importantly, functional connectivity also significantly differed between the "mild/tremor" and "motor & cognition" PD subtypes ($p = .05$), with qualitative intranetwork and internetwork connectivity differences involving the sensorimotor, subcortical, and cerebellar subnetworks.
Conclusions: Study results emphasize the importance and contribution of cognitive and psychiatric features to the overall pattern of phenotypic variability in PD and demonstrate functional connectivity differences related to these subtypes. Identification of PD subtypes and associated biological mechanisms could facilitate more personalized medicine approaches by improving patient stratification for triaging into different treatment strategies.

Title: Improving connectome based classification of parkinson's disease

Authors: *M. HARRISON, G. PRASAD, A. RAGOTHAMAN, P. THOMPSON;
Mark and Mary Neuroimaging and Informatics Inst., USC Imaging Genet. Ctr., Marina Del Rey, CA

Abstract: Parkinson's disease (PD) is a neurodegenerative disorder that targets dopaminergic hubs in the brain. Data-driven methods are currently being applied to map typical patterns associated with PD and its progression. In our study, we used 3 classifiers to identify features of brain connectivity that best distinguished a group of PD patients from healthy age and sex-matched controls. We also tested if we could improve classification using a reduced dimension (RD) connectome created based on a meta-analysis of PD. 153 participants (49 controls, 104 PD) were studied from the Parkinson's Progression Markers Initiative. Each participant's brain was scanned with structural T1-weighted and diffusion MRI, and processed using FreeSurfer to compute a cortical parcellation and Camino using probabilistic streamline tractography. We studied 6 networks. The first contained 68 cortical regions from FreeSurfer's Desikan-Killiany atlas (standard atlas). The remaining 5 contained {100, 200...500} equally sized random regions, computed using the k-means clustering algorithm on the vertices of the cortical mesh computed by FreeSurfer. Each of the 6 parcellations of the cortex was combined with tractography fibers to compute connectivity networks mapping the level of connectivity from the number of detected fibers that pass between regions.To compute a RD of each network, we restricted the cortical regions in each network to overlap regions implicated in a meta-analysis of PD (Shao et al. 2015; see Fig. 1). Full and simplified connectomes were analyzed using a linear support vector machine, linear discriminant, & logistic regression algorithms.The best classification balanced-accuracy assessed with 10-fold cross-validation was achieved using Linear-SVM for both full and reduced connectomes based on 100 regions (100-full 54.3% vs 100-rd 62.1%) with both performing better than chance (single-sign and binomial test $p<0.001$).The RD connectome

increased classification performance by around 8% compared to the full connectome, perhaps by emphasizing components and connections important to PD.

Title: Anatomical evidence for functional diversity in the human mesencephalic locomotor region

Authors: *S. B. SÉBILLE[1,2], H. BELAID[1,3], A.-C. PHILIPPE[1,2], B. LAU[1], C. FRANÇOIS[1], C. KARACHI[1,3], E. BARDINET[1,2];

Abstract: The lateral mesencephalon of the brainstem contains within its reticular formation the mesencephalic locomotor region (MLR), which is composed of two open nuclei: the pedunculopontine (PPN) and the cuneiform nuclei (CN). The MLR is important for a variety of functions in vertebrates, including locomotor control, sleep, attention, and even motivation. We used a diffusion weighted imaging-based method to understand how the MLR relates to these diverse functions in human. We sought to identify specific connections between the PPN and the CN and the basal ganglia, thalamus and cortex, examining the sensorimotor, associative and limbic parts of these different structures.
We used data from 30 healthy volunteers from the Human Connectome Project, running constrained spherical deconvolution to obtain probabilistic tractographies in a subject-specific native space from every voxel within the PPN or CN seed masks to the following target masks: basal ganglia (substantia nigra, ventral tegmental area, internal and external pallidum, striatum, subthalamic nucleus), centre-median-parafascicular thalamic nuclei, and cortex. We selected only fibers extremities ending in the target regions, and counted the number of extremities stopping in each target voxel to obtain a connectivity map. We thresholded the maps and binarized them to reduce false negatives.
We found that both the PPN and CN project to the basal ganglia and to the thalamus in a topographically organized manner. The most likely connections of the PPN were with the sensorimotor territories of these nuclei, whereas the least likely were with the associative and limbic territories. In contrast, the number of connections of the CN with the basal ganglia and thalamus was lower, and mainly concerned their limbic territories. Regarding cortical connectivity, the motor cortex had direct connections with the PPN and fewer with the CN. Weak connections were also observed between the limbic and insular cortices and the PPN and CN.
Our results suggest that the PPN and the CN belong to two different anatomo-functional networks, the PPN integrating mainly motor but also cognitive and emotional information whereas the CN is predominantly connected to limbic structures. These anatomical findings support the idea that the MLR in human may play an integrative and complex role beyond generating locomotor patterns.

Title: Alterations of regional cortical thickness associated with Parkinson's disease and essential tremor

Authors: *J.-R. DUANN[1], C.-M. CHEN[2], M.-K. LU[1], C.-H. TSAI[1];
[1]China Med. Univ., Taichung, Taiwan; [2]China Med. Univ. Hosp., Taichung, Taiwan

Abstract: Introduction: Previous neuroimaging work has used voxel-based morphometry (VBM) to find the structural differences caused by various neurological diseases. However, VBM-based methods rely on the image intensity changes only be partially related to the alterations in regional brain volume or cortical thickness. Here, we used the FreeSurfer-based analysis to extract the cortical thickness during the parcellation process of inflating a brain for statistical comparison between different subject groups. Methods: Thirty-six subjects, 12 for each of the healthy control (HC), Parkinson's disease (PD), and essential tremor (ET) subject groups, participated in this study. Each participant underwent a high-resolution structural MR brain imaging scan using 3D SPGR pulse sequence on a 3T MR scanner at China Medical University Hospital. The structural MR images were then analyzed using FreeSurfer (http://freesurfer.net) and the results of auto-segmentation and parcellation were used to extract the parameters of cortical thickness of various brain areas. Then, the FreeSurfer subroutine, 'qdec', was used to normalize the structural parameters using a surface-based method and regress the parameters against the of subject group, age, gender, etc., using a general linear model. The significance level was $p<0.005$ for the statistical analysis. Results: The brain areas with significant differences in cortical thickness were assessed using three different contrasts (HC vs. PD, HC vs. ET, and PD vs. ET). For HC vs. PD, PD patients manifested cortical thinning in the left middle temporal and superior frontal, and the right superior temporal, supramarginal, pars orbitalis and precuneus and cortical thickening in the left supramarginal and right parahippocampus. For HC vs. ET, ET patients manifested cortical thinning in the left middle temporal and right insula and cortical thickening in the left superior frontal, supramarginal, and right inferior parietal and fusiform cortices. For PD vs. ET, only the cortical thickness of the left lateral occipital cortex was larger in the PD patients as compared to ET patients. However, the left postcentral and precentral, and the right precuneus, inferior temporal, middle temporal, and middle and superior frontal areas had a larger cortical thickness in the ET patients. Conclusion: Because PD is a neurodegenerative disease, most of the significant brain areas manifested

cortical thinning. On the other hand, the ET patients manifested cortical thickening in most of the brain regions with significant cortical thickness changes. Such findings may lend themselves a possible way to clinically differentiate PD from ET.

Title: Free-water diffusion mri and bold imaging in parkinson's disease patients tested off and on antiparkinsonian medication

Authors: *J. CHUNG[1], R. G. BURCIU[1], E. OFORI[1], P. SHUKLA[1], M. S. OKUN[2,4], C. W. HESS[2,4], D. E. VAILLANCOURT[1,2,3,4];
[1]Dept. of Applied Physiol. and Kinesiology, [2]Dept. of Neurol., [3]Dept. of Biomed. Engin., Univ. of Florida, Gainesville, FL; [4]Ctr. for Movement Disorders and Neurorestoration, Gainesville, FL

Abstract: Parkinson's disease (PD) is a progressive movement disorder, linked to a loss of dopaminergic neurons in the substantia nigra pars compacta and reduced dopamine in the striatum. Recently, two promising non-invasive biomarkers have been established for progression in PD over a 1-year period of time. The first is free-water diffusion magnetic resonance imaging (dMRI) which identified a progressive increase in substantia nigra free-water over 1-year in PD, but not in a control group (Ofori et al. 2015; Brain). The second is task-based blood oxygen level dependent (BOLD) functional MRI (fMRI) which identified a reduction of contralateral and ipsilateral putamen and contralateral primary motor cortex over 1-year in PD, but not in a control group (Burciu et al. 2016; Neurology). It remains to be determined if either of these progression biomarkers are affected by acute administration of dopaminergic medication such as levodopa. If these markers are influenced by acute levodopa administration, their overall impact as progression markers would be far less than if these measures were unaffected. In the current study we evaluated whether a single dose administration of antiparkinsonian medication is associated with changes in free-water in the substantia nigra and other basal ganglia structures, and evaluated the BOLD fMRI signal during a force task in the putamen and motor cortex. Nineteen PD underwent dMRI and task-based fMRI one day apart, OFF and ON medication. The order of testing was counter-balanced across subjects. In the OFF condition, PD patients were

tested following a 12-h withdrawal from antiparkinsonian medication, whereas in the ON condition, patients were tested approximately 45 minutes after having taken their usual dose of antiparkinsonian medication. For dMRI, we computed free-water and free-water corrected fractional anisotropy within the following region of interests (ROIs): caudate, putamen, substantia nigra, and subthalamic nucleus. For task based-fMRI, we used a motor control paradigm that requires PD to produce force with their more affected hand. Percent signal change during force was calculated in a priori ROIs: contralateral and ipsilateral putamen, contralateral primary motor cortex, contralateral supplementary motor area, and ipsilateral superior cerebellum. Results showed no significant differences in dMRI and fMRI measures between the OFF and ON conditions. These findings suggest that acute, single dose administration of antiparkinsonian medication in PD has no effect on the free-water dMRI and task-related fMRI BOLD signal in key structures that have been previously shown to be potential progression biomarkers of PD.

Title: Parkinson’s disease and insula: a vbm analysis

Authors: *P. DMITRIEV[1], H. HUANG[1], C. PRICE[2], M. DING[1];
[1]J. Crayton Pruitt Family Dept. of Biomed. Engin., Univ. of Florida, Gainesville, FL; [2]Dept. of Clin. and Hlth. Psychology, Univ. of Florida, Gaineville, FL

Abstract: Parkinson’s Disease (PD) is a debilitating neurodegenerative disorder. Basal ganglia is among the most affected brain regions. Recent work suggests a connection between PD pathology and insula. We further examined this problem by acquiring T1 images from PD patients (n=38) and normal controls (n=52). A voxel based morphometry (VBM) analysis revealed the following results. First, in normal controls, there was a significant volumetric asymmetry between the left and the right insula (R > L), in agreement with prior findings. Second, the asymmetry was diminished and not statistically significant in PD patients. Third, gray matter volume in the left insula was not significantly different between PD patients and

normal controls. Fourth, gray matter volume in the right insula was significantly smaller in PD patients than in normal controls. These results (1) lend support to the suggested connection between PD pathology and insula and (2) demonstrate that the diminished asymmetry between left and right insula is due to atrophy of the right insula.

Abstract: The recent application of graph theory to brain network promises to shed light on complex diseases such as Parkinson's disease. The primary goal of this study was to investigate functional changes in sensorimotor and cognitive sub-networks in the patients with a focus on inter- and intra-connectivity organization in the disease-associated node and hub regions using the graph theoretical analyses. Resting-state functional MRI data of a total of 65 participants including 23 healthy controls and 42 patients were investigated in 120 nodes for local efficiency, between centrality, and degree. Hub regions were identified in each group. We found nodal and hub changes in patients compared with healthy controls including the right pre-supplementary motor area, left anterior insula, bilateral mid-insula, bilateral dorsolateral prefrontal cortex, and

right caudate nucleus. In general, within the sensorimotor network, key nodes (i.e. right pre-supplementary motor area and right mid-insula) displayed weakened connectivity, associated with more severe bradykinesia and impaired integration with default network regions. The left mid-insula lost as well its hub properties in patients. Within the executive cognitive sub-networks, the left anterior insular cortex lost its hub properties in the patients, while a new hub region was identified in the striatum (i.e. caudate nucleus) paralleled by an increased level of inter- and intra-connectivity in the bilateral dorsolateral prefrontal cortex possibly representing compensatory mechanisms. These findings highlight the diffuse changes in nodal organization and regional hub disruption, accounting for the distributed abnormalities across a large-scale brain network and clinical manifestations of Parkinson's disease.

Title: Intrinsic connectivity network activation during dual task performance in parkinson's disease patients with MCI

Authors: *B. JARRAHI[1], S. MCEWEN[1], L. HAWTHORNE[2], M. GOMEZ[2], B. FISHER[3], V. FILOTEO[4], G. PETZINGER[2];

Abstract: Mild cognitive impairment (MCI), particularly of the executive function subtype, which includes working memory, attention and dual tasking (DT), is the earliest and most prominent cognitive deficit in Parkinson's disease (PD). While alteration in cortical-striatal connectivity is thought to underlie MCI, studies are ongoing to fully elucidate specific connectivity networks sub-serving EF including DT performance. In this pilot study, we used independent component analysis (ICA) to study the intrinsic connectivity network (ICN) activation induced by the performance of a dual task complex sequential motor and audio task in

eight patients with PD- MCI who underwent functional magnetic resonance imaging (fMRI). The fMRI activation paradigm consisted of two conditions presented in a block design. The single task condition consisted of a sequential key-pressing task performed with both hands. The dual task condition was identical to the single task condition, expect that the patients was presented with an auditory sound, and was required to make a finger response by indicating how many sounds they heard during the course of that block. Imaging data were acquired using a Siemens Trio 3T MRI. Both task conditions engaged ICN 24 (a cerebellar network), ICN 33 (a dorsal attention network), ICN 34 (containing superior parietal cortex), and ICN 39 (a bilateral motor network including mid-cingulate). However, only the dual task condition led to increased activation of ICN 35, indicative of engagement of the bilateral dorsolateral prefrontal cortex and presumably related to the increased complexity of the task. Future studies are expected to shed more light on how the participation of these networks are involved in the putative attempt by the dopamine-denervated brain to overcome the functional deficit of the cortical-striatal circuitry in PD and the impact of exercise in restoring this connectivity and improving cognitive (executive) function.

Title: Structural changes associated with falls in Parkinson’s disease

Authors: H. OTOMUNE[1,2], *M. MIHARA[3,1], H. FUJIMOTO[1], Y. KAJIYAMA[1], K. KONAKA[1], H. MOCHIZUKI[1];

Abstract: Objectives: Gait and balance disorders are one of the common clinical feature of Parkinson’s disease (PD) and falls in PD has big impact on patient’s activity of daily living and quality of life. Although several risk factors are known, it is still unclear which brain region would be associated with falls. Here, we investigated brain structural difference between PD patients with and without falls using voxel-based morphometry (VBM).
Methods: We recruited 52 PD patients (28 men and 24 women, age 71.6±8.5, Hoehn-Yahr (H-Y) 2.9±1.0) admitted to our hospital. In addition to background characteristics, we evaluated gait

and balance ability, motor symptom and cognitive function. As an imaging analysis, we obtained 3D T1WI using 3 Tesla MRI scanner (GE Healthcare). We performed VBM analysis using Statistical Parametric Mapping 8 (SPM8) and compared the gray matter volume of the patients with and without falls, including age, gender, H-Y stage, MDS-UPDRS part 3, and freezing severity as covariates.
Results: Among 52 patients, 24 patients had experienced falls. There was no significant difference in motor symptom and cognitive function between patients with and without falls. But H-Y stages and freezing severity of the patients with falls are significantly higher than those of without falls. VBM analysis controlling several confounding factors revealed that patients with falls showed a significant gray matter volume reduction in the right inferior parietal lobule (IPL; MNI coordinates: x=45, y=-63, z=33, $p_{FWE\text{-}corr}$=0.006 at cluster level) and right parahippocampal gyrus (PHG; MNI coordinates: x=21, y= -10, z=-29, $p_{FWE\text{-}corr}$=0.013 at cluster level).
Conclusions: Our findings suggested that IPL and PHG may be associated with falls in PD. Considering the previous findings that these regions contribute to process and integrate sensory information to establish spatial orientation and "bodyshema" to maintain postural balance, our findings suggested that these area might play an important role in preventing fall in PD.

Title: Effects of dopaminergic medication on resting-state functional connectivity in Parkinson's disease

Authors: *H. TOGO[1,3], J. ROKICKI[2], H. MATSUDA[2], N. HAGA[3], M. MURATA[4], T. HANAKAWA[1];

Ctr. of Neurol. and Psychiatry, Kodaira-Shi, Japan

Abstract: Parkinson's disease (PD) is a progressive neurodegenerative disorder, characterized primarily by motor symptoms. Recently, a number of studies have begun to show a resting-state functional magnetic resonance imaging (rsfMRI) may provide a useful biomarker to help diagnose and/or evaluate PD patients. First, rsfMRI is suitable for observing functional connectivity (FC), which likely reflect pathophysiology in PD. Second, rsfMRI has advantage over other functional imaging methods since it is task-free and thus is not confounded by differences in task performance across groups or individuals. However, dopaminergic treatment potentially influence FCs, and this may make the interpretation of FCs difficult in clinical routines for PD. Because medication-on state patients are easier to be studied in clinical settings, it would be ideal if rsfMRI methodology is available for evaluating PD patients on medication. Therefore, we collected rsfMRI from PD patients on medication along with age- and gender-matched healthy control subjects (HC), and examined how medication states influenced FCs in PD patients. We studied 40 patients with PD and 40 HC. RsfMRI (TR=2.5 s) were acquired for 10 min with eyes open (Siemens, MAGNETOM Verio 3.0T). We used FSL (FMRIB's Software Library) for fMRI data analysis. Preprocessing included motion correction, slice timing correction, and spatial smoothing (6-mm FWHM). Next we performed individual-level independent component analysis (ICA) and auto-removal of noise components. We performed group-level ICA by concatenating all the data, dual regression analysis and permutation testing to compare PD data against HC data. Levodopa equivalent dose (LED) was calculated and incorporated in the statistical analysis. We identified 43 components in the group-ICA. Two types of permutation testing were performed. First, we performed a group comparison, with controlling age and scores of a cognitive testing. We found greater FC in the intra-basal ganglia network in PD than HC, but failed to find reduction of FC in PD. Next, we tested for positive or negative correlation between LED and FC in PD patients. We detected positive correlation between basal ganglia FCs and LED. These results indicated that we should carefully interpret FCs in PD on medication, because it is likely that basal ganglia hyper-connectivity in PD at least partly resulted from dopaminergic medication rather than pathophysiology of PD. In conclusion, medication states should be carefully taken into account to interpret FCs in rsfMRI studies on PD.

Title: Altered limbic connectivity is associated with anxiety in Parkinson's Disease

Authors: *H. MORGAN[1], C. LEDBETTER[2], E. DISBROW[3];
[1]LSUHSC Shreveport Sch. of Med., Shreveport, LA; [2]Neurosurg., [3]Neurol., LSUHSC Shreveport, Shreveport, LA

Abstract: Anxiety is a common non-motor symptom of Parkinson's Disease (PD). Alterations in connectivity in limbic regions such as amygdala and insula have been reported in generalized anxiety, social anxiety and panic disorders. However it is unclear if these abnormalities are common to PD-related anxiety or how dopamine (DA) impacts these changes. We hypothesized that PD-related anxiety is associated with changes in connectivity in limbic regions that are altered by DA replacement therapy. A query was performed in the Parkinson's Progression Markers Initiative (PPMI) database (www.ppmi-info.org). Exclusion criteria included: missing State Trait Anxiety Inventory (STAI) or anatomical MRI, age <55, not right handed, or had abnormal anatomy. 11 control and 60 PD subjects were included, 20 de novo and 40 DA replacement (PD DAR). We also included 17 controls from our lab with similar image acquisition parameters (n=28 controls). Image preprocessing and analysis were performed in SPM 12b. First- and second-level analyses were done in CONN toolbox version 15, using seeds for insula, amygdala, anterior cingulate, and accumbens. ROI-to-ROI and Seed-to-Voxel maps were created and connectivity differences and correlations with STAI scores were calculated. There were no differences across groups for age, MOCA or State or Trait anxiety measures. The PD DAR group scored significantly higher (more depressed) than controls on the depression measure, and PD groups showed increased processing time compared to controls. Insula, anterior cingulate, and accumbens had decreased connectivity in the PD DAR group when compared with controls. No connectivity differences were seen between PD groups, nor between de novo PD and control groups. Significant negative correlations between STAI trait scores and connectivity were found in the PD DAR group for insula with bilateral frontal operculum and inferior frontal gyrus, as well as amygdala with right anterior superior temporal gyrus. No correlations were found between STAI scores and connectivity of seeds of interest for the de novo PD and control groups. In the PD DAR group decreased connectivity in limbic regions was associated with increased anxiety.

Title: Three-dimensional representation of the human mesencephalic locomotor region

Authors: *A.-S. ROLLAND[1], F. PÉREZ-GARCIA[1,2], A. COLLOMB-CLERC[1], M. SANTIN[1,2], B. LAU[1], C. FRANÇOIS[1], M.-L. WELTER[1], E. BARDINET[1,2], C. KARACHI[1,3]; [1]ICM, Paris, France; [2]Ctr. de Neuro-Imagerie de Recherche (CENIR), Paris, France; [3]Dept. de Neurochirurgie, AP-HP, Paris, France

Abstract: In advanced Parkinson's disease (PD), new symptoms resistant to dopamine replacement therapy appear, such as gait and balance disorders, which are responsible for high morbidity and increasing mortality. A correlation between the occurrence of those symptoms and the loss of cholinergic neurons in the pedunculopontine nucleus (PPN) of the mesencephalic locomotor region (MLR) has been shown (Karachi et al, 2010). Recently, deep brain stimulation (DBS) of the PPN has been proposed to alleviate falls and freezing of gait in such patients (Stefani et al, 2007), although blinded clinical evaluation often fails to demonstrate significant alleviation (Ferraye et al, 2010; Moro et al, 2010). One possible explanation is inaccurate placement of DBS electrodes, as the anatomical boundaries of the PPN are poorly defined. Our goal was to obtain a 3D representation of the human MLR, formed by the PPN and the adjacent cuneiform nucleus (CN), based on histology and MRI, which would help accurately target the PPN in individual patients. One postmortem human brainstem was used in this study. Ultra high-field 3 and 11.7 Tesla MRIs were performed to obtain anatomical T1- and T2*-weighted images. The brainstem was then cut in transverse 50 microns regularly interspaced sections that were processed using Luxol Fast blue and choline acetyltransferase (ChAT) immunohistochemistry in order to visualize myelin fibers and cholinergic neurons, respectively. Stained sections were scanned with a nanozoomer to obtain high-resolution digital images that were used to draw exact contours of structures of interest and identify marked cholinergic neurons. All the data were co-registered and a 3D representation was obtained (3D Slicer). The PPN does not have precise boundaries and is defined by the location of cholinergic neurons. Therefore, we represented these neurons using a density map. The highest ChAT neuronal density was observed anteriorly, along the dorsal border of the superior cerebellar peduncle. We also contoured the adjacent CN, located between the inferior colliculus and the PPN. The medial lemniscus, the medial longitudinal fascicule, the superior cerebellar peduncle and the central tegmental tract were drawn using the myelin staining. In this study, we obtained a 3D representation of the PPN and the CN in a

reconstructed human brainstem. A dedicated deformation strategy will allow viewing the MLR of each patient MRI.

Title: Novel 2D standard coordinate space for sensorimotor cortex validated with high-resolution 7T rs-fMRI functional connectivity

Authors: *M. BRUURMIJN, P. A. CORNELISSE, W. SCHELLEKENS, M. A. H. RAEMAEKERS, M. J. VANSTEENSEL, N. F. RAMSEY;
Univ. Med. Ctr. Utrecht, Utrecht, Netherlands

Abstract: Resting-state fMRI (rs-fMRI) can reveal the functional connectivity between brain regions by correlating the time series from several locations. For the primary sensorimotor cortices (M1/S1), homotopic connection between the left and right hemisphere has been described on the group level in terms of similarity in location of a seed and the location of maximum correlation with this seed in the contralateral hemisphere (Van den Heuvel et al., 2010). However, a detailed comparison of the complete ipsi- and contralateral correlation patterns is informative for the connectivity between left and right M1/S1 within subjects and on the group level.Here, we use a new method for normalising M1/S1 within and between subjects, to facilitate easy comparison and to overcome individual anatomical variation. We use this method for determining the similarity of the correlation patterns of the left and right M1/S1 within subjects, and the similarity of connectivity patterns over subjects.Eight healthy volunteers (all right-handed male, age 48 ± 12 yrs) were included in a 7T rs-fMRI experiment consisting of two runs of 15 minutes each (EPI, TR = 1600 ms, voxel size = 1.463 mm). In the offline analysis, the borders of M1 and S1 were extracted from a flat map parcellation. Three 10th-order polynomials were fitted through these borders: through the central sulcus, through the anterior border of the M1, and through the posterior border of S1. By interpolating these borders, the M1/S1 area was resliced into a 28 × 84 tiled mesh. Data was smoothed, detrended, filtered, standardised, and mapped to the new mesh.Connectivity patterns were obtained per subject by

selecting each tile as seed, and calculating correlations with all other tiles in the ipsi- and contralateral hemisphere. For each seed, the Fisher transformed correlations were averaged over subjects, and the similarity of ipsi- and contralateral matrices was calculated by Pearson correlation.Visual inspection showed that different seeds generated different correlation patterns, indicating seed-selectivity of patterns. In 84% of all seed points, the correlation between the ipsi and contralateral pattern was significant. The average correlation over all seeds was 0.73 ± 0.12.In conclusion, we show that the transformation to 2D standard coordinate space yields good results for cross-hemisphere functional connectivity based on rs-fMRI. Most tiles exhibited an excellent agreement between the correlation patterns in both hemispheres, as expected from previous studies. The method may prove useful in quantifying sensorimotor connectivity patterns between hemispheres for research and for identification of abnormal topography.

Title: Parkinson’s Disease 6-OHDA model characterization using pharmacological MRI and MR spectroscopy in rats.

Authors: A. SHATILLO, K. LEHTIMÄKI, *L. KOISTINEN, R. PUSSINEN, A. NURMI; Charles River Discovery, Kuopio, Finland

Abstract: Parkinson’s Disease (PD) is a disabling neurodegenerative disorder that affects seven to ten millions of people worldwide. It is characterized by chronic progression of motor and cognitive dysfunction resulting from the loss of dopaminergic neurons. These neurons are mainly located in substantia nigra and striatum - primary targets for pharmacological modeling of PD in laboratory species, using 6-hydroxydopamine (6-OHDA) or 1-methyl-4-phenyl-1,2,3,6-tetra-hydropyridine (MPTP). In this work, we present in-vivo characterization of 6-OHDA induced PD model utilized in our pre-clinical drug testing routines by means of blood oxygen level-dependent (BOLD) pharmacological MRI (phMRI) and proton magnetic resonance spectroscopy (1H-MRS) in rats. Known dopaminergic stimulant amphetamine was used as a challenge for phMRI experiments. Unilateral degeneration of dopaminergic neurons and dopamine depletion in striatum was induced by stereotaxic injection of 10 µg 6-OHDA to the right medial forebrain bundle (MFB). Four weeks later, structural imaging, phMRI and MRS were performed in 11.7T

small-animal MRI system. Rats were initially anesthetized with Isoflurane for femoral artery and vein cannulation for blood gases analysis and drug delivery. After the surgery, anesthesia was switched to 1.5 g/kg urethane and animals were transferred into MRI system. First, high-resolution anatomical images in sagittal and axial planes were acquired to confirm the lesion. MRS spectra were acquired separately for ipsi- and contralateral parts of striatum using 3 mm x 3 mm x 4 mm voxel. Lastly, phMRI was performed using spin-echo EPI with time resolution of 2 s and in-plane spatial resolution of 390x390 μm, 13 x 1.5 mm slices covering whole cerebrum. One-hour experiment consisted of 20 min baseline, amphetamine bolus (1 mg/kg i.v.) and 40 min follow-up imaging. Presented MRS data confirms effective disruption of neuronal metabolism in ipsilateral striatum manifested in significant ($p<0.05$) decrease of N-acetylaspartate, myo-inositol and choline compared to non-lesion side. Interestingly, this difference was not apparent in striatal BOLD phMRI signal change following amphetamine injection, but very distinct in cortical areas, suggesting effective interruption of normal cortico-striatal pathway function. Taken together our data emphasizes high utility of non-invasive translatable functional magnetic resonance imaging and spectroscopy for PD research. Altered 1H-MRS metabolites profile, disrupted functional connectivity and responses to dopaminergic stimulation revealed by phMRI can serve as relevant targets for drug-testing and efficacy studies.

Title: Pet imaging of tau pathology in progressive supranuclear palsy

Authors: *S. COAKELEY[1,2,3], S. CHO[1,2,3], Y. KOSHIMORI[1,2,3], P. RUSJAN[3], A. GRAFF-GUERRERO[3], R. CHEN[1,2], A. LANG[1,2], L. KALIA[1,2], E. SLOW[1], S. HOULE[3], A. STRAFELLA[1,2,3];
[1]Movement Disorder Unit, Univ. Hlth. Network, Toronto, ON, Canada; [2]Krembil Res. Institute, Univ. Hlth. Network, Toronto, ON, Canada; [3]Res. Imaging Centre, Ctr. For Addiction and Mental Hlth., Toronto, ON, Canada

Abstract: ***Objective:*** This study aimed to determine whether there is an increase in [^{18}F]-AV-1451 uptake in the brains of progressive supranuclear palsy (PSP) patients compared to Parkinson's disease patients (PD) and healthy controls (HC).
Background: PSP is a rare form of parkinsonism that differs neuropathologically from other parkinsonian disorders; however, there is often an overlap of clinical symptoms, especially in the early stages of PSP. While PD, Lewy body dementia, and multiple system atrophy are classified as synucleinopathies, PSP is a tauopathy due to the aggregation of pathological tau in the brain. [^{18}F]-AV-1451 (also known as [^{18}F]-T807) is a positron emission tomography (PET) radiotracer that binds to paired helical filaments (PHF) of tau in Alzheimer's disease (AD), as shown previously in clinical studies. We investigated whether [^{18}F]-AV-1451could be used as biomarker for the diagnosis and disease progression monitoring in PSP.
Methods: A total of 12 patients (6 PSP: age 72.2±6.77, 4 female; and 6 PD: age 63.7±9.61, 3 female) and 10 age-matched HC (age 65.9±9.93, 8 female) were recruited. An anatomical MRI and a 90-minute PET scan, using [^{18}F]-AV-1451, were acquired from all participants. The standardized uptake value ratio (SUVR) from 30 to 60 minutes post-injection was calculated in each region of interest (ROI) with the cerebellum, as well as the corpus callosum as reference regions. ROIs were selected based on cortical and subcortical brain regions previously reported to present with tau pathology in PSP. A nonparametric Kruskal–Wallis test was employed to check for differences in SUVR between the three groups.
Results: Differences in age and gender across groups were not significant. There were no significant increases of [^{18}F]-AV-1451 SUVR in PSP compared to PD and HC in any of the tested cortical and subcortical ROIs. These results were reliable when analyzed using the two different reference regions (i.e. cerebellum and corpus callosum).
Conclusions: No differences in SUVR could be detected in any of our PSP patients compared to controls. Any uptake in tracer could have been potential off target binding. Our preliminary results suggest that using SUVR on [^{18}F]-AV-1451 images may not be an appropriate marker for abnormal tau deposition in PSP.

Title: Dopaminergic modulation of cognitive control and brain activation during stop signal task performance in early stage Parkinson's disease

Authors: *P. MANZA[1,2], M. MASSON[1], G. SCHWARTZ[1], J. IDE[1], S. ZHANG[2], C.-S. R. LI[2], H.-C. LEUNG[1];
[1]Stony Brook Univ., Stony Brook, NY; [2]Yale Univ., New Haven, CT

Abstract: Parkinson's disease (PD) is a neurodegenerative disorder characterized by loss of striatal dopamine and aberrant functioning in fronto-striatal circuits. Individuals with PD often experience problems with cognitive control, the ability to flexibly regulate behavior in the face of distraction or surprise. However, the extent to which these deficits are related to loss of dopamine, or modulated by dopamine-replacement therapy, remains unclear. To address this issue, we collected functional magnetic resonance imaging (fMRI) data while individuals performed the Stop-Signal Task (SST), a common cognitive control paradigm. Sixteen individuals with early-stage PD (Hoehn & Yahr stage I and II, ages 51-79, all drug naïve or "off" dopamine-replacement therapy for >12 hours pre-study) and age/sex-matched healthy controls participated in the study. In order to examine how dopaminergic medication impacts cognitive control performance and brain function, a subset of the individuals with PD completed the experiment a second time "ON" dopamine-replacement therapy (medication taken < 4 hours pre-scan; order of "ON" and "OFF" medication sessions was counterbalanced across subjects). In addition to standard SST analysis, we applied a Bayesian computational model to the behavioral data to make trial-to-trial estimates of anticipation and prediction error. We found that stop-signal reaction time (SSRT), the main measure of cognitive control in the SST, was significantly longer in the PD group than in the control group, suggesting a cognitive control deficit. Dopamine-replacement therapy improved SSRT, although the ON medication group still showed longer SSRT than controls. Deficits were observed despite no significant differences in go reaction time between groups, indicating that the results were not due to general motor slowing. Compared to controls, individuals with PD also showed reduced brain activation on stop trials in several cortical and subcortical regions. Dopaminergic medication modulated activations in some of these brain regions, particularly in premotor and motor cortex. Finally, brain activations to unsigned prediction error in the dorsal anterior cingulate cortex seem to be reduced in the PD group compared to controls. These results suggest that individuals with PD show reduced brain activations during stop-signal task performance and impaired neural responses to error, which are critical for optimal cognitive control in healthy adults.

Title: Flexibility of behavior and thinking in Parkinson's disease

Authors: *H. M. NGUYEN[1], C. I. HIGGINSON[2], K. LANNI[3], E. A. DISBROW[4]; [1]Pharmacology, Toxicology, and Neurosci., Louisiana State Univ. Hlth. Sci. Ctr. Shreveport, Shreveport, LA; [2]Ctr. for the Prevention and Rehabil. of Brain Injury and Dis. - Loyola Clin. Centers, Loyola Univ., Baltimore, MD; [3]Valley Psychological Ctr., Roseville, CA; [4]Louisiana State Univ. Hlth. Sci. Ctr. in Shreveport, Shreveport, LA

Abstract: Parkinson's disease (PD) is a neurodegenerative disorder that results in motor as well as specific cognitive deficits. We hypothesized that people with PD would have decreased flexibility of behavior compared to controls. The Delis Kaplan Executive Functions System (DKEFS) Sorting Test is used to measure executive functions including concept formation and reasoning, initiation of problem solving skills, transference of sorting concepts into action, inhibition of previous sorting responses (flexibility of behavior), and inhibition of previous description responses (flexibility of thinking).Seventy-six medicated early stage PD and fifty-eight control participants ages 50-85 were assessed with the DKEF Card Sorting Test. PD and control groups were not different for age, gender, years of education, premorbid IQ or Mini-Mental State Exam score. They did show significantly poorer performance on motor and switching measures. Mean total UPDRS score was 37.65 (SD 19.96). A multivariate ANOVA revealed significant differences between groups in Set Loss Errors ($p = 0.03$) and Total Free Sort Repeated Descriptions ($p = 0.016$). There were no significant differences between groups in other functions measured by the DKEFS Card Sorting Test, including repeated sorts which measures flexibility of action. Thus PD subjects showed decreased flexibility of thinking, and superior performance on set loss errors, indicating increased adherence to task rules. PD subjects also showed normal flexibility of behavior. A regression showed that the Free Sort Repeated Descriptions Total was negatively correlated with performance on the Symbol Digit Modality Test (a processing speed measure) $\beta = -.336$, $t(134) = -3.121$, $p = .002$ and trail making (a measure of switching) $\beta = -.249$, $t(134) = -2.319$, $p = .022$, both of which were impaired in the PD group. Thus, contrary to expectation, flexibility of behavior was intact while flexibility of thinking was impaired.

Title: Internally guided lower limb movement recruits compensatory cerebellar activity in Parkinson's disease

Authors: *J. H. DRUCKER[1,4], K. SATHIAN[1,4], B. CROSSON[1,4,5,7], K. M. MCGREGOR[1,4], L. C. KRISHNAMURTHY[4,6], V. KRISHNAMURTHY[1,4], A. BOZZORG[4], D. M. CORCOS[8], S. L. WOLF[2,4], M. E. HACKNEY[4,3];

Sci., Univ. of Queensland, Brisbane, Australia; [8]Physical Therapy and Human Movement Sci., Northwestern Univ., Chicago, IL

Abstract: Externally guided (EG) and internally guided (IG) movements (analogous to "following" vs. "leading" in partnered dance) recruit two parallel neural circuits, in which cortical motor neurons interact with either the cerebellum or striatum via distinct thalamic nuclei. EG movements rely more heavily on the cerebello-thalamo-cortical circuit, whereas IG movements rely more on the striato-thalamo-cortical circuit (Lewis, et al., Neuroscience 2007; 147(1):224-35). Because Parkinson's disease (PD) involves striatal dysfunction, individuals with PD have particular difficulty generating IG movements (Wu et al., *Neuroimage* 2011; 55(1):204-15). We hypothesized that when performing IG lower limb movements, individuals with PD might employ a compensatory strategy favoring the cerebellum over the striatum. In the current study, 22 older adults with mild-moderate idiopathic PD (age *M*=68.6, *SD*=9.7; Hoehn & Yahr *M*=2.3, *SD*=0.6), while off anti-PD medications, and 19 age-matched controls without PD (age M=65.6, SD=9.7) performed EG and IG rhythmic foot tapping tasks, counterbalanced in a block design, functional magnetic resonance imaging (fMRI) paradigm. All participants tapped with their right foot. The external guidance was paced by an assistant tapping participants' ipsilateral 3rd metacarpal in a pattern with .5s to 1s intervals, while internal guidance was based on pre-scan training. Neural activation was compared between tasks (EG vs. IG) and groups (PD vs. non-PD). Both groups employed the cerebellar and striatal motor circuits described above, with the PD group demonstrating less activation in the striatum and motor cortex than the non-PD group. Additionally, a task (EG vs. IG) by group (PD vs. non-PD) interaction was observed in the cerebellum, supporting the hypothesized compensatory shift in which the

dysfunctional striatum is assisted by the less affected cerebellum to accomplish lower limb movement. These findings will contribute to future investigations into the neural mechanisms of effective rehabilitation.

Title: Striatal Nurr1 expression causes pathophysiological changes which mimic levodopa-induced dyskinesias.

Authors: *R. C. SELLNOW[1,2], E. FLORES-BARRERA[3], A. R. WEST[4], K. STEECE-COLLIER[1], M. J. BENSKEY[1], I. M. SANDOVAL[1], N. KUHN[1], K. Y. TSENG[3], F. P. MANFREDSSON[1,5];

Abstract: Levodopa (L-DOPA) induced dyskinesias (LIDs) are a debilitating side effect that occur in the majority of Parkinson's disease (PD) patients treated with L-DOPA. LIDs are involuntary motor behaviors that include chorea, dystonias, and limb hyperkinesia that are distinct from parkinsonian motor behaviors. Despite this, L-DOPA remains the gold-standard treatment for the motor symptoms in PD. It has been shown previously by our group and others that an ectopic induction of the transcription factor Nurr1 in striatal medium spiny neurons (MSN) is associated with LIDs. Preliminary data from our laboratory suggests that recombinant adeno-associated virus (rAAV)-mediated overexpression of Nurr1 exacerbates the severity of LIDs, while rAAV-mediated knockdown of Nurr1 attenuates LIDs, suggesting a role of Nurr1 in LID development. In order to better understand the role of Nurr1 in LIDs, we are currently

investigating the effects of Nurr1 activity on plasticity and corticostriatal transmission. The goal of these studies was to determine if Nurr1 expression in the striatum—a region where Nurr1 is not normally expressed—can change: 1) electrophysiological activity of the striatum, and/or 2) morphology of striatal MSNs. We unilaterally delivered rAAV-Nurr1 or rAAV-GFP to the 6-hydroxydopamine (6-OHDA) lesioned striatum of Sprague-Dawley rats. Animals were not chronically treated with L-DOPA and thus did not become dyskinetic. The evoked striatal local field potential (LFP) following cortical stimulation was measured following a single dose of L-DOPA. GFP-treated animals showed an inhibition of the corticostriatal LFP response to L-DOPA while Nurr1-treated animals showed a potentiation of the response. Notably, cortically-evoked LFP recorded in rAAV-Nurr1 rats were virtually identical to that in subjects with established dyskinesias. This suggests that ectopic Nurr1 expression induces pathophysiologic changes in corticostriatal transmission similar to those observed in L-DOPA induced dyskinetic animals. Ongoing studies are directed at expanding these electrophysiological findings, as well as examining whether Nurr1 upregulation in the absence of L-DOPA also induces the hallmark LID-associated morphological changes (e.g. dendritic spine morphology) previously reported by us and others. Preliminary data suggest that rAAV-Nurr1 treated, L-DOPA naïve, parkinsonian rats exhibit a reduction in MSN spine density. Taken together, our findings suggest that Nurr1 activity may be involved in the spine loss observed in direct pathway neurons concomitant with LID as well as the formation of atypical corticostriatal synaptic connections.

Title: Priming of L-DOPA-induced dyskinesia in a mouse model of PD with 6-hydroxydopamine lesion

Authors: *Y. DING, J. GARCIA, T. CHEUNG, N. JOSHI, T. C. MA, U. J. KANG;
Dept Neurol, Columbia Univ., New York, NY

Abstract: L-DOPA-induced dyskinesia (LID) has been modelled in mice by observing abnormal involuntary movements (AIM) resulting from L-DOPA treatment after 6-hydroxydopamine (6-OHDA) lesion of striatal dopaminergic projections (Lundblad et al., 2004). LID becomes more pronounced in PD patients with both disease progression and prolonged L-DOPA exposure. The static nature of 6-OHDA lesions of the dopaminergic system allows the independent assessment of the contributions of lesion severity vs. chronic exposure to L-DOPA to LID. Unilateral 6-OHDA lesion of the median forebrain bundle (MFB) in mice usually results in severe dopamine depletion and shows robust AIM following the first exposure to L-DOPA; however, further increases in AIM from subsequent doses are often achieved by incrementing the dose of L-DOPA. Clinical studies have noted that the onset of LID coincides with onset of antiparkinsonian effects, and the latency to onset shortens during long-term L-DOPA therapy (Nutt et al, 2010). Our study examines changes in the severity and time course of AIM from a repeated, constant dose of L-DOPA (3 mg/kg, IP), and correlates LID behavior with markers of neuronal activation. We found that the latency to the onset of LID shortens with repeated exposure to L-DOPA in a mouse model with 6-OHDA lesion of the MFB. These changes correlated with increased ERK activation in cholinergic interneurons (ChI) in the denervated striatum, though total ERK activation, mostly reflecting medium spiny neurons (MSN), was reduced by repeated L-DOPA. These findings confirm our previous observations in aphakia mice with bilateral striatal dopamine loss due to pitx3 mutation (Ding et al., 2011) in the 6-OHDA model. We conclude that LID priming similar to clinical observations can be modeled in mice with a repeated, constant dose of L-DOPA. Under this paradigm, the sensitization of striatal ChI to repeated L-DOPA correlates better with LID priming than this change in MSN, suggesting differential roles of ChI and MSN in mediating LID. Title: Development of L-DOPA-induced dyskinesias in a rat model is reduced by sub-anesthetic ketamine infusions

Authors: A. J. FLORES[1], M. J. BARTLETT[1], A. H. ZEHRI[1], K. L. PARENT[2], M. L. HEIEN[2], S. J. SHERMAN[1], *T. FALK[1];

Abstract: Ketamine is an FDA-approved drug with a known safety profile. Low-dose, sub-anesthetic ketamine infusions have been shown to be an effective therapy for depression, posttraumatic stress disorder (PTSD) symptoms, and chronic pain states. Ketamine is known to change oscillatory electric brain activity. Hypersynchronous electric activity in the brain, also seen in the basal ganglia, is shared between migraine headaches, depression, PTSD, Parkinson's disease (PD) and L-DOPA-induced dyskinesia (LID). Therefore, we have recently investigated the use of low-dose ketamine and have shown a long-term therapeutic effect (reduced dyskinesia, improved on time, and reduced depression) of low-dose ketamine infusion in 5 PD patients (Sherman SJ, et al., *Case Reports in Neurology* 2016; 8:53-58). We also evaluated ketamine's ability to reduce established LID in a pre-clinical model, where low-dose infusions of ketamine led to a long-term decrease of abnormal involuntary movements (AIMs) in a dose-dependent manner (Bartlett MJ, et al., *Neuroscience Letters* 2016; 612:121-125). We now extend these findings to an evaluation of low-dose ketamine's ability to suppress the development of LID. 20 microgram of 6-hydroxydopamine (6-OHDA) was injected unilaterally into the medial forebrain bundle (MFB) of male Sprague-Dawley rats to create a PD model. Rats (n = 9 per group) were then primed with escalating daily *i.p.* doses of L-DOPA (Days 0-13: 6 mg/kg; Days 14-28: 12 mg/kg). Rats were also given vehicle, 10 mg/kg *R*-ketamine, or 20 mg/kg racemic ketamine on days 0, 7, 14 and 21 in a series of injections over 10 hrs (5x *i.p.* injection, 2 hours apart; and co-injected with L-DOPA at the 5th injection). The AIMs were scored every 3 - 4 days to assess LID severity, and differences were evaluated with ANOVAs and Tukey post hoc tests. Here we show that throughout and after 28 days of L-DOPA-priming, PD rats treated once per week with low-dose racemic ketamine for 10 hrs had a 50% reduction in their total limb, oral and axial AIMs scores as compared to those treated with vehicle ($p<0.05$), indicating a potential early utility for low-dose ketamine to prevent development of severe LID. The *R*-ketamine-treated rats showed no reduction in their AIMs scores. After harvesting striatal and nigral tissue we will investigate striatal dopamine content with HPLC-EC, as well as changes in expression of cFos and key proteins in the mTOR / Erk1+2 / Akt pathways with semi-quantitative western analysis. This novel use of low-dose sub-anesthetic ketamine infusions could lead to rapid clinical translation, creating a novel treatment for depression and pain states, common comorbidities in PD, as well as a dual therapy for LID.

Title: Analysis of inflammatory mediators in a mouse model of L-DOPA induced dyskinesia

Authors: *G. D. ABREU[1], M. S. PEREIRA[2], L. A. DA COSTA[3], M. A. DA ROCHA[1], E. A. DEL BEL[1];
[1]Dept. of Morphology, Physiol. and Basic Pathology FORP, [2]Dept. of Physiol. FMRP, [3]Dept. of Neurol. FMRP, Univ. of Sao Paulo, Ribeirao Preto, Brazil

Abstract: One of the most common treatment for Parkinson's disease is long-term treatment with L-DOPA, which usually induces the onset of side effects as L-DOPA-induced dyskinesia (LID). LID is characterized by severe axial, limb, locomotor and orofacial abnormal involuntary movements (AIMs). Lesion plus chronic treatment with L-DOPA facilitates the arise of an inflammatory environment within the striatum. Our aim was to evaluate if there is a modulation of inflammatory mediators in hemiparkinsonian mice treated with L-DOPA. We performed the apomorphine rotational test and selected C57BL/6 mice with more than 4 contralateral rotations/minute to compose the experimental groups 6-hydroxydopamine (6-OHDA; n=8). To compose the L-DOPA group, mice with a 6-OHDA lesion received L-DOPA (25 mg/kg+Benserazide 10 mg/kg i.p.) for 21 days. Animals with more than 50% of maximum global AIMs scores were selected. L-DOPA induced the manifestation of intense AIMs during the 21 days of treatment, differently from 6-OHDA group (treatment: $F(1,14)=259,1$ $p<.05$). Treatment with L-DOPA significantly increased the number of COX-2-positive neurons in the lesioned striatum, rostral (side: $F(1,26)=3,851$ $p>.05$; treatment: $F(1,26)=4,818$ $p<.05$; interaction $F(1,26)=8,994$ $p<.05$), medial (side: $F(1,26)=18,47$ $p<.05$; treatment $F(1,26)=16,10$ $p<.05$; interaction $F(1,26)=15,82$ $p< .05$) and caudal (side: $F (1, 26)=26,83$ $p<.05$; treatment $F(1,26)=12,98$ $p<.05$; interaction $F(1,26)=12,88$ $p<.05$). Similarly, NF-ƙB was increased in animals treated with L-DOPA (student's t unpaired test: $t=3,510$ $df=6$; $p<.05$). To further understand the participation of glial cells in the inflammation, we quantified IBA-1 and GFAP positive cells in the striatum by immunohistochemistry. Our results showed in mice IBA-1 cells were not responsive to L-DOPA treatment into rostral (side: $F(1,26)=3,051$ $p>.05$; treatment: $F(1,26)=4,557$ $p< .05$; interaction: $F(1,26)=0,6375$ $p>.05$), medial (side: $F(1,26)=8,351$ $p<.05$;

treatment: F(1,26)=5,352 p<.05; interaction: F (1,26)=1,666 p>.05) and caudal striatum (side: F(1,26)=27,56 p<.05; treatment: F(1,26)=4,557 p<.05; interaction: F(1,26)=1,588 p>.05). There was a reduction of GFAP-positive cells into the striatum rostral (side: F(1,26)=40,42 p<.05; treatment: F (1,26)=6,582 p<.05; interaction: F(1,26)=3,763 p> .05) medial (side: F(1,26)=96,19 p<.05; treatment: F (1,26)=28,92 p<.05; interaction: F (1,26)=20,80 p<.05), and caudal (side: F(1,26)=49,69 p<.05; treatment: F (1, 26)=7,451 p<.05; interaction: F (1,26)=1,720 p>.05). Here, we suggest that in mice L-DOPA promotes the onset of inflammation independent of glial cells expression.

Abstract: Long-term administration of L-DOPA, the mainstay therapy for Parkinson's disease (PD) patients, is accompanied by the development of dyskinesia, a disabling motor complication that dramatically affects patients’ quality of life. L-DOPA-induced dyskinesias (LID) have consistently been related to abnormal dopaminergic transmission, with dysfunctions in down-stream signaling of the D_1 receptors as the most characterizing feature. Our group has recently demonstrated that the inhibition of 5α-reductase (5AR), the rate-limiting enzyme for neurosteroids synthesis, elicits marked anti-dopaminergic effects. We found that the 5AR inhibitor finasteride (FIN) normalized several behavioral alterations induced by the administration of dopaminergic agonists, through a negative post-synaptic modulation of D_1 receptor in the striatum. Since LID is closely related to abnormal striatal dopamine D_1 signaling, the aim of the present study was to investigate whether the pharmacological blockade of this

enzyme may impact on the development and expression of dyskinesia induced by both L-DOPA and SKF 82958, the full selective D_1 agonist. Adult male and female rats were monolaterally lesioned with 6-OHDA and subjected to chronic L-DOPA administration. First, we assessed the acute effect of different doses of FIN (15-60 mg/kg) on established dyskinesia, in male and female 6-OHDA-lesioned rats. Based on these results, we then evaluated the impact of chronic FIN treatment (30-60 mg/kg) on drug-naïve and L-DOPA-primed 6-OHDA-lesioned rats. In addition, to investigate whether the effects of FIN on LID may be ascribed to a modulation of D_1 receptors, dyskinesias were assessed in 6-OHDA-lesioned rats treated with SKF 82958 in combination with FIN. The results of the present study indicated that acute injections of FIN reduced LID in both male and female 6-OHDA-lesioned rats in a dose-dependent manner. Similar to the acute treatment, chronic FIN injections significantly dampened dyskinesia in both drug-naïve and L-DOPA-primed rats. Interestingly, FIN treatment was also able to counteract the expression of dyskinesia induced by SKF 82958 administration. To our knowledge, this is the first study that highlights a possible role of 5AR and its related neurosteroids in the pathophysiology of LID, and suggests FIN as a promising therapeutic agent for the treatment of dyskinesia. Furthermore, these results support recent clinical findings showing therapeutic properties of FIN in pathological conditions related to abnormal striatal dopamine transmission, such as Tourette Syndrome and impulse control disorders.

Title: Prophylactic effects of atypical anti-depressant Vilazodone on L-DOPA-induced dyskinesia and striatal gene expression

Authors: *A. TAYLOR, S. MEADOWS, N. CHAMBERS, Y. AVNOR, N. VILCEUS, L. GROSS, C. BISHOP;
Psychology, Binghamton Univ., Binghamton, NY

Abstract: The standard treatment for mid- to late-stage Parkinson’s disease (PD) is DA replacement therapy via L-DOPA. While initially effective at relieving parkinsonian motor

symptoms, chronic use leads to abnormal involuntary movements (AIMs), known as L-DOPA induced dyskinesia (LID). Previous research has also shown that repeated exposure to L-DOPA leads to an upregulation of striatal gene expression for preproenkephalin (PPE), preprotachykinin (PPT), preprodynorphin (PPD) and c-fos. In recent years, research has shown that pharmacological targeting of the serotonin 1A receptor (5-HT_{1A}R) or the serotonin transporter (SERT) can reduce LID, although to this point, clinical efficacy has been limited. Our laboratory recently identified the FDA-approved anti-depressant Vilazodone, a partial 5-HT_{1A}R agonist and a SERT inhibitor, as a potential novel therapeutic compound for LID management. The aim of this study was to determine the preventative effects of Vilazodone against behavioral manifestation of LID development and on upregulation of dyskinesia-related transcripts. Using a between-subjects design, adult rats received unilateral sham or 6-OHDA lesions and were administered daily injections of Vilazodone (0, 10, 20 mg/kg; s.c.) 5 minutes prior to L-DOPA (0 or 6 mg/kg; s.c.) for 22 days. AIMs and forepaw adjusting steps were recorded every 7 days to measure dyskinesia development and motor performance, respectively. Animals were sacrificed on treatment and striatal tissue was collected for analysis via real time-polymerase chain reaction (RT-PCR). Behavioral results revealed that when administered just before L-DOPA, Vilazodone prevented the development of LID in 6-OHDA lesioned rats, without interfering with L-DOPA's motor efficacy. RT-PCR results showed that Vilazodone treatment reduced expression of the dyskinesia-associated transcripts PPE, PPD and c-fos that are typically elevated with L-DOPA administration, suggesting key neurosubstrates underlying the behavioral effects. Thus, Vilazodone's unique ability to co-target 5-HT_{1A}R and SERT provides a promising strategy for preventing both the behavioral manifestations and signaling changes underlying LID.

Abstract: L-dopa-induced dyskinesia (LID) is one of the most common and frequently dose-limiting complications of pharmacologic therapy for Parkinson disease (PD). These typically choreiform movements, usually occurring at the time of peak levodopa effect, occur in 40% to 50% of patients after 5 years of therapy but have a reported incidence as high as 94% in a carefully conducted prospective study of patients under treatment for 15 years. Among the cellular alterations underlying LID, impairment of cortico-striatal synaptic plasticity is the main electrophysiological signature associated with the appearance of abnormal involuntary movements (AIMs). The rationale for testing Xenon in LID was based upon its NMDA receptor antagonistic properties an action similar to amantadine, the only one agent to date to effectively reduce LID. Here, we show that xenon (xenon-O2 50%/50%) reduces L-DOPA-induced abnormal involuntary movements (AIMs) in the 6-OHDA-lesioned rat and the MPTP monkey models of Parkinson's disease, with comparable efficacy than amantadine. LID are associated with an inability to depotentiate the L-DOPA-permitted long-term potentiation of the glutamatergic cortico-striatal synapses. Using acute cortico-striatal brain slices, we showed that xenon enables depotentiation of cortico-striatal synapses in dyskinetic mice, strongly grounding the mechanism of action

Title: MPTP (1-methyl-4-phenyl-1,2,3,6- tetrahydropyridine)-induced mouse model of Parkinson's disease - comparison of different dosing approaches.

Authors: J. PUOLIVÄLI, *R. O. PUSSINEN, J. KURKIPURO, T. HUHTALA, A. NURMI;
Charles River Discovery, Kuopio, Finland

Abstract: Parkinson's disease (PD) is a neurodegenerative disorder characterized by tremor, rigidity, slowness of movement, and difficulty with walking and gait. The main pathological feature of PD is the cell death of dopaminergic neurons located in the substantia nigra pars compacta (SNc). These dopaminergic neurons project to the striatum as well as to a number of other subcortical regions. MPTP (1-methyl-4-phenyl-1,2,3,6- tetrahydropyridine) is a neurotoxin that produces a parkinsonian syndrome in both humans and experimental animals. Systemic administration of MPTP to non-human primates and mice causes irreversible and selective loss of dopaminergic neurons in SNc, and depletion of striatal dopamine (DA) levels. DA plays an important role in the mediation of movement, cognition and emotion. Loss of DA-containing neurons in striatum, results in a loss of DA transporters (DAT) in the presynaptic nerve terminals and hence the reduction of DAT density is inversely correlated with the severity of motor dysfunction. The purpose of this study was to investigate the effects of different MPTP dosing approaches on dopaminergic brain functions in C57BL/6J male mice. MPTP was administered intraperitoneally (i.p.) or subcutaneously (s.c.) at different doses (16 - 20 mg/kg) two times a day with 3h-interval on two consecutive days. After 4-11 days of recovery mice were euthanized, and brains used for measurement of striatal DA levels by HPLC, analysis of SNc dopaminergic neurons by tyrosine hydroxylase (TH) immunohistochemistry, and striatal DAT using SPECT/CT with cocaine analogues such as b-CIT (123I). These results show s.c. MPTP dosing results in more profound striatal DA depletion compared i.p. MPTP treatment (94% vs. 77%). The decrease of DAT density in striatum was observed already 4 days after MPTP, and significant decrease was seen after 11 days.

Title: The impact of dopaminergic lesions on cognition; insights into non-motor parkinson's disease symptomology

Authors: E. HERNANDEZ, J. RAMOS, C. AVILA, L. C. GUTIERREZ, A. PEREZ, L. DE LA TORRE, *E. CASTANEDA;
Univ. of Texas at El Paso, El Paso, TX

Abstract: Although Parkinson's disease is currently classified as a motor disorder, a substantial portion of patients also displays cognitive deficits, symptoms that may present prior to motor impairment. Therefore, the aim of the present study was to identify the extent of dopamine depletion, in an animal model of Parkinson's disease, in which cognitive deficits manifest. To explore this, rats received bilateral intranigral infusions of the neurotoxin 6-hydroxydopamine, and animals were assigned into three different lesion groups: mild (30-69%), moderate (70-89%), and severe (>90%). Animals were assessed on their ability to learn a visual stimulus response task across 5 test days. Subsequently, rats were then shifted to a response-learning task for 4 days. After behavioral testing, post-mortem monoamine levels were assayed from the dorsal striatum, nucleus accumbens and medial prefrontal cortex. The results for visual association performance demonstrated that rats with mild lesions performed better than controls during day 3 of testing. In the response task, the data during the acquisition phase indicate that animals with mild lesions performed significantly worse than control animals, which was days 1-2 when improvement was steep. Current analyses aim to elucidate whether cognitive deficits exist in the ability of rats with compromised dopamine to shift strategies when they transition from the visual association to the response task. . Future work will examine additional cognitive abilities, such as the five choice serial reaction time task, to determine the breadth of cognitive disruption. Early detection of such cognitive impairments among Parkinson's patients may serve as an important diagnostic criterion during early onset of the disease.

Title: Evaluation of the effects an implant TiO2DA inserted in the caudate nucleus in hemiparkinsonism rat model induced on motor activity and its relationship to the levels of dopamine and serotonin

Authors: *D. DIAZ DIAZ[1], P. VERGARA ARAGON[1], J. J. SANTILLAN-CIGALES[1], A. MIRELES-MONZON[2], R. GONZALEZ TREJO[1], G. VALVERDE AGUILAR[3]; [1]PHYSIOLOGY, UNAM, CIUDAD DE MEXICO, Mexico; [2]PHISIOLOGY, UNAM, MEXICO, Mexico; [3]PHYSICAL, INSTITUTO POLITECNICO NACIONAL, CIUDAD DE MEXICO, Mexico

Abstract: *Introduction*. Parkinson's disease (PD) is characterized by typical motor symptoms (rigidity, tremor, postural inestability and bradykinesia) and non-motor symptoms: anxiety, depression, chronic fatigue and sleep disorders. Anxiety and depression in PD patients mainly associated with three neurotransmitters; dopamine, norepinephrine and serotonin.
Objective. Determine the effects of an implant TiO2DA inserted in the caudate nucleus in a rat model hemiparkinsonism induced on motor activity and its correlation with dopamine and serotonin levels.
Material and methods. Male Wistar rats (250-300 g) were used, which were randomly divided into 4 groups: a) control b) injury (Lx); c) Lx+implant (Lx+I); d) Implant (I). For 21 days post-injury motor activity was evaluated next tests: 1. The exploration behavior of rats was conducted into acrylic box, the test was recorded for five minutes, and were assessed global activity time, and inactivity time; 2. The rotational behavior was rated after subcutaneous administration of apomorphine (0.05 mg/kg), and was recorded for fifty minutes, through count of spins; 3. For the swimming forced test, was evaluated the activity and inactivity during 1 min in the fishbowl and test was recorded. In each group, determinations levels dopamine and 5-HT were performed, by means of HPLC.
Results. The exploratory behavior in the Lx group showed a decrement significative of activity exploratory regarding control group, for the other hand, Lx+I group enhanced the activity exploratory and movements in relationship to Lx group, showing similar behavior to the control group. The I group not showed significantly difference to control group. In the rotational behavior, the control group rats showed spins to the predominant side, Lx group increased the number of spins toward contralateral injury side with respect control group, Lx + I group revealed similar activity to control group and showed significant difference to Lx group. In the swimming force test the Lx + I group, increased significantly swimming behavior in relationship to Lx group. Implant group showed hyperactivity in swimming behavior.
Conclusions. Implant placement (TiO2DA) in rats hemiparkinsonian improved motor activity due to increased levels of DA in striatum and increased in the concentrations of 5HT in striatum, moreover correlating with improvement in the condition of adaptability. The results obtained in our model suggest that the TiO2DA implant in the caudate nucleus of rats induces a beneficial effect that can be attributed to the dopamine released from the TiO2DA complexes into caudate nucleus.

Abstract: Parkinson's disease (PD) is a complex disorder involving a myriad of symptoms including motor dysfunction, emotionality, and cognitive deficits. Although nigrostriatal dopaminergic loss is pronounced in PD, it is not the only region affected. Degeneration of the dorsal raphe nucleus (DRN) and the locus coeruleus (LC) is believed to contribute to the development of non-motor symptoms of PD which include depression, anxiety, and cognitive abnormalities. Non-motor symptoms greatly affect the quality of life of individuals with PD, highlighting the importance of identifying animal models that recapitulate both motor and non-motor aspects of the disease. Here, we have assessed the DJ-1 knockout (KO) rat to determine if it is effective in modeling PD symptomatology. Complete loss of the DJ-1 gene leads to an autosomal recessive early-onset familial form of PD. The DJ-1 protein itself is involved in many different functions such as maintenance of mitochondrial integrity. Our previous work has shown that DJ-1 KO animals begin to exhibit motor hyperactivity as early as 4 months of age and display cognitive deficits at 15 months compared to control wildtype (WT) rats. Preliminary stereological cell counts at 17 months revealed no dopaminergic neuronal loss in the substantia nigra pars compacta (SNpc), a strong trend for loss of serotonergic neurons in the DRN, and significant loss of noradrenergic neurons in the LC in DJ-1 KO rats. In the current study, we performed non-motor tests (novel object recognition, spontaneous alternation T-maze, forced swim test) at an early time point to determine if there are cognitive and emotionality changes prior to middle age. The DJ-1 KO animals, at approximately 4 months of age, displayed short term memory deficits in the spontaneous alternation T-maze test and cognitive deficits in the

novel object recognition task. In the forced swim test, DJ-1 KO rats exhibited an increase in immobility compared to WT animals, indicating increased behavioral despair. Animals were sacrificed at two time points (at 5 and 8 months of age) and stereological cell counts of monoaminergic neurons of the SNpc, DRN, and LC are ongoing to determine if degeneration occurs before 17 months. We are also performing high performance liquid chromatography on multiple brain regions to determine the concentration of dopamine and its metabolites. Mitochondrial dysfunction is being evaluated via a Seahorse analysis of mitochondria in the SNpc, DRN, LC, and striatum. These results to date highlight the utility of the DJ-1 KO rats for evaluation of non-motor symptoms and corresponding neurodegeneration as a prodromal model of PD.

Title: Sociosexual motivation deficits in the absence of olfactory dysfunction in the Pink1 -/- rat model of Parkinson disease

Authors: *H. N. MULHOLLAND[1], M. P. KURUP[1], K. M. YANG[2], M. R. CIUCCI[3]; [2]Neurosci. Training Program, [3]Communication Sci. and Disorders, [1]Univ. of Wisconsin-Madison, Madison, WI

Abstract: We have recently characterized behavioral phenotypes of Pink1 -/- rats in terms of gross and fine sensorimotor function, oromotor function, and vocalization. Previously, we found that vocalization deficits occur in the preclinical period (2-8 months) and progressively worsen over time. These deficits were accompanied by α-synuclein aggregation within the periaqueductal gray, which integrates vocal motor function with emotional states. The protocol to elicit these 50-kHz calls uses a sociosexual paradigm. As sexual dysfunction is a prominent

non-motor sign of Parkinson Disease (PD), the contribution of this dysfunction to communication interactions within this model is unknown. We hypothesized that the Pink1 -/- rat would show sexual dysfunction at an early age that would persist over time. 18 male Pink1 -/- animals and 12 age matched wild-type (WT) controls were assayed for sociosexual interest at 6, 8, and 10 months of age. Each animal was placed in the home cage with a sexually receptive estrous female for 5 minutes or up to 2 intromissions. The following variables were analyzed in order to obtain a composite sociosexual score: latency to mount, number of intromissions, number of mounts, time spent sniffing female, time spent in pursuit, and time spent in the same half of the cage. This assay's composite score are currently being validated and tested for reliability. As olfactory deficits could be a confounding factor in sexual interest, we also tested olfactory discrimination. Each animal was placed in the home cage for 2 minutes with three wooden balls, each one scented with either an unfamiliar female, unfamiliar male, or home cage scent. Time spent sniffing each ball was analyzed by blinded raters, and the discrimination index was calculated. We found that the Pink1 -/- animals had significantly increased latencies to mount and decreased composite sociosexual scores as compared to WT controls. Pink1 -/- animals also showed greater avoidance of the female compared to WT animals, spending a lower percentage of time in the same half of the cage. However, there were no significant differences in olfactory discrimination or time spent sniffing the female between WT and Pink1 -/- rats. This indicates that the animals' decreased interest in social or sexual interaction is likely not due to deficits in olfaction. This suggests that the Pink1 -/- rat experiences sexual dysfunction that may contribute to deficits in social communication. This is important to consider when assaying vocal sensorimotor control. This work contributes to our ongoing efforts to characterize the Pink1 -/- rat as a useful model for studying complex brain and behavioral relationships with regard to PD.

Title: Levodopa improves a subset of motor function associated with nigrostriatal deficits in a Pink1 -/- rat model of Parkinson disease

Authors: *C. A. KELM-NELSON, K. M. YANG, M. R. CIUCCI;
Dept. of Surgery, Div. of Otolaryngology, Univ. of Wisconsin Madison Dept. of Surgery, Madison, WI

Abstract: Hereditary Parkinson disease (PD) is linked to homozygous mutations in the *Pink1* gene and hypothesized to influence mitochondrial responses to cellular stress, implicated in proteinaceous inclusions, and may be linked to nigrostriatal dopamine depletion. Here, we use the genetic rat model of PD, *Pink1* -/-, to model early-onset PD behavioral deficits as well as characterize molecular dysfunction. Recent data show that at 8 months of age male *Pink1* -/- rats exhibit (A) early and progressive motor deficits as compared to wildtype (WT) controls, (B) a 50% reduction in tyrosine hydroxylase-positive cells in the substantia nigra, (C) no reduction in tyrosine hydroxylase density in the striatum, and (D) proteinase-K insoluble alpha-synuclein aggregations in the substantia nigra, but not the striatum. We hypothesize that motor deficits are linked to preliminary nigrostriatal cell dysfunction. In experiment 1, we used *Pink1* -/- (n=12) and WT (n=6) animals to investigate whether key genes involved in dopaminergic and cellular activity in the substantia nigra and striatum are dysregulated using real-time qPCR to analyze the relative expression of mRNAs encoding: tyrosine hydroxylase, dopamine beta hydroxylase, dopamine receptor 1 and 2, dopamine active transporter, catechol-O-methyltransferase, monoamine oxidase A and B, alpha-synuclein, ATPase type 13A2, and glutamate decarboxylase 1. We found a significant downregulation of dopamine receptor 1 and glutamate decarboxylase 1 in the substantia nigra suggesting a deficit in neuronal transmission. We also observe a trend for an upregulation in dopamine active transporter in the striatum of *Pink1* -/- animals compared to WT suggesting a possible mechanism of compensation for nigral cell loss. We did not see significant differences in other gene expression. In experiment 2, we treated *Pink1* -/- rats (n=8) with a therapeutic oral dose of levodopa, and subsequently analyzed motor skills. We found that levodopa significantly improved forelimb and hindlimb gait, but did not increase overall motor activity. There was also a trend for levodopa to decrease the time to traverse and number of foot faults on a challenge beam. We did not see improvement in fine motor patterns in paw grip on a ladder test, or in ultrasonic vocalizations measuring cranial sensorimotor dysfunction. These results suggest that pharmacological replacement with levodopa improves some, but not all motor deficits and consistent with our evolving hypothesis that differences in neural substrates and non-dopaminergic mechanisms may contribute to the early pathogenesis of motor behaviors in the *Pink1* -/- rat model of PD.

Abstract: The complex neuropathology underlying ingestive deficits of Parkinson Disease (PD) is poorly understood. One of the key regions that controls ingestive function, the dorsal motor nucleus of the vagus (DMV), is considered to be a critical trigger region in PD pathology, as it has been shown to incur pathological aggregation of alpha synuclein (a-syn) protein as well as high levels of cell death in the earliest stages of PD in human patients. Recent work has shown that the Pink1 knockout (-/-) rat model of PD shows early and progressive physiological deficits in ingestive behaviors, including oropharyngeal swallowing and defecation and pathological aggregation of a-syn in regions of interest controlling these behaviors, including the DMV. In this model, we analyzed optical density of the microglia marker OX-42 in the DMV and showed that contrary to our hypothesis, OX-42 was significantly decreased in ten month-old Pink1 -/- animals (n=12) compared to age-matched wild-type controls (n=12) (t 1, 23=, p<.01), despite co-occurring with a-syn aggregation that is known to trigger microgliosis. To further investigate this finding we performed immunohistochemistry for OX-42, GFAP, and IL-1B on brain tissue sections from the same rats. In the current work, we speculate that a decrease in OX-42 signal could occur via two mechanisms: 1.) a decrease in microglial cell number and 2.) a decrease in the amount and complexity of processes stemming from microglial cells. We hypothesize that 1). microglial cells in the DMV of Pink1-/- rats will show less immunoreactivity for the pro-inflammatory cytokine interleukin 1 beta (IL-1B) and 2).astroglial cells will show alterations to morphology (shorter and reduced number of processes) and a reduction in cell number similar to microglial cells. Microglial and astroglial cell counts as well as the proportion of microglial cells immunopositive for IL-1B will be quantified using the optical fractionator probe in Stereoinvestigator. Further, the average area occupied by glial cells will be quantified. Preliminary qualitative assessment in a subset of these data suggest that there is a reduction in

the number of glial cells in the DMV at 10 months of age in Pink1 -/- animals compared to wild-type controls; the full data set will be presented. These findings may contribute to our understanding of how PD pathology manifests in terms of alterations to glial structure and function and, thus, central nervous system immune and ingestive function.

Title: Immune effect in brain substantial nigra induced by endogenous neurotoxins on rat parkinson’s disease model

Authors: F. SUN, *Y. DENG, Z. CHEN, H. MA;
Beijing Inst. of Technol., Beijing, China

Abstract: Up to now Parkinson's disease (PD) still doesn’t have effectively therapeutic strategies. According to the pathogenesis of PD, a hypothesis are proposed that oxidative stress can lead to lipid peroxidation, produce reactive oxygen species (ROS) and a series of small molecule active aldehyde.Active aldehyde and dopamine (DA) can produce catechol tetrahydroisoquinolines (CTIQs) in the brain including salsolinol (Sal) and N-methylsalsolinol (NMSal), These CTIQs can be metabolized via N-methylation and oxidation to cytotoxic MPP+-like neurotoxins that in turn inhibit mitochondria Complex I which leads to decreasing ATP content in tissue and makes a vicious cycle that finally leads to neurodegeneration,meanwhile,regulatory T Cells (Treg), effector T cells (Teff) response operation and microglia selective activation in the immune system , which might play an important role in PD. In this study, we sought to determine the tolerance dose of endogenous neurotoxins on rat model and whether PD is associated with leukocyte infiltration and microglia activation within substantial nigra (SN) region affected by NMSal, if so, whether this process

contributes to dopaminergic neuron (DN) degeneration. We used adult male wistar rats to establish PD rat model via injecting concentration gradient of endogenous neurotoxin,NMSal(100nmol,250nmol,500nmol) or 6-Hydroxydopamine (6-OHDA) into right SN region by stereotaxic apparatus. At 2, 4, 8 weeks post-surgery, the rats were performed in motor behavior test and sacrificed later for other experiments.The results revealed that stereotaxic injection of endogenous neurotoxin or 6-OHDA decreased the density of tyrosine hydroxylase(TH) which is the specific mark of DN. The overall level of injury showed a dose trend of NMSal, interestingly, the injury induced by 100nmol NMSal was showed at 4, 8 week, which suggest that toxicity of NMSal was increased by cyclic hypothesis in vivo. The infiltration of leukocyte in brain was detected subsequently, and the results showed that T lymphocytes infiltrated the damaged brain area and there is dose effect in the level of infiltration, which increased with the NMSal dose. The activation of microglia was then detected by specificity mark, which indicated that microglia are activated in the injured area, and the activated level of microglia became higher with the aggravation of the injury,which might induce apoptosis in neuronal cells. This study mainly investigated the possible role of neural immune interactions in the pathogenesis of PD, and puts forward the possible research direction in the basic experiment and clinical application.

Title: The PLP-alphaSYN mouse model for multiple system atrophy as a drug screening tool

Authors: L. HÄRTNER[1], T. KEIL[1], M. KREUZER[2], E. M. FRITZ[1], G. WENNING[3], N. STEFANOVA[3], *T. FENZL[1];
[1]Univ. of Innsbruck, Innsbruck, Austria; [2]Emory Univ., Atlanta, GA; [3]Med. Univ. Innsbruck, Innsbruck, Austria

Abstract: Multiple System Atrophy (MSA) is a rapidly progressing, fatal neurodegenerative disease.
Clinical symptoms include parkinsonism, cerebellar ataxia, autonomic failure and sleep symptoms. Sleep related symptoms, such as rapid eye movement sleep behavior disorder (RBD), breathing disorders and restless legs syndrome are very common in MSA patients and precede MSA diagnosis. The PLP-αSYN mouse model for MSA is a very well established animal model that shows a strikingly similar behavioral phenotype. Novel findings of MSA-related sleep symptoms would further increase face validity. Additionally, longitudinal age- and disease-related differences in the EEG could be utilized to establish predictive validity for the first time in this animal model.
We performed chronic, longitudinal EEG recordings in freely behaving young MSA mice without MSA-like motor symptoms and in old MSA mice showing an extensive behavioral phenotype. The recordings were completed with age-matched young and old C57BL\6 N controls (BL6).
Young MSA animals showed increased rapid eye movement sleep (REMS) during the inactive period and increased spectral power of the EEG during wakefulness and REMS, compared with old MSA animals and BL6- controls. In addition, old MSA mice showed REMS without atonia (REM-A), a major symptom of RBD and MSA.
On the one hand our findings further increase face validity of the PLP-αSYN mouse model for MSA. On the other hand we could establish predictive validity for the first time: The finding of increased spectral power is in striking accordance to studies in humans with idiopathic REMS behavior disorder (RBD), which is a strong precursor of neurodegenerative diseases, such as MSA. Early treatment strategies could be tested in the PLP-αSYN model with novel drugs preventing symptoms such as shifts in spectral power or increased REMS. Additionally, late abatement strategies could be tested in the animal model with novel drugs which decrease REM-A.

Title: Investigating the influence of erythropoietin in a 6-OHDA mouse model of Parkinson's disease

Authors: *A. M. THOMPSON, S. P. HAYLEY;
Neurosci., Carleton Univ., Ottawa, ON, Canada

Abstract: Background: Parkinson's disease (PD) is a neurodegenerative disorder characterized by the loss of dopaminergic neurons in the substantia nigra. The motor symptoms of PD do not appear until the majority of dopaminergic neurons have been lost; as such, a clinically relevant toxin-based model of PD was selected to reflect the neuronal environment at the time of diagnosis. Trophic factors are a family of brain-nourishing proteins that support the growth and survival of neurons. Indeed, many trophic factors have demonstrated promise as both protective and potentially regenerative therapeutic options in models of stroke and spinal cord injury. More recently, trophic factors have been utilized in models of neurodegenerative disease, including PD. Erythropoietin (EPO) is a hematopoietic cytokine best known for its role in the development and differentiation of immature erythrocyte cells. More recent research has revealed a potential role for EPO and its receptor in the prevention of neuronal cell death. As such, it has become an attractive candidate for models of neurodegenerative disease. The current study sought to investigate the effects EPO in a unilateral 6-hydroxydopamine (6-OHDA) mouse model of PD. **Methods:** Male C57/Bl mice underwent stereotaxic surgery, during which they were administered either 15U or 20U of EPO directly into the left substantia nigra, followed by 12ug of 6-OHDA into the left striatum. Behavioural measures investigated gait and coordination and included the CatWalk and the Rotarod. Immunohistochemistry was performed on sections of the striatum and substantia nigra (TH and CD68). Stereological counts were performed to determine the number of TH-positive cells in the substantia nigra. **Results:** Striatal lesions were moderate overall, with a mean of approximately 40%. Ipsilateral cell counts revealed significant loss of TH-positive cells in the substantia nigra in all treatment groups when compared to the saline/saline control. Behavioural data revealed alterations in gait and coordination following 6-OHDA administration, and further suggested that EPO may be modulating this response. Immunohistochemical analysis revealed that EPO may be modulating the inflammatory response via the activation of microglia, and thus influencing the survival of neuronal cells. **Conclusion:** Central EPO administration influenced both the behavioural outcomes and cellular function in a toxin-based mouse model of PD.

Title: α-synuclein oligomer preparations induce neurodegeneration and cognitive decline: a novel model for Parkinson's disease

Authors: *P. GOETGHEBEUR, P. HOUSSET, N. FISCHER, Y. TERROIRE, S. COLIN, A. ALLOUCHE, V. KOZIEL, A. KÖPKE, T. PILLOT;
Synaging, Vandoeuvre les Nancy, France

Abstract: α-synuclein pathology is clearly linked to Parkinson's disease (PD) and related mild cognitive impairment and dementia, which happen early in the disease process. Drug discovery for PD needs translational in vitro and in vivo models that are recapitulating natural disease onset. Here, we report novel in vitro and in vivo models employing minute amounts of highly reproducible α-synuclein oligomer (aSO) or fibrillar (aSF) preparations.
We first evaluated the effect of aSO and aSF on primary mouse neurons. Both preparations induce dose-dependent increase in neurodegeneration over time, distinct from the effects of amyloid-β oligomers (AbO). Cell shrinkage and destruction of the entire neuronal network takes place within 72h. These effects are greater for aSO and on striatal neurons rather than for aSF and on hippocampal neurons. aSO-induced neurodegeneration was attenuated by brain-derived neurotrophic factor in a dose dependent fashion, providing a positive control for assays. aSO-induced neurodegeneration was also assessed in IPS cell-derived human neurons using neuron specific enolase as a specific readout for neuronal survival. The benefits of epigallocatechin gallate, as well as rescuing antibodies were successfully investigated in these assays.
Finally, we assessed the effect of a single striatal injection of minute aSO or aSF amounts in mice for the induction of behavioral changes: a profound deficit in the novel objet recognition test was observed from day 15 up to the maximum investigated time period of three months for aSO, indicating neurodegeneration in the perirhinal cortex. However, up to three months, no deficit in the pre-frontal cortex based Y-maze assay, or typical α-synuclein pathology could be detected. On the other hand, aSF induced clear α-synuclein pathology within a fortnight, but no detectable cognitive decline before three months.

Title: Exploring the role of HIF-1 as a facilitator of exercise-induced neuroplasticity in the MPTP mouse model of Parkinson's disease

Authors: *M. R. HALLIDAY, M. W. JAKOWEC, G. M. PETZINGER;
Dept. of Neurol., USC, Los Angeles, CA

Abstract: Dysregulation of hypoxia-inducible factor 1 (HIF-1) signaling pathways have been implicated in Parkinson’s disease (PD). Studies in animal models of PD have evaluated the efficacy of pharmacological stabilization of the oxygen-labile HIF-1α subunit, and have reported normalization of dopamine neurotransmission, protection of dopaminergic neurons, and improved motor performance. Apart from these studies, exercise has also been implicated in modulation of neurotransmission, altering synaptogenesis, and improving motor performance in animal models and patients with PD. Recent studies from our lab and others have shown that HIF-1α expression levels are increased in the brain after exercise. While the relationship between HIF-1 and exercise have not yet been fully elucidated, taken together, these findings suggest a potential interaction between the two. In this study we explore the role of HIF-1 as a critical regulatory element in cellular adaptation to increased metabolic demand imposed by aerobic exercise (treadmill running) and as a facilitator of experience-dependent neuroplasticity in the MPTP mouse model of PD. Here, we show that HIF-1α and several HIF-1 target genes controlling the regulation of energy metabolism, neurogenesis, and angiogenesis are upregulated within the striatum, a motor region that has been shown to be targeted by exercise-induced neuroplasticity, after intensive treadmill exercise.

Title: Investigating the effect of exendin (EX-4) on hyposmia and the piriform cortex in a novel rat model of early stage Parkinson's disease (ESPD).

Authors: *E. SCHUL, A. CONSTANTI, A. MERCER;
Pharmacol., UCL Sch. of Pharm., London, United Kingdom

Abstract: Parkinson's Disease (PD) is a progressive neurodegenerative disorder of which the underlying cause remains unknown; however, neuroinflammation has been hypothesized to be a key player. It is classically characterized by the loss of dopamine (DA) in the substantia nigra (SN) leading to motor symptoms; and early loss of noradrenaline (NA) has also been reported. In addition, Non-Motor symptoms (NMS), such as olfactory deficits, often precede the motor symptoms. Therefore, a novel toxin model mimicking the early stage of PD focusing on the loss of NA preceding DA loss was designed. The effects of a peptide drug exendin-4 (EX-4), approved for the treatment of type 2 diabetes mellitus (T2DM) and in clinical trial for Parkinson's disease, were investigated in the ESPD model.
Establishment of the novel rat ESPD model was carried out by confirming the presence of olfactory deficits as a NMS, measuring the levels of DA and NA synthesis, and identifying the presence of neuroinflammation. Male Wistar rats received a single intraperitoneal administration of N-2-chloroethyl-N-ethyl-2-bromobenzulamine (DSP-4) to induce the loss of NA, followed by the intrastriatal administration of 6-hydroxydopamine (6-OHDA) to induce the loss of DA.
An overall olfactory deficit was found in the ESPD model and interestingly, could be reversed by EX-4 treatment. Characterization of the cellular populations in the piriform cortex (PC) demonstrated an increase of neuroinflammation. This was indicated by the increase in glial fibrillary acidic protein (GFAP) and CD11b expression in astrocytes and microglia, respectively, using immunohistochemistry analysis in the ESPD model compared with the sham control. In addition, immunofluorescence analysis revealed the loss of the normally distinct PC lamination in the ESPD model when compared with the saline treated animals. Also, a nearly complete loss of glutamic acid decarboxylase-67-positive (GAD-67+) interneurones expressing parvalbumin (PV), calbindin (CB) and calretinin (CR) across all layers was observed in the ESPD model. A moderate loss was demonstrated in interneurones expressing cholestocystokinin (CCK) across all

layers. All observed changes, except for the loss of CCK+ interneurones, were improved by treatment with EX-4.
It is proposed that these cellular changes observed in the PC could potentially underlie the behavioural changes in olfaction observed in the novel ESPD model. More importantly, the findings from this study strongly support a role for EX-4 as a potential novel candidate for PD therapy in the future.

Title: DPI-289, a novel delta opioid agonist / mu opioid antagonist, has potential to provide an L-DOPA-sparing approach in Parkinson's disease.

Authors: T. H. JOHNSTON[1], *M. P. HILL[1], E. VERSI[2], S. H. FOX[1], B. E. REIDENBERG[3], J. M. BROTCHIE[1];
[1]Atuka Inc., Toronto, ON, Canada; [2]Eboo Paharmaceuticals Inc., Durham, NC; [3]Weill Cornell Med., New York, NY

Abstract: L-DOPA-induced dyskinesia (LID) remains a significant problem in the management of PD. A therapy that could enhance L-DOPA actions without exacerbating dyskinesia would allow L-DOPA reduction to be implemented as a means to avoid the impact of LID. In rodent and non-human primate (NHP) models of PD, delta opioid receptor agonists have anti-parkinsonian actions while mu opioid antagonists can reduce the expression of LID. DPI-289 is a novel, small molecule drug with a combination of delta opioid agonist and mu opioid antagonist (DAMA) actions. We hypothesised that the combined actions of a DAMA would provide an enhancement of L-DOPA actions that were not associated with increased L-DOPA-induced dyskinesia. Eight female cynomolgus macaques were rendered parkinsonian with MPTP. LID was established by repeated once daily L-DOPA therapy. The actions of DPI-289 (1-20mg/kg, p.o.) on motor activity, parkinsonism and dyskinesia, as monotherapy and in combination with L-DOPA were evaluated. For each animal, two doses of L-DOPA were defined, high and low (LDh and LDl) so as to provide either a maximal anti-parkinsonian benefit with dyskinesia or a threshold anti-parkinsonian benefit without dyskinesia. As monotherapy, DPI-289 (10 and

20mg/kg) had significant, though incomplete, anti-parkinsonian actions lasting approximately 4 h. These benefits were not associated with dyskinesia. Thus, DPI-289 (20 mg/kg) decreased parkinsonism by 19% and increased activity by 67% 0-6 h ($P<0.001$ and $P<0.05$ respectively, *cf.* vehicle treatment). In contrast, LDh alleviated parkinsonism, but this was accompanied by significant levels of dyskinesia. LDh provided a 50% reduction in parkinsonism over 0-6 h ($P<0.01$) and 151% increase in activity ($P<0.05$). The combination of DPI-289 (20 mg/kg) and LDl provided anti-parkinsonian benefits greater than LDl alone without eliciting any significant dyskinesia. Thus, the combination of LDl and DPI-289 reduced parkinsonism for up to 6 h ($p<0.01$ *cf.* vehicle alone), longer than either LDh, LDl or DPI-289 alone, with parkinsonism being reduced by 35% and activity increased by 90% (both $P<0.05$ *cf.* vehicle alone). Combination therapy resulted in no change in levels of dyskinesia compared to LDl alone. The actions of the L-DOPA/ DPI-289 combination were qualitatively distinct to those of high dose L-DOPA alone, being especially pronounced on postural and attentional deficits. No adverse effects of treatment were observed at any period during the study. In MPTP-lesioned NHPs, the novel DAMA compound DPI-289 provided an enhancement of L-DOPA actions that has potential to be translated into a therapeutically-useful L-DOPA-sparing strategy.

Title: Dopamine neurons of the substantia nigra, cultured from Parkin, but not Pink1 or DJ-1 KO mice show altered survival, mitochondrial oxidative phosphorylation and axonal growth.

Abstract: Many mutations in gene products such as Parkin, Pink1, DJ-1, LRRK2 and α-synuclein have been linked to familial forms of Parkinson's disease (PD). Although the consequences of these mutations, such as alteration in mitochondrial function and pathological protein aggregation, are only slowly starting to be better understood, little is known about the reasons why alterations in such ubiquitous cellular mechanisms lead to selective loss of restricted subsets of neurons, including substantia nigra (SNc) dopamine (DA) neurons. Recent work showed that one of the reasons underlying the high vulnerability of SNc DA neurons is their particularly high basal rate of mitochondrial oxidative phosphorylation (OXPHOS), which appears to be a consequence of their highly complex axonal arborization. Here we examined whether axonal growth and basal mitochondrial function are altered in postnatal SNc DA neurons cultured from Parkin, Pink1 or DJ-1 KO mice. We provide evidence for increased basal OXPHOS and reduced survival of SNc DA neurons with complex axonal arbors in Parkin KO DA neurons, with the remaining neurons, having a smaller axonal arborization, showing reduced vulnerability to MPP+, associated with reduced expression of the DA transporter. Finally, we provide evidence for an implication of glial cells in the reduced resilience of DA neurons. We found that Parkin KO glial cells showed an increased rate of glycolysis, with no changes in net ATP production, and a reduced rate of cell proliferation. Strikingly, culture of Parkin KO SNc DA neurons with WT astrocytes prevented the loss of neurons. Our data provide new insights into the complex relationship between mitochondrial function, axonal growth, glial cell function and genetic risk factors linked to PD.

Title: Differential vulnerability to a-synuclein pathology among neuronal subpopulations

Authors: *E. LUNA[1], D. RIDDLE[2], V. M. Y. LEE[2], K. C. LUK[2];
[1]Perelman Sch. of Med. At the Univ. of P, Philadelphia, PA; [2]Dept. of Pathology and Lab. Med., Perelman Sch. of Med. at the Univ. of Pennsylvania, Philadelphia, PA

Abstract: Parkinson's disease is typified by the intraneuronal accumulation of misfolded a-synuclein (a-syn) accompanied by the degeneration of specific neuronal populations. Studying how a-syn inclusions are linked to neuronal loss has proven to be challenging since few model systems reliably and concomitantly exhibit a-syn pathology and neurodegeneration. We have developed a model system for examining the neurotoxicity caused by a-syn pathology, using pre-formed a-syn fibrils (PFFs) to seed pathology in primary WT hippocampal cultures. Using this system, we aim to identify cellular degenerative pathway(s) induced by a-syn pathology and determine whether neuronal subpopulations differ in their responses to PFF treatment. We use immunocytochemistry for neuronal markers (NeuN, MAP2, and neurofilament light chain) to show that PFFs reproducibly lead to neuronal loss and toxicity in WT but not *Snca*-/- neurons, supporting that endogenous a-syn is necessary for pathology formation and toxicity. Furthermore, a fibrillar conformation, such as that found in PFFs, is necessary to induce pathology and cell death since treatment with monomeric a-syn did not elicit either phenotype. Both the amount of a-syn pathology formed and neuronal loss show a dose dependent relationship with PFF seeding concentration, suggesting that pathological burden correlates with the degree of neurodegeneration. In particular, we found that CA1 and CA3 hippocampal glutamatergic neurons expressing the transcription factor Math2 are especially vulnerable to PFF induced toxicity, whereas other neuronal subtypes are generally resistant, regardless of neurotransmitter type. Our ongoing experiments will determine the mechanisms of this vulnerability and resistance to pathology displayed by these specific subpopulations of neurons.

Abstract: [Objective] Parkinson's disease (PD) is a common neurodegenerative disorder caused by genetic and environmental factors, and characterized by degeneration of dopaminergic (DA) neurons in the substantia nigra. Molecular mechanisms underlying the loss of these neurons are still unknown. PARK2 is the most frequent autosomal recessive PD, caused by mutations of parkin, an E3 ubiquitin ligase. Induced pluripotent stem cells (iPSCs) derived from PARK2 patients have been established, and increased oxidative stress was observed in neurons differentiated from these iPSCs (Imaizumi Y et al., 2012). In this study, we established an in vitro disease modeling and compounds screening platform using DA neurons differentiated from PARK2 iPSCs to identify compounds neuroprotective of DA neurons. [Methods] We developed an efficient and robust differentiation protocol for generation of DA neurons from iPSC-derived neural stem cells. Using PARK2 iPSC-derived DA neurons, we performed a high-content imaging assay in a 96-well plate format. [Results] Primary screening with a set of 1,165 compounds of an existing drug library was completed, followed by a concentration-response follow-up study. We found compounds that exhibited potential neuroprotective effects on PARK2 iPSC-derived DA neurons. [Conclusion] We demonstrated the feasibility of the phenotypic screening using PARK2 iPSC-derived DA neurons, and found compounds that showed potential neuroprotective effects on PARK2 iPSC-derived DA neurons. These compounds may help to identify causes of the onset of PARK2 and potential new drugs and treatments for PD.

Title: Selective deletion of Vglut2 in dopamine neurons increases vulnerability of midbrain dopamine neurons to MPTP

Authors: *H. SHEN, R. M. MARINO, G. BI, K. CHEN, G. MADEO, P.-T. LEE, T.-P. SU, Z. XI, A. BONCI;
NIDA/IRP, Baltimore, MD

Abstract: Parkinson's disease (PD) is a neurodegenerative disorder caused by abnormal degeneration of dopaminergic neurons in the *substantia nigra pars compacta* (SNc). Recent studies suggest that a subpopulation of DA neurons in the midbrain co-expresses vesicular glutamate transport 2 (Vglut2) and co-releases glutamate and DA in the projection field - the striatum. Conditional knockout of Vglut2 gene (Vglut2-cKO) in DA neurons reduces DA neuron growth and survival in vitro cell cultures, suggesting that Vglut2 may be neuroprotective to midbrain DA neurons. However, it is unknown whether a reduction or loss of Vglut2 in DA neurons increases vulnerability or susceptibility of midbrain DA neurons to the neurotoxins MPTP. To test this hypothesis, we first used Vglut2-floxed mice crossed with DAT-cre mice to generate Vglut2-cKO in DA neurons ($Vglut2^{flox/flox;DAT\text{-}Cre}$). We then compared the neurotoxic effects of MPTP on midbrain DA neurons and locomotion between Vglut2-cKO mice and control mice. We found that: 1) Vglut2-cKO in DA neurons did not significantly alter basal levels of locomotion, midbrain TH-immunostaining and DA cell counting. However, Vglut2-cKO in DA neurons significantly attenuated striatal dopamine or glutamate response to methamphetamine and locomotor response to methamphetamine; 2) MPTP (18 mg/kg × 4 with 2-hr injection interval, s.c) caused more DA neuron death/loss in the SNc and VTA in Vglut2-cKO mice than in control mice; and 3) Vglut2-cKO in DA neurons also increased MPTP-induced locomotor impairment as assessed by Open-field locomotion, Rotarod performance, and Parallel Rod Activity. These findings suggest that selective deletion of Vglut2 in DA neurons significantly attenuates DA neuron functional response to the psychostimulant methamphetamine in vivo and increases susceptibility (toxicity) of midbrain DA neurons to the neurotoxins MPTP in mice. To further confirm this finding, we will use transgenic techniques to increase Vglut2 expression in midbrain DA neurons, and then determine whether increased Vglut2 expression in midbrain DA neurons will produce a neuroprotective effect against MPTP induced DA neuron death. These studies may increase our understanding regarding the factors that contribute to the vulnerability of DA neurons, and help facilitate the discovery of new targets for treatment of symptoms related to loss of DA neurons *(Supported by NIDA IRP).*

Abstract: Parkinson’s disease (PD) is one of common neurodegenerative disease such as Alzheimer’s disease and Huntington’s disease. PD is characterized by the loss of dopaminergic neurons in substantia nigra and subsequently impaired movement in elderly population. The minority of PD pathology (~10%) caused by genetic problem from PD related genes involving α-synuclein (α-syn) and PTEN induced kinase 1 (PINK1). We immortalized canine cells by transduction of myc oncogene which is driven by inducible Tet-on system. We designed bicistronic retroviral vector containing mutant genes of α-syn and PINK1 and generated immortalized canine somatic cells over-expressing double mutant genes (DLT3-SP). These cells didn’t show any defect before differentiation, whereas apoptosis in DLT3-SP cells were observed during differentiation of dopaminergic neuron. These results suggested that DLT3-SP cells were used as in vitro PD model to screen the therapeutic agent for PD as well as source to generate canine PD in vivo model by nuclear transfer. This work was carried out with the support of "Cooperative Research Program for Agriculture Science & Technology Development (Project No.PJ01179203)" Rural Development Administration, Republic of Korea.

Title: Inhibition of intraneuronal acidification causes the retraction of human A9/A10 dopaminergic neurites in culture.

Authors: A. ESSEX[1], E. BATCHELDER[1], J. EVANS[1], *O. COOPER[2];
[1]Phenovista Biosci., San Diego, CA; [2]People Biosci., Boston, MA

Abstract: The vacuolar type ATPase (V-ATPase) regulates intraneuronal acidity and the function of several organelles implicated in the cell biology of Parkinson's disease (PD). Bafilomycin A1 (BafA1) and concanamycin A (ConA) are molecules that inhibit V-ATPase. Both molecules prevent the acidification of lysosomes and cause Parkinson's disease (PD)-associated phenotypes in culture. Here we build upon these findings using purified human induced pluripotent stem cell (iPSC)-derived neurons that include a subpopulation of A9/A10 type dopaminergic (DA) neurons. High throughput, high content image analysis revealed that both ConA and BafA1 reduced the area of DA neurites (tyrosine hydroxylase immunoreactive) without DA neuronal loss. Furthermore the neuritic area and number of non-DA neurons (TH-) were unaffected by the low concentrations of ConA and BafA1. Concomitant with this degenerative neuronal response, RAB7+ puncta accumulated in human DA neurons. While the feedback mechanisms across endo-lysosomal pathways in vulnerable human neurons require further study, these data suggest a context for modeling aspects of PD pathobiology using human iPSC-derived neurons for drug discovery.

Title: Functional electrophysiological phenotyping of human iPSC-derived neurons grown on MEAs - a novel approach for *In vitro* disease modeling of neurodegenerative diseases

Authors: *B. M. BADER, K. JUEGELT, O. H.-U. SCHRÖDER;
NeuroProof GmbH, Rostock, Germany

Abstract: Today, numerous differentiation protocols exist for generating human induced pluripotent stem cell-derived (hiPSC) neuronal cultures. Noteworthy, more and more protocols reveal neurons with spontaneous electrical activity with different qualities however. Moreover, one of the most important concerns is their physiological relevance needed for disease modeling e.g. for Parkinson's disease. This question cannot be answered in general, but a lot of empirical data contribute to a more and more comprehensive picture. We aim to understand and compare the differences between multiple hiPSC neuronal cultures by comparing them to a well-known reference: the robust electrical functional activity patterns from primary murine neuronal cell cultures recorded with multiwell micro-electrode arrays (MEAs, Axion Biosystems, Inc.). As a result of their phenotypic receptor and neuron type composition, primary neuronal cell cultures show very specific and complex activity pattern after four weeks in vitro. This complexity results from a high level of organization e.g. synaptic connectivity of different neuronal types in network cultures. Using multi-parametric analysis of MEA data we generated a fingerprint for different primary cultures using hundreds of datasets and classified them correctly. Primary tissue cultures include frontal cortex, hippocampus, hypothalamus, midbrain/cortex and spinal cord. We cultured different commercially-available hiPSC neurons (e.g. from Axiogenesis or CDI) on MEAs and recorded their activity development for 4 weeks and also computed fingerprints at different developmental stages. We show that during in vitro development the hiPSC neurons change their phenotypic similarity profile when compared to the primary culture reference database. Moreover, these phenotypes can be changed by addition of growth factors such as GDNF which increases the similarity between human dopaminergic and ventral primary mouse midbrain neurons. Also, neurotoxins change the phenotype. We show that reduction of similarity to midbrain phenotype induced by dopaminergic neuron-specific toxins can be reversed by known neuroprotectants such as GDNF and BDNF. In conclusion, we provide a functional tool to characterize neuronal phenotypes from hiPSC neurons to adapt differentiation protocols to reach a more relevant phenotype, and to use the complete phenotype for disease-relevant in vitro modeling.

Title: Single cell longitudinal changes in golgi complex in a human neuron model of parkinson's disease and its prognostic value for degeneration

Authors: *A. RAVISANKAR[1,2], A. K. LEE[1,3], G. SKIBINSKI[1,3], S. FINKBEINER[1,4,5,6]; [1]Gladstone Inst. of Neurolog. Dis., The J.David Gladstone Institutes, UCSF, San Francisco, CA; [2]The Taube/Koret Ctr. for Neurodegenerative Dis., San Francisco, CA; [3]Taube/Koret Ctr. for Neurodegenerative Dis., San Francisco, CA; [4]Biomed. Sci. Grad. Program, [5]Neurol. and Physiol., [6]Grad. Program in Neurosci., Univ. of California, San Francisco, San Francisco, CA

Abstract: Parkinson's disease (PD) is the second most common neurodegenerative disease, affecting 7–10 million people worldwide. α-synuclein is a major component of Lewy bodies, which is one of the pathological hallmarks of this debilitating disease. Duplication and triplication mutations in *SNCA*, the gene that codes for α-Synuclein, is known to cause PD. Although α-synuclein has been linked to the disruption of Golgi homeostasis, its contribution to PD remains unclear.

Using human neurons differentiated from induced pluripotent stem cells (iPSCs) obtained from healthy individuals, we are investigating the effects of α-synuclein overexpression on the Golgi complex. We use robotic microscopy (RM) to longitudinally track live neurons over their complete life times. As we follow individual neurons, we have the dynamic range and sensitivity to capture cellular events that lead to occurrence of disease-associated phenotypes such as neuron survival and neurite arborization. Our method also provides sufficient resolution to identify dose-dependent effects of α-synuclein on cellular phenotypes, including Golgi complex morphology, which can be quantitatively measured and linked to the fate of the neuron. Using powerful statistical survival models, we can determine if morphological changes in the Golgi apparatus has prognostic significance in α-synuclein-associated neurodegeneration.

Characterizing the effects of α-synuclein expression on neuronal phenotypes is critical for understanding the mechanism of α-synuclein-associated neurodegeneration and for developing

therapeutic strategies for PD. (Supported by the Michael J Fox Foundation, NIH Common Fund and NINDS).

Abstract: Human embryonic stem (hES) cells hold promise in the fight against neurodegenerative diseases. Their ability to self-renew and differentiate into diverse neural lineages makes them attractive candidates for transplantation therapy. One of the most successful applications of stem cell therapy is transplantation of non-matched fetal brain tissue into patients with Parkinson's disease. In this scenario, the patient is given immunosuppressive drugs, such as FK506 or Cyclosporin A, to promote transplant acceptance. Although chronic immunosuppression is necessary to mitigate rejection of human tissue allografts, it has severe side-effects, including infections and malignancies. One alternative to immunosuppressive therapy is matching donor and recipient immune molecules. Arguably the most important of these are human leukocyte antigens (HLAs); in particular, HLA-A and HLA-B. We have established a pre-clinical platform to test the relative contribution(s) of HLA haplotypes to neural stem cell transplant tolerance. To that end, we have determined *how many degrees of freedom from a perfect HLA match are permissible without transplant rejection*. Due to substantial

differences between mouse and human immune systems, it has been difficult to translate these types of studies into the clinic. We have broken this barrier by using “humanized” mice, which allow us to replace the endogenous mouse immune system with human immune cells derived from human hematopoietic stem cells (hHSCs). To investigate the immunogenicity of human embryonic stem cell (hESC)-derived neuronal progenitors, we haplotyped and differentiated hESC lines and reconstituted NOD-scid-il2rγc (NSG) mice with hHSCs to perform HLA haplotype “mix and match” transplants in the right striatum. Remarkably, we find immune tolerance of neural stem cell transplants with only 50% match at the HLA-A locus; irrespective of the mismatch at HLA-B, -C, -DR, or DQ. In concert, we observe marked reduction in cellular apoptosis of transplanted neural progenitor cells. Taken together, our results demonstrate that humanized mice are an important pre-clinical tool to understand HLA-dependent immunogenicity of stem cell-derived transplants in the CNS.

Title: Nna1 and NnaD proteins promote mitochondrial fusion, implicating deranged mitochondrial dynamics as a basis for neuron cell death in purkinje cell degeneration mice

Authors: *A. R. LA SPADA[1], S. GILMORE-HALL[2], J. KUO[2], C. BENNETT[2], M. ELLISMAN[3], G. PERKINS[2];
[1]Sanford Consortium for Regenerative Medicine, MC0642, Univ. of California San Diego, LA Jolla, CA; [2]Univ. of California San Diego, La Jolla, CA; [3]Natl. Ctr. for Microscopy and Imaging Res., UCSD, La Jolla, CA

Abstract: The *purkinje cell degeneration* (*pcd)* mouse is a classic model of cerebellar and retinal degeneration, which arises due to recessive loss-of-function mutations in the *Nna1* gene. Nna1 is a highly conserved cytoplasmic carboxypeptidase, although its substrates and function remain

unclear. Loss of Nna1 or its *Drosophila* homolog, NnaD, yields neurological phenotypes in mice and flies. *pcd* mice exhibit ataxia resulting from a rapid loss of >99% of Purkinje cell neurons in the cerebellum. Retinal photoreceptors also degenerate in *pcd* mutant mice, and *pcd* mutant males are sterile. Disruption of *NnaD* in *Drosophila* leads to larval lethality and a droopy wing phenotype, which led us to uncover mitochondrial dysfunction as a central feature in NnaD loss-of-function disease pathogenesis. Further studies then indicated that mitochondrial dysfunction is a key contributing factor for disease onset and progression in *pcd* mice. To further elucidate the function of Nna proteins in mitochondria, we conducted a fly-based genetic screen of different mitochondrial processes and found that larval lethality of NnaD mutant flies could be modified by altering the dosage of genes encoding proteins that regulate mitochondrial dynamics. We found that inhibition of mitochondrial fission through loss-of-function of *drp1* suppressed larval lethality in $NnaD^{PL90}$ mutant flies. Electron microscopy analysis of $NnaD^{PL90}$ $drp1^{TM26}$ double mutant flies revealed that *drp1* dosage reduction mitigated the excessive mitochondrial fragmentation in *NnaD* flies. To determine the basis for Nna1 regulation of mitochondrial dynamics, we generated a mammalian cell culture model of *pcd* using genome editing technology to knock-out *Nna1* expression in retinal pigmented epithelial (RPE) cells. *Nna1Δ* cells displayed mitochondrial fragmentation and a reduction in mitochondrial membrane potential. Conversely, overexpression of wildtype Nna1, but not an enzymatically-dead Nna1 mutant, increased the tubular mitochondrial network, and protected these elongated mitochondria against mitochondrial stress-induced fragmentation. Our results thus reveal a novel and evolutionary conserved role for Nna1 and its homologs in promoting mitochondrial fusion, and suggest that the rapid, dramatic death of Purkinje cell neurons in *pcd* mice likely stems from a dysregulation of mitochondrial dynamics.

Abstract: Methamphetamine (MA), a psychostimulant, not only is abused worldwide but also gives rise to neurotoxicity in the hippocampus and striatum, resulting in cognitive impairments and hippocampal volume reduction. The cellular and molecular mechanisms associated with hippocampal impairments due to MA remain unknown. To investigate the differentially expressed genes and their regulatory mechanisms by MA, we performed large-scale transcriptome profiling using RNA-seq technology after acute and chronic MA administration in cynomolgus macaques, *Macaca fascicularis* that have been used biopharmaceutical studies. The functions and networks of analyzed differentially expressed genes (DEGs) were classified using GO analysis tool (DAVID) and IPA software. Some transcripts were verified by real-time RT-PCR (RT-qPCR). Based on the GO analysis, the genes associated with the regulation of ARF GTPase activity and vesicle localization were upregulated and the genes associated with cytoskeleton organization and phagocytosis were downregulated in acute MA compared to the control. The top network identified by IPA analysis using DEGs contained genes associated with cell-to-cell signaling and interaction, cellular function and maintenance, and molecular transport. On the other hand, the genes associated with the regulation of cell proliferation and angiogenesis were upregulated and the genes associated with synaptic transmission, the regulation of dendrite development and neuron differentiation and neuron adhesion were downregulated in chronic MA, showing that chronic treatment of MA may cause the impairment of neurogenesis in the hippocampus. In addition, the top network identified by IPA analysis using DEGs contained genes associated with cellular assembly and organization, cellular function and maintenance, and molecular transport. As a result of RT-qPCR, expression patterns of PFN2, ENO2, CHRD and BMP4 mRNAs were similar to the results from RNA-seq. Our results give the insights into their correlated molecular mechanisms as well as genes regulated in the impaired hippocampus by acute and chronic MA administration.

Title: Primary neuronal cell culture model for cortical spreading depression and membrane permeability changes detected in this model

Authors: *Y. CETIN TAS, E. SEKERDAG, Y. GURSOY-OZDEMIR;
Grad. Sch. of Hlth. Sci., Koc Univ., Istanbul, Turkey

Abstract: Neuronal transient membrane permeability changes were reported to occur in different in-vivo conditions like cortical spreading depression (CSD), ischemia, subarachnoid hemorrhage and brain trauma. This may lead to initiation of neuroinflammation and headache formation. CSD is proven to cause pannexin-1 (Panx1) megachannel openings leading to increased membrane permeability. CSD has been successfully triggered in vivo via application of potassium-chloride (KCl) directly to the brain tissue. In vitro KCL application to primary neuronal cultures may simulate same effect leading to depolarization of neurons.
In this study, in vitro primary neuronal cell culture model for CSD and membrane permeability changes were simulated via application of KCL. To identify increased membrane permeability, propidium iodide (PI), a fluorescent molecule which does not naturally permeate live neurons was chosen. Primary neuron cultures grown up on PDL extracellular matrix. Mature neurons (DIV 14) were treated with 25 µmol of PI for 10 min followed by the application of KCl in different concentrations. NaCl and feeding medium were used as control groups. Application of KCl lead to increased membrane permeability to PI in a concentration dependent manner, whereas NaCl and the feeding medium did not caused any permeability increase. 1M KCl lead to significant PI uptake whereas, 0.3M KCl was shown to be insufficient, suggesting a minimum concentration of KCl for channel activation.
Our studies provide an easy method for simulating CSD in vitro, without the need for live animal subjects. And it may be a screening method for new therapeutic approaches.

Title: Biased agonists of the dopamine d3 receptor alleviate motor and dyskinesia symptoms of parkinsons disease

Authors: *S. KORTAGERE, W. XU;
Microbiology and Immunol., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Dopamine D3 receptor (D3R) has been suggested to play a critical role in the etiology of both Parkinson’s disease (PD) and levodopa (L-dopa)-induced dyskinesia (LID). Several dopaminergic agents including L-dopa have been used as therapeutic agents for Parkinson’s disease with limited success for therapy. We have recently designed a class of atypical D3R agonists (SK609 and SK608) with functional selectivity to G-protein dependent, but β-arrestin independent signaling features. In addition, these atypical agonists do not induce desensitization of D3R but induce dose- and time-dependent internalization of D3R over expressed in CHO cells. These results are in complete contrast with the signaling properties of other known D3R agonists such as Dopamine and PD128907, which induce desensitization but not internalization of D3R. D3R are only known to undergo pharmacological sequestration in response to these known D3R agonists. Our compounds, improved motor impairments associated with PD-like symptoms in a 6-OHDA induced hemiparkinson rat model of PD. In rodents, chronic treatment of SK609 or SK608 did not induce abnormal involuntary movements (AIMs) but significantly reduced AIMs induced by L-dopa when used adjuvantly with L-dopa. Our results suggest that the internalization of D3R induced by SK608 contributes to the re-sensitization of D3R signaling and receptor trafficking which may explain its novel therapeutic efficacy observed in alleviating the symptoms of PD in rodent models of LID and PD.

Title: Neurochemical profile of a novel allosteric potentiator of the dopamine D1 receptor

Authors: *J. FALCONE[1], S. N. MITCHELL[2], G. CARTER[2], D. L. MAREN[1], J. KATNER[1], E. CHERNET[1], R. WRIGHT[1], H. WANG[1], J. W. RYDER[1], M. S. MORIN[1], D. GEHLERT[1], M. P. JOHNSON[1], J. P. BECK[1], J. HAO[1], M. M. MENEZES[1], R. F. BRUNS[1], K. A. SVENSSON[1]; [1]Neurosci., Eli Lilly and Co., Indianapolis, IN; [2]Eli Lilly and Co., Erl Wood, United Kingdom

Abstract: DETQ is a potent and selective dopamine D1 receptor potentiator that is active in several behavioral models (see abstracts by Heinz et al and Svensson et al at this meeting). We wished to explore the neurochemical basis for the behavioral effects of DETQ. Due to low affinity of DETQ in rodents, the current studies were carried out in transgenic mice in which both copies of the murine D1 receptor were replaced with its human counterpart (hD1 mice) (see Svensson et al). Receptor expression in hD1 mice was characterized using autoradiography of the D1-selective antagonist 3H-SCH23390. The pattern of D1 receptor distribution was very similar in wild-type and hD1 mice, but the absolute level of expression was about 50% lower in hD1 mice. Using microdialysis in freely moving hD1 mice, DETQ and the D1 agonist SKF82958 increased extracellular levels of acetylcholine and histamine in cortical and subcortical areas. At a high dose we also observed enhanced extracellular levels of norepinephrine in the prefrontal cortex. Furthermore, a low dose of DETQ elevated hippocampal acetylcholine levels in an additive fashion with the acetylcholinesterase inhibitor rivastigmine. Brain levels of the histamine metabolites tele-methylhistamine and tele-methylimidazole acetic acid were also elevated in both microdialysate and post-mortem tissue samples. The increases in brain histamine metabolites produced by DETQ were not present in wild-type mice, indicating that the effects were mediated via the D1 receptor. Overall, these neurochemical changes correlated with brain exposure of DETQ and also with the behavioral effects (see Svensson et al.) Effects on brain cyclic nucleotide levels were studied after microwave fixation of the forebrain. Levels of cGMP were elevated in the striatum after both DETQ and SKF82958. Further changes in downstream signaling were explored measuring phosphorylation of the transcription factor CREB and the AMPA receptor GluR1. Both DETQ and SKF82958 increased pCREB and pGluR1 in the brain. Together, these data provide neurochemical evidence for enhanced synaptic plasticity of DETQ and SKF82958. In conclusion, our in vivo neurochemical data support the proposal that the D1 potentiator DETQ selectively enhances D1 receptor function in the brain. Studies of neurotransmitter release, second messengers, and downstream

signaling support a potential utility for D1 potentiators to enhance cognitive function in CNS disorders.

Title: Optogenetic activation of striatal D1 medium spiny neurons regulates dyskinesias in parkinsonian mice

Authors: *X. A. PEREZ, D. ZHANG, T. BORDIA, M. QUIK;
SRI Intl., Menlo Park, CA

Abstract: Dyskinesias are a disabling motor complication that arises with prolonged L-dopa treatment. Evidence suggests that direct pathway medium spiny neurons (D1 MSNs) play a primary role in the development of dyskinesias. D1 receptor agonists produce dyskinesias in animal models while D1 antagonists inhibit their occurrence. Additionally, genetic deletion of the D1 receptor and chemical ablation of D1 MSNs decreases L-dopa-induced dyskinesias (LIDs). However, the precise role and contribution of D1 MSNs to LIDs are uncertain. We therefore used optogenetics, a technology that allows for precise modulation of specific neurons *in vivo,* to investigate whether direct control of striatal D1 MSN activity regulates abnormal involuntary movements (AIMs) in parkinsonian mice. Mice expressing cre-recombinase under the control of the D1 receptor promoter were unilaterally lesioned with 6-hydroxydopamine. AAV5-ChR2-eYFP or AAV5-control-eYFP was injected into the dorsolateral striatum, and optical fibers implanted. After stable virus expression, mice were optically stimulated and AIMs rated. Single pulse and burst D1 MSN stimulation induced the expression of oral AIMs in L-dopa naïve ChR2-eYFP mice. By contrast, none of the stimulation paradigms enhanced AIMs in control-eYFP mice. L-dopa treatment alone induced dyskinesias to a similar extent as optical stimulation. Unexpectedly, combined L-dopa administration and stimulation resulted in an additive increase in dyskinesias. These data indicate that complex adaptive responses extending

beyond activation of D1 and/or D2 receptors contribute to the expression of dyskinesias. Molecular studies indicate that changes in pERK are involved. Optical stimulation did not ameliorate parkinsonism in L-dopa naïve mice. However, it improved it in L-dopa primed mice to a similar extent as L-dopa administration. These results suggest that improvements in motor control require plasticity changes in both the D1 and D2 striatal output pathways, which only occur with L-dopa treatment. Altogether, the data provide direct evidence that striatal D1 MSN stimulation regulates motor control and is sufficient to induce LIDs.

Title: The allosteric dopamine D1 receptor potentiator, DETQ, ameliorates the impairment in NOR induced by subchronic phencyclidine in humanized D1 knock-in mice: A potential new strategy for treating cognitive disorders.

Authors: *L. RAJAGOPAL[1], F. MATRISCIANO[1], M. HUANG[1], K. A. SVENSSON[2], H. Y. MELTZER[1];
[1]Psychiatry and Behavioral Sci., Northwestern Univ. Feinberg Sch. of Med., Chicago, IL;
[2]Neurosci. Discovery, Eli Lilly & Co., Indianapolis, IN

Abstract: Dopamine (DA) D1 receptors play a major role in working memory, declarative memory, and executive functions. While enhancing D1 receptor stimulation has been a target for Parkinson's (PD) and Alzheimer's disease (AD) and schizophrenia, development of orthosteric D1 agonists has been unsuccessful due, in part, to D1 receptor desensitization (Arnsten et al., 2015) Activating D1 receptors by allosteric D1 potentiation DETQ, (Beadle et al., 2014) may be more effective. Due to a species difference in DETQ's binding to D1 receptors, we examined the cognitive behavioral effects of *DETQ, in* mice genetically modified to express humanized D1 DA receptors ("hD1kI mice"). Subchronic pretreatment with phencyclidine (scPCP), a noncompetitive NMDA receptor antagonist, bid, for 7 days, produces an enduring deficit in novel object recognition (NOR). We also examined the neurotransmitter release induced by DETQ using microdialysis in hD1KI mice. hD1kI mice showed a persistent NOR deficit after withdrawal from sub-chronic PCP. This deficit was reversed by pretreatment with DETQ (10, 30

and 60 mg/kg, i.p.) but not 3 mg/kg given 30 min prior to acquisition. Acute pretreatment with the D1 DA receptor orthosteric agonists, SKF-38393 (3 mg/kg, i.p.) and SKF-82958 (0.3 mg/kg, i.p.), or the acetylcholinesterase inhibitor, rivastigmine (1.0 but not 0.03 or 0.3 mg/kg, i.p.), also restored NOR. The ameliorative effect of DETQ 1.0 mg/kg was blocked by the D1 antagonist, 0.1 mg/kg, SCH39166. DETQ had no effect on NOR in WT mice. In prefrontal cortex and hippocampus of hD1kI mice, the behaviorally effective dose of DETQ (30 mg/kg, i.p.) moderately increased ACh release, but had no effect on the efflux of DA, NE, 5-HT, glutamate, or GABA. Similar results were obtained after repeated injections for seven days. Interestingly, in scPCP-treated mice, the acute DETQ-induced ACh efflux was absent, indicating that the release of ACh was not essential for ability to restore NOR in scPCP mice. Taken together, these results show that DETQ reverses the declarative memory deficit induced by scPCP treatment, as does D1 orthosteric agonists, supporting the potential clinical utility of D1 PAMs for treating cognitive deficits, in PD, AD, and other types of cognitive impairment, including age-associated cognitive impairment. Further studies of DETQ in combination with cholinesterase inhibitors and other potential cognitive improving agents are indicated.

Abstract: Allosteric potentiators increase the affinity of endogenous agonist, amplifying physiological control circuits. Because a potentiator depends on endogenous tone, its effects are predicted to be self-limiting and less prone to rapid tolerance development compared to direct-acting agonists. Our objective was to test this hypothesis using DETQ, a novel dopamine D1 receptor potentiator. DETQ has high affinity for the human D1 receptor, but it is 70-fold less potent at the rodent D1 receptors. To overcome this limitation, we created a transgenic mouse expressing the human D1 receptor (hD1 knock in mice). Homozygotes showed normal behavior and breeding. After oral dosing, DETQ caused a dose-dependent 10-fold increase in locomotor activity in habituated hD1 mice but not in wild-type mice, implying a requirement for the human D1 receptor. The increase in locomotor activity was blocked by the D1 antagonist SCH39166 and by pretreatment with a high dose of reserpine, indicating that the behavioral response is dependent on endogenous dopamine release. At higher doses, the response to DETQ reached a plateau even though brain concentrations of unbound drug continued to rise. In contrast, the D1 agonists SKF82958 and A-77636 showed bell-shaped dose-response curves, with a decrease in locomotor activity at the highest doses. The suppression of locomotor activity at high doses was due to competing stereotyped behaviors such as intense grooming. The stereotyped behaviors were not seen with DETQ, providing evidence that the response to DETQ is less liable to cause overstimulation. In repeated dosing over four days, the locomotor response to DETQ was maintained, whereas the response to A-77636 showed rapid tolerance. In hD1 mice treated with a low dose of reserpine, DETQ restored locomotor activity to untreated control levels; this model is relevant to stand-alone therapy in mild-to-moderate Parkinson's disease. After a high dose of reserpine, DETQ acted synergistically with L-DOPA in restoring locomotor activity. DETQ also increased wakefulness and was found to be effective in a behavioral despair model. We also compared DETQ with SKF82958 for efficacy in the Y-maze. While both compounds enhanced the number of arm entries in a dose-dependent fashion, DETQ maintained spontaneous alternation even at high doses, whereas higher doses of SKF82958 decreased alternation (a potential sign of cognitive dysfunction). Finally, DETQ increased spontaneous eye blink rate in the rhesus monkey, a response related to central D1 activation. These results confirm that D1 potentiators may possess advantages over D1 agonists for the treatment of Parkinson's disease and other CNS disorders.

Abstract: Allosteric potentiators of the dopamine D1 receptor could be useful for treatment of Parkinson’s disease, schizophrenia, depression, ADHD, and narcolepsy. We identified a novel D1 potentiator (DETQ) by high-throughput screening followed by iterative chemical optimization. In a HEK293 cell line expressing the human D1 receptor, agonist-stimulated cAMP production was measured in the presence of an EC20 concentration of dopamine using homogeneous time resolved fluorescence (HTRF) technology. DETQ potentiated the dopamine response with a mean EC50 of 5.8 nM and mean efficacy corresponding to 95% of the maximum response to dopamine. In the absence of dopamine (agonist mode), the maximum efficacy of DETQ was 11.6% with an EC50 of 30 nM; based on the initial slopes of the two curves (Ehlert R-ratio), DETQ was thus 43-fold less potent as an allosteric agonist than as a potentiator. When

concentration-response curves for dopamine were carried out at multiple DETQ concentrations in the cAMP assay, DETQ shifted the dopamine curve 21-fold to the left with a K_B of 26 nM. In experiments measuring binding of the D1 antagonist 3H-SCH23390 to the human D1 receptor, 100 nM DETQ caused a 5-fold leftward shift in the concentration-inhibition curve for dopamine, indicating a direct effect of DETQ on the D1 receptor. The potency of DETQ in the cAMP assay was about 50-fold lower at the mouse and rat D1 receptors than at human, rhesus, and dog D1 receptors. DETQ was inactive at concentrations up to at least 10 uM when tested in agonist and potentiator modes at related receptors, including D2, D5, β1, β2, β3, and 5HT6. DETQ was also inactive in binding and/or functional assays at a large set of unrelated targets. These results suggest that DETQ could be a useful tool to probe applications of dopamine D1 potentiators for CNS disorders.

Title: Neurodegeneration of the nigrostriatal dopaminergic pathway in a rat model of chronic hyperglycemia.

Authors: J. RENAUD, K. DUFRESNE, C. LAVOIE, *M. MARTINOLI;
Dept. of Med. Biol., Univ. Quebec, Trois-Rivieres, QC, Canada

Abstract: Hyperglycemia is a known cause of oxidative stress reported to inflict damage to the nervous system. Epidemiological evidence demonstrates a significant correlation between diabetes and neurodegenerative disorders, including Alzheimer’s disease [1] and Parkinson’s disease [2]. Recently, we showed that elevated levels of glucose induce death in dopaminergic neuron cultures through oxidative and apoptotic mechanisms [3,4]. AIM: In this respect, the goal

of this study was to characterize dopaminergic neurodegeneration in a streptozotocin-nicotinamide rat model of chronic hyperglycemia. In addition, we investigated the presence of neuroinflammation around brain regions that are dense in dopaminergic neurons. METHODS: Rats were injected with nicotinamide followed by streptozotocin to cause the depletion of pancreatic insulin-producing cells. Metabolic measurements established that these rats were chronically hyperglycemic, as demonstrated by abnormal plasma insulin levels, glycated hemoglobin, glucose tolerance, polyuria, polydipsia, and polyphagia. After 5 months, rats were sacrificed and brain tissues were harvested to perform immunoblotting and immunohistochemistry. RESULTS: Our data demonstrate the presence of dopaminergic neurodegeneration and neuroinflammation in the streptozotocin-nicotinamide model. In particular, levels of tyrosine hydroxylase, a key enzyme in dopamine synthesis, and dopamine transporter (DAT) were reduced in the midbrains of hyperglycemic rats. CONCLUSION: These results evoke a link between hyperglycemia and dopaminergic neurodegeneration, providing new insight on the higher occurrence of Parkinson's disease in diabetic patients. 1. Title: A locus coeruleus-ventral periaqueductal gray arousal circuit: Subcellular localization of the alpha-1 adrenergic receptor

Authors: *D. A. MITRANO[1], S. FEKIR[2], L. ODIL[2], D. WEINSHENKER[3];

Abstract: Sleep disorders currently affect over 50 million Americans. One way to identify circuits and molecules regulating arousal is to study sleep abnormalities that manifest as symptoms of other neurological disorders, such as Parkinson's disease (PD), since the underlying neuropathology may provide clues about affected brain regions and neuronal populations. Excessive sleepiness manifests early in PD and represents one of its most common and debilitating non-motor symptoms, but has always been puzzling because the midbrain dopamine (DA) neurons that degenerate in PD do not appear to regulate sleep/wake cycles. An understudied population of DA neurons in the brainstem ventral periaqueductal gray (vPAG) that promotes wakefulness was recently identified, but these neurons do not degenerate in PD. It has been suggested that dysfunction rather than degeneration of vPAG DA neurons may cause sleepiness, but information about how they are regulated or connected to PD is lacking. Based on preliminary data and previous research showing the wake-promoting effect of the dopaminergic drug modafinil requires alpha-1 adrenergic receptor (α1AR) activation in the vPAG, norepinephrine (NE) increases excitation of vPAG DA neurons via α1ARs and α1ARs are expressed on putative excitatory elements in the vPAG, the goal of this study is to determine the localization and neurochemical identity of α1AR-containing elements and DA neurons in the vPAG. Using immunohistochemistry at the electron microscopic (EM) level we have found that the α1AR is enriched on presynaptic elements and putative glial elements. Next, we used double labeling EM techniques to assess the neurochemical identity of α1AR-containing elements. Preliminary results indicate minimal colocalization of the α1AR with TH (tyrosine hydroxylase; marker for DA neurons) and vGluT1 (marker for glutamatergic neurons). The next step will be analyzing the colocalization of the α1AR with vGluT2 (marks a population of glutamatergic neurons distinct from vGluT1), EAAT2 (marker for glutamatergic astrocytes) and GABA. This study aims to provide a comprehensive neuroanatomical map of LC-vPAG DA neuron connectivity and vPAG DA neuron output.

Title: Effects of monoaminergic systems degeneration on the neuronal activity of suprachiasmatic nucleus

Authors: *A. TINAKOUA[1,2], N. LAKHDAR-GHAZAL[1], A. BENAZZOUZ[2];
[1]Univ. Mohammed V- Fac. of Sciences, URBRNE, Rabat, Morocco; [2]Bordeaux University, Neurodegenerative diseases Institute, CNRS UMR 5293, Bordeaux, France

Abstract: Parkinson's disease (PD) is a neurological disorder, characterized by motor disabilities, such as akinesia, rigidity and tremor at rest, which are considered as a consequence of the degeneration of dopamine (DA) nigro-striatal neurons. Nevertheless, PD is also characterized by non-motor symptoms (anxiety, depression and sleep disorders), which may be related to the perturbation of other neurotransmitter systems, such as the noradrenergic (NA) and serotonergic (5-HT) systems of the locus coeruleus and dorsal raphe nucleus respectively. As a part of the non-motor symptoms, the circadian rhythms of behavior start decades before the onset of motor deficits. Our hypothesis is that the depletion of monoamines may be involved in the pathophysiology of circadian rhythms, which are poorly studied in the context of PD. The present study aimed to investigate the effects of DA depletion and the combined depletion of DA and NA or/and 5-HT, on the neuronal activity of suprachiasmatic nucleus (SCN) using *in vivo* extracellular electrophysiology. In control rats, the firing rate of SCN neurons was 1.61 ± 0.16 spikes/sec, the pattern was bursty in 56%, irregular in 31% and regular in 13% of the recorded neurons. Compared to control animals, DA depletion alone significantly enhanced the proportion of irregular SCN neurons (48.4%) and decreased the percentage of bursty neurons (39%). When DA depletion was combined with that of NA or 5-HT, the proportion of irregular neurons was higher (50.7% and 49.2% respectively) and that of bursty pattern was lesser (35.29% and 38.8% respectively) compared to control animals. The combined depletion of the three monoamines significantly increased the proportion of irregular neurons (66.3%) and decreased that of bursty cells (25.7%). Furthermore, the firing rate was also affected in depleted rats. In rats with DA and NA or 5-HT depletion, the firing rate of SCN neurons significantly increased compared to control rats (2.92±0.27 and 3.41±0.46 spikes/s respectively, $p<0.05$). In rats with triple depletion the firing rate was higher (4.23±0.47 spikes/s) compared to control rats ($p<0.01$) and DA depleted rats (2.43±0.31 spikes/s, $p<0.05$). Our results provide the first evidence for the involvement of monoaminergic systems in the modulation of the firing rate and patterns of SCN neurons, suggesting new insight into the involvement of these electrophysiological changes in the pathophysiology of circadian rhythms disruption in PD.

Title: DJ1 deficiency disrupts mitochondrial function and neuronal growth

Authors: *R. CHEN, J. WU, P. MIRANDA, K. ALAVIAN, E. JONAS;
Dept. of Intrnl. Med., Yale Sch. of Med., New Haven, CT

Abstract: Parkinson's disease (PD), including Familial PD, is a progressive neurodegenerative disorder characterized by loss of dopaminergic (DA) neurons in the substantia nigra pars compacta (SNpc). So far, a large number of mutation sites in DJ1, a peptidase C56 family protein, were identified to be likely related to neurodegenerative diseases. We study the DJ1 knockout (KO) mouse as a model to understand the mechanism of DJ1 in PD. Previously we demonstrated that overexpression of WT DJ1 significantly increases ATP levels in HEK293 cells, and we showed that midbrain cells have higher ATP levels than midbrain cells from DJ1 KO. Now we find that DJ1 directly binds to ATP synthase β subunit and closes a leak present in mitochondrial inner membrane. To determine the function of DJ1 and its disease-associated point mutant (A104T) at the ATP synthase, we studied mitochondrial membrane potential. We find that both WT and mutant DJ1 increase mitochondrial membrane potential in rat hippocampal neurons, measured by TMRM, but that the mutant has much lower membrane potential than WT, consistent with the mutant increasing inner membrane leakiness. In keeping with this, we show that ATP synthase c-subunit mRNA levels are increased in DJ1 KO midbrain cells. This finding provides an explanation for the increased inner membrane leak because we know from our previous work demonstrating that the c-subunit is the mPTP that a leak channel within the c-subunit opens under pathological conditions and when the F_1 (containing the β subunit) moves away from the mouth of the pore. A leaky inner mitochondrial membrane produces mitochondrial inefficiency, consistent with our finding that DJ1 KO DA neurons have defective neurite growth and that midbrain cells release high amounts of LDH during development. To rescue the defective neurite outgrowth in DJ1 KO DA neurons, we plan to decrease the amount of c-subunit leak channel in mitochondrial membrane. We are also interested in distinguishing the mitochondrial Ca^{2+} buffering abilities between WT and KO cells upon action potential firing. Thus, our study has uncovered an important role of DJ1 in Parkinson's disease. Specifically, DJ1 affects mitochondrial inner membrane properties and thereby cell metabolism and neuronal development. This may ultimately provide novel insights

into PD pathogenesis and possible therapeutic options.

Title: Human COMT over-expression increases L-DOPA-induced dyskinesia in male but not in female mice

Authors: *O. SOLÍS CASTREJÓN[1,2], J.-R. GARCÍA-MONTES[1,2], P. GARCÍA-SANZ[1,2], A. S. HERRANZ[3], M.-J. ASENSIO[3], G. KANG[4], N. HIROI[4], R. MORATALLA[1,2];

Abstract: Catechol-O-methyl-transferase (COMT) degrades dopamine and its precursor L-DOPA. Given that this enzyme plays a critical role in regulating synaptic dopamine actions, we investigated the effects of heightened levels of COMT on dopamine-regulated motor behaviors and molecular alterations in mice. Male and female COMT over-expressing (Tg-COMT) mice and their wild-type (WT) littermates received unilateral 6-OHDA lesions in the dorsal striatum and were chronically treated with L-DOPA. Our results show that male, but not female, Tg-COMT mice showed higher levels of dyskinesia compared to their WT littermates. By contrast, L-DOPA treatment induced indistinguishable levels of contralateral rotations between male and female Tg-COMT and WT littermates Chronic L-DOPA treatment induced higher levels of FosB and phospho-acetylated histone 3 in male lesioned Tg-COMT mice, compared to their WT

counterparts. Moreover, we studied striatal tissue levels of 3-Methoxytyramine, a dopamine metabolite, and observed that this metabolite was increased in the lesioned striatum of dyskinetic Tg-COMT male mice; no difference was seen between female Tg-COMT mice and their WT littermates. Finally, we determined 5-hydroxytryptamine striatal levels and found that COMT overexpression do not impact in the content of this neurotransmitter in dyskinetic animals. Our results demonstrate that FosB induction and histone phosphorylation were correlated with L-DOPA-induced dyskinesia and suggest that increased COMT activity exerts sexually dimorphic effects on L-DOPA-induced dyskinesia and molecular alterations in the striatum.

Title: Lack of histamine increases levodopa-induced axial dyskinesia in mice

Authors: *S. K. NOUSIAINEN[1], S. LEINO[1], P. PANULA[2], S. RANNANPÄÄ[1], O. SALMINEN[1];

Abstract: The dopamine replacement therapy with L-DOPA is the most effective treatment for motor symptoms of Parkinson’s disease (PD). A disadvantage of L-DOPA treatment is abnormal involuntary movements (AIMs, also called L-DOPA-induced dyskinesia, LID) which will develop in most patients 4-6 years after the initiation of the treatment. In addition to the loss of brain dopamine (DA) neurons, other neurons like histamine (HA) neurons are affected in PD. In addition, HA neurons can take up L-DOPA and convert it to DA and thereby affect PD treatment. In this project we examined the role of HA in LID in a 6-hydroxydopamine (6-OHDA) lesioned mouse model using histidine decarboxylase knockout (HDC KO) mice. HDC KO mice do not synthesize histamine whereas the histamine neurons are not morphologically altered. Female HDC KO mice and their littermate wild type mice underwent a stereotaxic surgery where the striatum was unilaterally lesioned by two injections of 6-OHDA. To study the interactions between pharmacological agents and the absence of histamine amphetamine- and apomorphine-induced rotation tests were performed. Injection of the indirect DA agonist

amphetamine tended to induce more ipsilateral rotations in wildtype mice than HDC KO mice and injection of the direct DA agonist apomorphine tended to induce more contralateral rotations in HDC KO mice than in wildtype mice. These results suggest that the lack of histamine could have a protective effect against the lesion while at the same time the DA receptors might be more sensitised. To study LID, daily L-DOPA injections were given and dyskinesias recorded and analysed with a novel scoring method. When only successfully lesioned mice (based on immunohistochemical staining of the DA neurons of substantia nigra) were included in analyses, more severe axial dyskinesia was observed in HDC KO mice than in wild type mice but no differences in orolingual or forelimb dyskinesia between genotypes were observed. When comparing total dyskinesia scores between moderately and severely dyskinetic animals a clear tendency of HDC KO mice to develop more severe dyskinesia was observed. In conclusion, these results suggest that when the brain histaminergic system is genetically dampened, the mice develop more severe LID than control animals. The underlying mechanism could be that the histamine neurons lacking the histamine synthetizing enzyme can replace their histamine synthesis with dopamine synthesis as a compensatory mechanism and cause an imbalance during the dopamine replacement therapy and induce more severe dyskinesia.

Title: M4 muscarinic receptor antagonism worsens L-DOPA- induced dyskinesia

Authors: *N. E. CHAMBERS, E. SHEENA, A. TAYLOR, L. GROSS, C. TASBER, S. SINGER, S. BOSSERT, M. CONTI, S. MEADOWS, K. LANZA, C. BISHOP; Binghamton Univ., Binghamton, NY

Abstract: Parkinson’s disease, a neurodegenerative disorder characterized by the loss of nigrostriatal dopamine (DA) neurons, results in motor deficits such as bradykinesia, akinesia, tremor, and postural instability. Standard treatment for PD remains DA replacement with L-DOPA; however, its chronic use leads to L-DOPA-induced dyskinesia (LID), which is characterized by abnormal involuntary movements (AIMs). Recent research suggests that acetylcholine (ACh) and DA maintain a balance in a normal striatum; however, this balance is disrupted in PD and in LID. Normally, DA acts to decrease ACh levels by stimulating DA D2

receptors on the striatal cholinergic interneuron (ChI); whereas, ACh can either up- or down-regulate striatal DA levels through ACh receptors located on nigrostriatal terminals. In PD, ACh is up-regulated due to a lack of DA-induced inhibition of the ChI. Additionally, ACh plays an important role in modulating striatal signaling through ACh receptors located on glutamatergic terminals and GABAergic neurons. Therefore, targeting ACh receptors could modulate dyskinesia. In particular, the m4 muscarinic ACh receptor (m4R) is well-positioned to modulate dyskinesia, given its presence on various striatal neurons including medium spiny neurons, cholinergic interneurons, and glutamatergic terminals from the cortex and thalamus. To probe effects of m4R actions on dyskinesia, the current study investigated the effects of Tropicamide (an m4R-preferring antagonist) on L-DOPA and DA agonist-induced dyskinesia, as well as the striatal contribution of these effects. Using a within-subjects design, in the first experiment, hemi-parkinsonian rats were administered Tropicamide 5 minutes before L-DOPA, SKF81297 (a DA D1 receptor agonist), or Quinpirole (a DA D2 receptor agonist). In the second experiment, using a within-subjects design, hemi-parkinsonian rats were injected intrastriatally with Tropicamide prior to systemic injections of L-DOPA. In each experiment, 10 minutes after the administration of L-DOPA, SKF81297, or Quinpirole, AIMs were rated for each rat for 1 minute every 10 minutes for 180 minutes. Motor behavior was also measured in animals receiving L-DOPA using the forepaw adjusting steps test. The results suggest that m4R antagonists can worsen dyskinesia (although these effects are specific to L-DOPA) without affecting L-DOPA's motor efficacy, and therefore may be a promising pharmaceutical target for treating LID. Additionally, the results of the current study suggest that the effects of m4R antagonism on dyskinesia are based in the striatum.

Title: Prolyl oligopeptidase regulates dopamine transporters in the nigrostriatal tract in mice

Authors: *U. JULKU[1], A. PANHELAINEN[2], S. TIILIKAINEN[1], M. SAVOLAINEN[1], T. MYÖHÄNEN[1];
[1]Div. of Pharmacol. and Pharmacotherapy, Univ. of Helsinki, University of Helsinki, Finland;
[2]Inst. of Biotech., Univ. of Helsinki, Helsinki, Finland

Abstract: Aplha-synuclein (aSyn) is the main component of the Lewy bodies, a histopathological finding of Parkinson's disease. Prolyl oligopeptidase (PREP) is a serine protease that binds directly to aSyn and accelerates its aggregation *in vitro*, and PREP enzyme inhibitors have shown to block the aggregation process *in vitro* and in cellular models, and also enhanced the clearance of aSyn aggregates in transgenic mice models. Although PREP has several known substrates, the physiological and pathological roles have remained unclear. PREP inhibitors have caused alterations in dopamine (DA) and metabolite levels in nigrostriatal pathway, and PREP localizes in GABAergic and DAergic neurons of nigrostriatal tract. However, the functions of PREP in nigrostriatal pathway are unclear. Moreover, aSyn is shown to have physiological functions in DA release and storage in nigrostriatal pathway.
The aim of the study was to characterize the role of PREP in nigrostriatal DAergic and in GABAergic systems of C57Bl/6 (wt) and PREP knock-out (PREP-KO) mouse, and the effects of PREP overexpression by AAV-hPREP on these systems by using conventional microdialysis, no-net-flux microdialysis and tissue HPLC analysis. Function of dopamine transporter (DAT) was examined by fast-scan cyclic voltammetry and Western blotting.
Overexpression of PREP did not have effect on baseline level of striatal DA and its metabolites in microdialysis study in wt mice, but amphetamine administration caused decrease in GABA and metabolites of DA. PREP overexpression increased concentrations of DA and its metabolites in striatal tissue in wt mice, and as did the returning PREP to substantia nigra of PREP KO mice, measured by tissue HPLC. AAV-PREP also increased the level of DAT in striatum in wt mice measured by Western blot. Extracellular concentration of DA was increased in striatum of PREP-KO mice in no-net-flux microdialysis study. DA release was similar in PREP-KO mice and in wt littermates but DA re-uptake was delayed in PREP-KO mice in fast-scan cyclic voltammetry measurements in acute striatal slices.
Our results suggest that PREP does not have direct effect on DA release but regulates the functions of DAT, possibly by controlling the transport of DAT into the striatum or synaptic membrane.

Title: Dopamine transporter deficiency syndrome: Disease modelling in zebrafish

Authors: *K. REID[1], A. ELSER[2], J. RIHEL[3], M. A. KURIAN[4], R. J. HARVEY[2];
[1]Pharmacol., [2]UCL Sch. of Pharm., London, United Kingdom; [3]UCL, London, United Kingdom;
[4]UCL Inst. of Child Hlth., London, United Kingdom

Abstract: Dopamine transporter deficiency syndrome (DTDS) is caused by mutations in *SLC6A3*, encoding the human dopamine transporter (hDAT). DTDS associated mutations result in diminished dopamine/Na^+ binding affinity, reduced cell-surface expression or a loss of post-translational glycosylation, leading to loss of function of the dopamine transporter. Patients classically present with infantile-onset progressive parkinsonism-dystonia. As the disease progresses, patients develop hypokinesia with parkinsonian features, and in the absence of disease modifying therapies, many DTDS patients die in adolescence. The aim of this study was to generate a stable zebrafish DAT mutant in order to model DTDS in a vertebrate model system, which could then be utilised in high-thoroughput drug screens. CRISPR/Cas9 genome editing technology was employed with the integration of next-generation sequencing to generate a stable DAT zebrafish mutant. DAT depletion, likely by RNA nonsense mediated decay, was confirmed using whole mount *in situ* hybridisation. No difference was observed in the survival of DAT mutant fish up to the age of 3 months post fertilization and adult fish were fertile and able to produce progeny at a similar rate to wild-type fish. However mutant zebrafish do appear smaller and have a delayed development in comparison to wild-type controls. The expression levels of key dopaminergic signaling proteins, including D1 and D2 dopamine receptors, were found to be reduced in DAT mutant zebrafish as detected by qPCR, which is in line with studies performed on the mouse model of DTDS. Behavioural tracking studies reveal that mutant zebrafish larvae displayed a hyperkinetic state up to the age of 8 dpf, with no defects observed in sleep behavior, coinciding with preliminary investigations pharmacological inhibition of DAT. This phenotype also coincides with the mouse model of DTDS in addition to patient symptoms. In the future, the mutant zebrafish will be used in a medium- to high-throughput small molecule screen in order to identify novel pharmacotherapies that could potentially halt or slow disease progression in individuals with DTDS

Title: Teleost ventral diencephalon and mammalian substantia nigra as homologs

Authors: B. FRESHNER[1], D. DOLCE[1], C. GOHLICH[2], R. LAUX[2], *E. B. GAHTAN[1,2]; [1]Psychology, [2]Biol., Humboldt State Univ., Arcata, CA

Abstract: The substantia nigra (SN) pars compacta is a midbrain dopaminergic nucleus that plays a critical role in voluntary motor control in mammals and is a main site of cell loss in Parkinson's disease. Different animal models may be best for studying different elements of Parkinson's-related neurodegenerative process, and recently zebrafish models have been proposed for high- throughput genotype and drug screens aimed at understanding and modifying cellular and molecular level disease processes. Zebrafish have multiple central dopaminergic nuclei and previous research has suggested that dopaminergic neurons in the ventral diencephalon (vDC) contribute to motor control and is an evolutionary homolog of the mammalian SN. The current study sought to replicate the link between the zebrafish vDC and motor control, previously shown using pharmacological lesions, by laser ablating individual neurons in the vDC in a transgenic line in which these neurons express GFP under the control of the dopamine transporter promoter. Bilateral ablation of the second diencephalic clusters within the vDC resulted in decreased spontaneous swimming activity ($t(30) = 3.598$, $p = .001$, $d = 1.27$). Vital staining with propidium iodide confirmed that laser ablations were effective and specific to the targeted neurons. These effects are consistent with pharmacological lesions targeting the same neurons in zebrafish and add to evidence that the zebrafish vDC is functionally homologous to the mammalian SN.

Abstract: About ten percent of Parkinson's disease cases are due to gene mutations, including those in *PARK2*. Hallmark symptoms of PD are due to severe dopaminergic neuronal loss in the substantia nigra *pars compacta*, which modulates activity of the basal ganglia. These symptoms include resting tremor, rigidity, postural instability, difficulty initiating movement, and insomnia. Motor deficits and dopaminergic neuron loss have been observed in *Drosophila melanogaster* carrying the $park^{25}$ loss-of-function allele of the *Drosophila PARK2* homologue *parkin,* suggesting that these motor deficits may be due to decreased dopamine levels; however, previous studies reporting aberrant motor function do not discriminate between neurogenic and myogenic deficits. In order to address whether the $park^{25}$ allele causes neurogenic motor deficits, we performed photoaffinity and sleep behavior assays in which we placed individual flies in 5 mm diameter glass tubes and recorded infrared beam breaks in order to determine activity. We found that although $park^{25}$ homozygotes have the same level of activity in complete darkness, they spend less time in a lighted area than control flies when we placed flies in 250mm long glass tubes in which one end is exposed to light. To test sleep behavior, we measured activity for 20 days under a 12/12-hour light/dark cycle. $Park^{25}$ mutants have longer sleep bouts, more total sleep time, and decreased sleep latency early in adult life. Female mutants continue to be less active than controls up to day 20, while male mutants are only less active in early adult life. Our results resemble those previously reported for dopamine deficient *Drosophila*; this supports that the $park^{25}$ allele causes dopamine deficiency. Further, because $park^{25}$ homozygotes have the same levels of activity as controls during an equilibration period, we suggest that the proposed dopamine deficiency causes $park^{25}$ homozygotes to have aberrant function of the central complex, a group of brain structures that are functionally homologous to the mammalian basal ganglia. To address whether photoaffinity loss and sleep behavior changes are due to loss of dopamine activity, we will repeat our studies in $park^{25}$ flies over-expressing dopamine reuptake transporter-targeted miRNA. Our results suggest that the $park^{25}$ mutation causes aberrant

function of the central complex in *Drosophila*, further substantiating the use of this model for exploration of PD pathology and therapeutic target identification.

Title: The Synaptojanin SAC1 domain, mutated in Parkinson's disease, is required for synaptic macroautophagy.

Authors: *R. VANHAUWAERT, S. SOUKUP, S. KUENEN, N. SCHOOVAERTS, L. BOUNTI, J. SWERTS, S. VILLAIN, P. VERSTREKEN;
CME / VIB11, KU Leuven / VIB, Leuven, Belgium

Abstract: Parkinson disease causing mutations in different proteins that regulate synaptic vesicle endocytosis have been identified, but the role of the pathogenic mutants has not been tested *in vivo*. One of the proteins, Synaptojanin is an evolutionary very well conserved phosphoinositide phosphatase that in all species tested plays a role in the uncoating of clathrin-coated synaptic vesicles. The protein harbors two phosphoinositide phosphatase domains; an inositol-5-phosphatase domain that is important for the dephosphorylation of $PI(4,5)P_2$, strongly implicated in endocytosis, and a SAC1 phosphatase domain. The SAC1 domain is mutated in Parkinson's disease and when mutant it fails to dephosphorylate PI(3)P and PI(4)P. However, the synaptic function of the SAC1 domain remains unclear, nor is it known how the pathogenic mutations in the SAC1 domain disrupt neuronal function. Here we show that at glutamatergic excitatory synapses, the Parkinson-causing mutation in *synaptojanin* does not affect synaptic vesicle endocytosis but that it completely blocks synaptic autophagy. Autophagosome formation requires PI(3)P and we find that synaptic autophagosomes in *synaptojanin* mutants harbor increased Atg18a, a PI(3)P binding protein. Using FRAP we show that Atg18a fails to leave nascent autophagosomes in *synaptojanin* mutants, blocking autophagosome formation and the recruitment of Atg8a/LC3 at synapses. Functionally, deregulation of Synaptojanin-dependent autophagy in fruit flies causes reduced lifespan and neurodegeneration. Our data indicate that at

synapses, the inositol-5-phosphatase domain of Synaptojanin is needed for endocytosis while the SAC1 domain is required for autophagosome formation. This is interesting because the tightest binding partner of Synaptojanin, EndophilinA, was also recently shown to be required for synaptic macroautophagy and this function connects to at least two other Parkinson's disease genes, LRRK2 and Parkin, suggesting that dysfunction of synaptic macroautophagy may be a common theme in this disorder.

Title: DREADD modulation of transplanted dopamine neurons reveals a novel Parkinsonian dyskinesia mechanism mediated by the serotonin 5-HT6 receptor

Authors: *P. ALDRIN[1], A. HEUER[2], G. WANG[3], B. MATTSSON[3], M. LUNDBLAD[2], M. PARMAR[2], T. BJÖRKLUND[3];

Abstract: Brain repair, trough grafting of dopaminergic neuroblasts has over the past three decades emerged as a promising therapy for patients with Parkinson's disease. Although clinical benefits were observed in early clinical trials, later double blinded trials displayed highly variable clinical outcome. In order to address this issue, we have developed an animal model based on grafting dopaminergic neuroblasts from the ventral mesencephalon of embryonic TH-Cre knock-in rats that were transduced in situ using AAVs, in order to express DREADDs (Designer Receptors Exclusively Activated by Designer Drugs). This approach enabled selective, non-invasive, orthogonal, chemical modulation of activity of grafted dopaminergic neurons. Using this approach, we are able to demonstrate that selective activation of grafted dopaminergic neurons through DREADDs can significantly potentiate graft mediated therapeutic recovery. However, DREADD mediated activation of dopaminergic fetal grafts also induced graft induced dyskinesias (GIDs), one of the major side effects observed in a significant number of patients

that have received dopaminergic fetal grafts. Although the specific pathways involved in the development of GIDs remain poorly understood our experimental data suggest a significant involvement of the Gs coupled 5-HT6 receptor driving GIDs through a cAMP mediated pathway in grafted dopaminergic neurons supporting previous clinical observations implicating serotonergic neurotransmission. Indeed, we also identified high levels of 5-HT6 expression in clinically relevant human grafts, implicating a similar mechanism of action in patients suffering from GIDs. In order reduce the risk of developing GIDs, we propose to use DREADDs in combination with CRISPR-Cas9 genome editing techniques in order to knock down 5-HT6 expression in grafted dopaminergic neurons. This would allow for a significant recovery in motor function without the major side effects associated with dopaminergic grafts.

Title: Inhibition of leukotriene receptors restores cognition in an animal model of PD.

Authors: J. MARSCHALLINGER[1], N. PILLICHSHAMMER[1], J. GARNWEIDNER-RAITH[1], B. KLEIN[1], E. ROCKENSTEIN[2], S. COUILLARD-DESPRES[1], E. MASLIAH[2], *L. J. AIGNER[1];
[1]Paracelsus Med. Univ., Salzburg, Austria; [2]UC San Diego, La Jolla, CA

Abstract: Leukotrienes, inflammatory mediators of inflammation, are well-studied in the field of asthma and allergy. In the brain, elevated leukotriene levels are reported in acute as well as chronic lesions (eg Alzheimer´s disease), and increasing concentrations of the leukotriene-producing enzyme 5-LOX have been demonstrated in the aged brain and in Parkinson´s disease (PD). Here, elevated leukotriene signaling might be involved in neuroinflammatory processes and in the development of dementia in PD. With respect to aging, we recently demonstrated that a 6-week oral treatment of young (4 months) and aged (20 months) rats with the leukotriene receptor inhibitor montelukast resulted in reduced neuroinflammation, enhanced neurogenesis, and remarkably, in a restoration of cognitive functions in aged rats. Now, we examined whether montelukast has beneficial effects on cognition in a PD animal model. We used 6 month-old PDGF-ß α-Syn transgenic mice, which are characterized by microgliosis, deficitis in neurogenesis, and by cognitive impairments. Mice were treated orally with montelukast or vehicle (saline solution) daily for 6 weeks, and several behavioral tests (Open Field, Buried Food Test, Elevated Plus Maze, Morris Water maze) were performed. We analyzed CNS pharmacology and showed that, after oral administration, montelukast entered the brain of the treated animals. In respect to cognition, the 6-week treatment with montelukast lead to significant improvement in learning and memory in the PD mice. Histological analysis of the hippocampus showed that the beneficial effects of montelukast on cognition in PD mice are accompanied by altered microglia morphology and altered expression of inflammation markers. Based on the current data, we suggest montelukast as a promising drug to ameliorate dementia in PD.

Title: Antipsychotics and extrapyramidal side-effects in rats: there are circadian and age differences

Authors: S. HUSSAIN, *I. C. SUMAYA;
Psychology - 24 DDH, California State Univ. Bakersfield, Bakersfield, CA

Abstract: Schizophrenia is a serious mental disorders characterized by the hallmark symptoms of psychosis, disorganized thought, hallucinations and delusions. Whereas the majority of mental disorders can be treated with both pharmacological and psychological interventions, in the case of schizophrenia, the use of pharmacological therapeutics is inevitable and remains the only viable treatment strategy. These treatment strategies include antipsychotics that target the dopaminergic neurotransmitter system and specifically show high affinity for the D2 dopamine receptors serving to block the transmission of dopamine. Although these dopamine antagonists show high efficacy resulting in improvement in symptomology it is not without a price. The price is paid in the basal ganglia and the extrapyramidal system that relies on dopamine for the proper initiation and execution of voluntary motor behavior. Extrapyramidal side effects include hypokinesia, the inability to initiate a voluntary movement. In a previous study, Sumaya et al., (2001) found in young rats that the antipsychotic, fluphenazine, did not induce hypokinesia in the dark phase indicating possible circadian differences in the antipsychotic. As a follow-up to these findings haloperidol (HAL) treatment was investigated in the light and dark phases in both young and adult rats. Young (2 mo, n= 28) and adult (10 mo, n=26) male Sprague Dawley rats were treated with HAL (1 mg/kg ip, 1% lactic acid) in the light (1000 hr) and dark (2200 hr) phases and hypokinesia was measured using the bar test (max bar time 1800 sec). In young rats during the light phase, as expected, HAL induced high levels of hypokinesia as compared to the controls (VEH: 7.07 $\pm$ 1.82 sec: vs HAL: 862.28 $\pm$ 291 sec). However, during the dark phase HAL induced significantly lower amounts of hypokinesia as compared to the light phase treated HAL rats (Dark: 109 $\pm$ 68.75 sec vs Light: 862.28 $\pm$ 291 sec). In adults rats (10 mo) during the light phase, rats treated with HAL showed the greatest amount of hypokinesia of all ages tested (HAL: 1600 $\pm$ 157 sec vs VEH: 8.28 $\pm$ 1.74 sec) with a similar strong effect of hypokinesia in the dark phase (HAL: 1525.71 $\pm$ 177.10 sec vs VEH: 12.8 $\pm$ 7.6 sec). First, these data corroborate previous results showing a differential effect of D2 antagonists in the light and dark phases,

however, these differential effects are absent in older animals. In the aggregate, these results provide first time data that Haldol is ineffective during the dark phase depending on the age.

Title: Intra-accumbens but not intra-striatal infusions of haloperidol, induce inverse incentive learning in rats

Authors: *J. F. ROCCA[1], C. J. RATTRAY[1], C. DI PROSPERO[2], R. J. BENINGER[1]; [1]Psychology, [2]Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada

Abstract: Inverse incentive learning, or the loss by stimuli of the ability to elicit approach and other responses, gradually develops when animals are given low doses of certain D2-like receptor antagonists, such as haloperidol or spiroperidol. Here, we investigated the role of the nucleus accumbens and dorsal striatum in this behaviour. In experiment 1, Wistar rats were given intra-accumbal infusions of haloperidol (5, 10, 15 μg/0.5 μl/side) prior to being placed in a test box with their forepaws on a horizontal bar 10 cm above the floor, and infusions of vehicle 30 min after testing (paired groups). A control group was instead given vehicle prior to exposure to the test box and received haloperidol (10 μg/0.5 μl/side) 30 min after testing (unpaired group). Descent latency -- the time until the first active paw movement related to descent from the bar -- was recorded. In experiment 2, rats received haloperidol (paired group), infused into the dorsal striatum at a dose of 10 μg/0.5 μl/side prior to being placed in a test box. In both experiments, animals were conditioned in this manner for 9 days, followed by a saline-only test day (day 10). In experiment 1, all groups had similar descent latencies on day 1, but those that received 10 or 15 ug/0.5 μl/side (paired) showed increased (i.e., sensitized) descent latencies across the following 8 days. On the saline-only test day, the 10 and 15 ug/0.5 μl/side (paired) groups showed a conditioned increase in descent latency. In experiment 2, the paired group did not show sensitized descent latencies across conditioning days or on the saline-only test day. These data implicate nucleus accumbens dopamine neurotransmission in inverse incentive learning. This phenomenon may be involved in some aspects of the motivational abnormalities seen in disorders of dopamine neurotransmission.

Title: Local dopamine release induced by nucleus accumbens deep brain stimulation confirmed by electrochemistry

Authors: *L. G. ANDRES-BECK[1], M. L. SETTELL[2], H.-K. MIN[3], K. LEE[4];
[1]Mol. Pharmacol. and Exptl. Therapeut., Mayo Grad. Sch., Rochester, MN; [2]Neural Engin. Labs., [3]Radiology, Physiol. and Biomed. Enginering, [4]Neurologic Surgery, Physiol. and Biomed. Engin., Mayo Clin., Rochester, MN

Abstract: Introduction: Deep brain stimulation (DBS) of the nucleus accumbens (NAc) has become an effective therapy for treatment refractory obsessive-compulsive disorder (OCD), with human patients experiencing an average decrease in OCD symptoms of 50%. However, the mechanism underlying the efficacy of DBS treatment is unknown. Previous research has identified striatal dopamine release as a possible contributing mechanism underlying DBS treatment and we therefore seek to determine the local effect of DBS on dopamine activity using electrochemistry to measure dopamine release in response to stimulation.
Methods: Domestic swine underwent unilateral DBS electrode implantation of the NAc. Then, a carbon fiber recording electrode was placed 2mm anterior to the stimulating electrode, also in the NAc. Fast scan cyclic voltammetry recordings were taken using the WINCS Harmoni system and dopamine response to stimulation was measured at varying voltages and frequencies of stimulation (3V, 5V, or 7V at 130Hz; 30Hz, 60Hz, or 130Hz with 5V).
Results: Stimulation of the NAc induced acute, local dopamine release in the NAc, with signature oxidation current at +0.6V and reduction current at -0.2V. Dopamine could be consistently evoked with stimulation parameters of 5V and 130Hz. There was a significant difference in dopamine response between different voltage stimulations ($n=4$, $p<0.05$).
Conclusion: DBS stimulation of the NAc induces local dopamine release as measured by electrochemistry. If supported by further studies, these findings of NAc DBS-evoked dopamine release could have implications for understanding the circuitry effects of NAc DBS, since stimulated brain networks are anatomically and functionally segregated within the basal ganglia

thalamocortical system and are represented in distinct functional motor, associative, and limbic cortical regions.

Abstract: A number of studies have begun to address the role of the mTOR signaling pathway in lifespan extension and neurodegeneration. In *C. elegans*, reduced protein translation significantly extends lifespan, a phenomenon corroborated by Ames dwarf mice that are long-lived. To establish a model system to study reduced protein translation and its effect on normal neuronal health, aging, and neurodegenerative disorders, such as Parkinson's disease (PD), we have generated a mouse model overexpressing eiF4E-binding protein 1 (4EBP1). We found that primary cortical neurons from 4EBP1 overexpressing (OE) transgenic mice display significantly decreased cell death upon exposure to Rotenone, Maneb, Paraquat or Brefeldin A in comparison to neurons form control non-transgenic littermates. Furthermore, primary hippocampal neurons from 4EBP1 OE mice displayed decreased cell death when exposed to α-synuclein preformed fibril (PFF)-mediated cytotoxicity. Further studies indicate an induction of the mitochondrial unfolded protein response in 4EBP1 OE primary cortical neurons upon Brefeldin A stress. Moreover, 4EBP1 OE in primary cortical neurons and cell lines treated with Brefeldin A reveal an up-regulation in the RNA expression levels of multiple genes important for maintaining mitochondrial health, including genes on the glycolytic pathway, reactive oxygen species defense pathway, and in the mitochondrial unfolded protein response. Our results thus indicate that reduced protein translation, via over-expression of 4EBP1, is neuroprotective in a variety of PD models.

Title: Astaxanthin attenuates neurodegeneration and neuroinflammation in a mouse model of parkinson's disease

Authors: B. GRIMMIG[1], L. DALY[1], C. HUDSON[2], *P. C. BICKFORD[3,2];
[1]Neurosurg. and Brain Repair, Univ. of South Florida, Tampa, FL; [2]Res. Service, James A Haley Veterans Hosp., Tampa, FL; [3]Neurosurg. and Brain Repair, USF Morsani Col. of Med., Tampa, FL

Abstract: Astaxanthin (AXT) is a xanthophyll carotenoid produced by marine algae and has diverse biological activities. The chemical structure of AXT is distinguished from other carotenoids by the presence of two polar ionone moieties that cap both ends of a hydrophobic region, thus allowing the molecule to span the lipid bilayer. Although it is best known as a potent antioxidant, it also has a putative role as an anti-inflammatory agent and the capacity to enhance mitochondrial function. These biological process are known to be involved in the pathogenesis of PD, implicating AXT as a potential therapeutic agent for the intervention of the development of Parkinsonian symptoms. Given the role of oxidative stress and inflammation in the progression of many neurodegenerative diseases, we examined the efficacy of AXT in the prevention MPTP induced dopamine cell death in mice. Here, we show that the administration of 3mg/kg of algae derived AXT reduced neurotoxicity in a mouse model of Parkinson's disease. After a four week pretreatment of AXT supplemented diet, AXT treated mice demonstrated preserved tyrosine hydroxylase (TH) immunoreactivity in the substantia nigra (SN) and striatum after MPTP exposure (10 mg/kg administered hourly for a total of 40mg/kg) compared to the control diet. This observation was corroborated by retention of NeuN staining in the SN of AXT treated mice. Furthermore, AXT administration was able to interrupt the neuroinflammatory process known to contribute to neurodegeneration in this model. We demonstrate that AXT neuroprotection was associated with attenuated microglial activation indicated by reduced immunohistochemical detection of IBA-1 in the SN and striatum of AXT treated mice. We are exploring a dose

response relationship of AXT's ability to rescue dopaminergic neurons from an MPTP insult in both young and aged mice. Taken together, these data suggest that AXT is neuroprotective in the CNS against MPTP neurotoxicity.

Title: Which dopamine neurons live or die in Parkinson's: a balancing act between protective astrocytes and damaging microglia.

Authors: *E. W. KOSTUK, J. CAI, L. IACOVITTI;
Farber Inst. for Neurosciences - Dept. of Neurosci., Thomas Jefferson Univ., Philadelphia, PA

Abstract: Parkinson's Disease (PD) is characterized by selective degeneration of dopaminergic (DA) neurons of the substantia nigra pars compacta (SN) while neighboring ventral tegmental area (VTA) DA neurons are spared. Mechanisms underlying the selective protection of the VTA and susceptibility of the SN are still unknown. Previously, we demonstrated that SN and VTA neurons are greatly protected by factors released by VTA, but not SN, astrocytes. Also in vivo studies indicate a disparity in the number of glia within these two regions: the VTA has more astrocytes and the SN more microglia. Thus, we sought to determine whether the ratio of astrocytes and microglia to neurons plays a role in the protection of the VTA from and susceptibility of the SN to PD. Utilizing an hTH-GFP reporter rat developed by our lab we were able to sub-dissect the SN and VTA regions from P1-5 midbrains to generate regionally specified astrocytes (A_S, A_V) and microglia (MG). Astrocytic layers were established prior to addition of isolated E14.5 hTH-GFP rat SN (N_S) or VTA (N_V) neurons to establish homotypic (HM) and heterotypic (HT) astrocyte-neuron cultures of varying ratios (1:1, 2:1, 4:1). Cultures matured for 7 days before the addition of either PBS or 50μM of the PD toxin MPP^+. In HM cultures, A_S were unable to protect N_S from MPP^+ toxicity in all ratios, however A_V robustly protect N_V at higher ratios (2:1, 4:1). Additionally, in HT conditions, A_S failed to protect N_V from toxicity (all ratios) while A_V prevented MPP^+ toxicity in N_S (2:1, 4:1). To examine the potential role of microglia, MG were added at a 1:1 ratio to neurons in astrocyte-neuron co-cultures. In HM

A_S+N_S cultures, MG from cortex, SN or VTA similarly exacerbate MPP^+ toxicity of N_S. However, A_V robustly protect N_V from toxicity despite the addition of all regional MG. Furthermore, in HT A_V+N_S cultures, N_S are protected even in the presence of exacerbating MG, whereas in cultures of A_S+N_V, MG do not further exacerbate N_V vulnerability to MPP^+ toxicity. Therefore, we conclude that vulnerability of SN neurons may not depend upon the ratio of astrocytes to neurons, as increasing this ratio did not prevent toxicity, rather the results support our previous finding that astrocytes are regionally specified and only A_V can protect N_S and N_V. In contrast, MG do not exhibit regional specificity. MG exacerbate toxicity of N_V and N_S in the presence of non-protective A_S, but not protective A_V. These results suggest that vulnerability within the SN is multifactorial and potentially due to lack of support from astrocytes combined with deleterious effects of microglia while the protection of VTA stems from protective astrocytes that counter the effects of damaging microglia.

Abstract: Convincing evidence indicates that advanced glycation end-products and danger-associated protein S100B play a role in Parkinson's disease (PD). These agents operate through receptor for advanced glycation endproducts (RAGE), which displays distinct isoforms playing protective/deleterious effects. However, nature of RAGE variants has been overlooked in PD studies. Hence, we attempted to characterize RAGE regulation in early stages of PD striatal pathology. A neurotoxin-based rodent model of PD was used in the present study, through administration of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) to C57BL/6 mice. Animals were euthanized 6 hours post- MPTP to assess S100B/RAGE contents (RT-qPCR, ELISA), RAGE isoforms density (WB) and cellular distribution (IHC). Dopaminergic and gliotic status were also mapped (HPLC-ED, WB, IHC). At this preliminary stage of MPTP-induced PD in mice, RAGE inhibitory isoforms were increased whereas full-length RAGE was not affected. The cytoprotective RAGE phenotype paired an inflammatory and pro-oxidant setting fuelling DAergic denervation. Increased RAGE inhibitory variants occur in astrocytes showing higher S100B density but not overt signs of hypertrophy or NF-kB activation, a canonical effector of RAGE. These findings expand our understanding of the toxic effect of MPTP on striatum and offer first *in vivo* evidence of RAGE being a responder in early stages of astrogliosis dynamics, supporting a protective rather tissue-destructive phenotype of RAGE in initial phase of PD degeneration. These data lay the groundwork for future studies on the relevance of astrocytic RAGE in DAergic neuroprotection strategies.

Title: Neuroprotective effects of GDNF splice isoforms

Authors: *A.-M. PENTTINEN[1], M. H. VOUTILAINEN[1], M. KOSKELA[1], R. K. TUOMINEN[2], B. K. HARVEY[3], M. SAARMA[1], M. AIRAVAARA[1];

Abstract: Glial cell line-derived neurotrophic factor (GDNF) has been shown to promote the survival and function of the nigrostriatal dopaminergic pathway *in vitro* and *in vivo*. GDNF has two major splice isoforms, full-length pre-α-pro-GDNF (α-GDNF) and shorter pre-β-pro-GDNF (β-GDNF), which has a deletion of 26 amino acids in the pro-region. We have previously shown α-GDNF to be localized in Golgi complex and secreted constitutively, whereas the β-GDNF is primarily localized in vesicles and is secreted activity-dependently. Until now the research has focused on the full-length α-GDNF and less is known about the biology of the shorter β-isoform. The neuroprotective effects of GDNF isoforms were studied in a partial 6-hydroxydopamine (6-OHDA) rat model of Parkinson's disease. Unilateral overexpression of GDNF isoforms or green fluorescent protein (GFP) was induced by administration of double-stranded adeno-associated virus serotype 1 encoding pre-α-pro-GDNF, pre-β-pro-GDNF, or GFP to the striatum of male Wistar rats. Three weeks later, the degeneration of nigrostriatal pathway was induced by intrastriatal injection of 6-OHDA. The behavioral effects were analyzed by drug-free cylinder test and amphetamine-induced rotations, and the changes on the histological level by tyrosine hydroxylase (TH) and dopamine transporter (DAT) immunohistochemistry. Both GDNF isoforms protected the striatal DAT-positive neurites from 6-OHDA-induced neurotoxicity, whereas striatal TH levels were similar in all groups. However, in the substantia nigra both GDNF isoforms were able to protect TH-positive cell bodies. The data suggest both isoforms, α- and β-GDNF, to have a neuroprotective effect in the partial 6-OHDA model of Parkinson's disease.

Title: BDNF's role in the action of vagus nerve stimulation to treat Parkinson's disease

Authors: *A. FARRAND[1,2], R. GREGORY[1,3], K. HELKE[3,4], V. HINSON[5], H. BOGER[1,2]; [1]Neurosciences, [2]Ctr. on Aging, [3]Comparative Med., [4]Pathology, [5]Neurol., Med. Univ. of South Carolina, Charleston, SC

Abstract: Vagus nerve stimulation (VNS) is currently used in the clinic to treat both epilepsy and depression. It is thought to act via brainstem nuclei, such as the locus coeruleus (LC), to help increase BDNF and TrkB activation in target areas and play a protective role, while reducing the inflammation that exacerbates neurodegeneration. In Parkinson's disease (PD), the noradrenergic (NE) neurons of the LC degenerate prior to the dopamine (DA) neurons in the substantia nigra (SN), making VNS a potentially less-invasive therapy than deep brain stimulation. Our lab has shown that in a double-lesion model of PD, VNS improves locomotor activity, increases tyrosine hydroxylase (TH)-positive neurons in the SN and the LC, and increases BDNF expression in the respective target regions. Therefore, our current hypothesis is that VNS uses a BDNF-TrkB dependent mechanism to reduce inflammation and protect cells in these areas. We examined this by utilizing a double lesion model that mimics the deficits seen in PD. Using adult male rats, we administer the NE neurotoxin DSP-4 (50 mg/kg, ip), followed seven days later by the DA toxin 6-OHDA (6 μL, bilateral intrastriatal). Immediately following 6-OHDA, rats in the VNS group also received vagus cuff implants and headcaps that are later attached to the VNS stimulator which emits precise bursts of stimulation at a set amplitude and rate. Ten days following the 6-OHDA lesion, rats received two sessions of VNS per day for two weeks, measuring locomotor activity during the afternoon session each day. A subset of VNS rats also received daily injections of the TrkB antagonist ANA-12 (0.5 mg/kg, ip) prior to their afternoon VNS session. Immediately following VNS on the last day, rats were euthanized, and the right frontal cortex, hippocampus, and dorsal striatum were dissected to analyze BDNF, TrkB, and phospho-TrkB levels. The left hemisphere was sectioned for immunohistochemical staining of TH, the astrocytic marker GFAP, and the activated microglial marker OX-6. Rats in the VNS group have increased levels of BDNF in both the frontal cortex (LC target) and the dorsal striatum (SN target), and decreased inflammatory markers in both the SN and the LC compared to non-stimulated lesioned rats. These data suggest that BDNF plays a role in the action of VNS to decrease inflammation and provide protection for neurons in these major areas affected in PD. Studies are ongoing in the lab to further elucidate the role of TrkB and its downstream effectors in this pathway, as well as determining the dependence on this mechanism in the rats that received ANA-12. Collectively, these data support the potential of VNS as a novel treatment option for PD.

Abstract: Parkinson's disease (PD) is a multifactorial neurodegenerative disease that has been linked to several pathogenic events like lysosomal and mitochondrial impairment, oxidative stress and programmed cell death. So far, none of the clinical trials carried out to halt the progression of the disease have succeed. One possible explanation of this systematic failure is that the majority of the strategies tested were focusing only on one of the pathogenic mechanism. Based on the same rationale, a strategy that targets several pathogenic mechanisms at the same time may have much higher probability to be successfully translated into clinical practice as a neuroprotective strategy. TFEB has gained momentum since it was demonstrated that it is a master regulatory gene for lysosomal biogenesis and autophagy. However, based on HeLa cells studies the majority of TFEB putative direct targets are not directly related to lysosomes or autophagy. For instance, there are genes encoding proteins involved in mitochondrial function, protein biosynthesis and survival pathways. Therefore, we hypothesized that TFEB activation may counteract several of the pathogenic mechanisms linked to PD. However, only the effect on

the autophagy-lysosomal degradation pathway has been assessed in neurons overexpressing TFEB. In this study, we first assessed the general effect of overexpressing TFEB in nigral dopaminergic neurons in vivo by means of an adeno-associated viral vector. After that, we assessed the neuroprotective effect of TFEB overexpression in the MPTP mouse model of PD and its mechanisms of neuroprotection. We demonstrate that TFEB overexpression has a neurotrophic effect that involves an increase of protein biosynthesis, cell body growth, neurite outgrowth and an increase of dopamine released in the striatum. Moreover, TFEB overexpression completely prevents MPTP-induced neuronal atrophy and cell death. Even though TFEB overexpression compensates lysosomal impairment, its broader influence on several pathways and organelles, like mitochondria, may explain its neuroprotective effect. In this regard, TFEB promotes the activation of pro-survival pathways that explain both the neurotrophic and neuroprotective effects. Our results confirm that TFEB is targeting several pathogenic pathways linked to PD, increasing the potential of boosting TFEB activity as a disease modifying strategy.

Abstract: The estradiol is a neuroactive steroid that has a neuroprotective role in several models of neurologic diseases. The present study shows the antioxidant effect of β-estradiol-3-benzoate (EB) on the neurotoxicity of MPP+ in rat. In striatum brain region were measurement dopamine

and lipid peroxidation levels and glutathione peroxidase and superoxide dismutase activities (both isoenzymes. SOD-Zn, Cu and SOD-Mn) at after of the neurotoxin intracerebral injection. All male animals were gonadectomized and 30 days after were treated with EB for 11 days each 48 h. At 6 day of EB treatment was injected MPP^+. The results show that the treatment with EB remained significantly the DA levels (80 %) and decreased the lipid peroxidation levels (56 %) induced by MPP^+. These neurochemical parameters correlated with the decreased of circling behavior (45 %) and with remained the survival rate (45 %) of dopaminergic neurons in the SNpc in this Parkinson´s disease model. While, that the treatment of EB not increased the enzymatic activities of glutathione peroxidase and superoxide dismutase. The EB has an antioxidant effect against the MPP+ toxicity without the classical antioxidant systems participation, suggesting a possible activation of other antioxidant enzymes, such as paraoxonases.

Abstract: Parkinson's disease is a neurological syndrome characterized by the irreversible loss of dopaminergic neurons in the nigrostriatal pathway of unknown etiology, environmental causes

have been proposed through molecules, such as 1-methyl 4-phenylpyridinium (MPP^+), which induce a selective toxicity towards dopaminergic neurons. Another hypothesis, is the loss of dopaminergic neurons by an increase in the catabolism of dopamine across the monoamine oxidase (MAO) enzyme that produced reactive oxidant species. *In vivo* studies have demonstrated that hydroxytyrosol (HT) is a potent antioxidant in the central nervous system. In the present study, evaluated the effect of HT on MAO activity in the corpus striatum (CS) *in vivo* and *in vitro*. Wistar male rats received a single dose of 1.5 mg/Kg of HT intravenously. Five minutes later, the animals received a intrastriatal stereotaxic micro-injection of 10 µg MPP^+ dissolved in 8µL of sterile saline solution and MAO activity was assayed by formation of 4-hydroxyquinoline 2h later. For *in vitro* studies, HT (10µM-1000µM) was added to brain tissue homogenates to assay MAO activity. Pretreatment with HT significantly reduced (20% and 60%) the MAO-A and MAO-B activity in the CS respectively ($p < 0.05$). This inhibitory effect was corroborated with the *in vitro* determination of IC50 by each isoform (MAO-A = 386µM, MAO-B = 295µM). An inhibitory effect of HT on MAO activities may be involved in neuroprotective effect of this natural phenylethanoid. Since MAO-B inhibition reduces neurodegeneration in clinical trials for Parkinson's disease, our results suggest that HT may be useful to prevent neuronal death in this neurodegenerative disorder.

Title: Developmentally dependent perinuclear ubiquitin accumulation in a symptomatic model of DYT1 dystonia

Authors: *S. S. PAPPAS, W. DAUER;
Dept Neurol., Univ. of Michigan, Ann Arbor, MI

Abstract: Dystonia is movement disorder characterized by prolonged involuntary abnormal movements. DYT1, the most common inherited dystonia, is caused by a loss of function mutation in the gene *Tor1a*, which encodes the endoplasmic reticulum/nuclear envelope-localized AAA+ ATPase TorsinA. TorsinA is believed to play roles in protein quality control and degradation, protein secretion, and trafficking of membrane-bound proteins. We modeled DYT1 dystonia in mice by deleting *Tor1a* in disease-relevant forebrain neurons. These mice

exhibit abnormal twisting movements coinciding with forebrain maturation, and these movements are suppressed by an anticholinergic used clinically. Striatal cholinergic interneurons degenerate coincident with abnormal movement onset, while all other striatal neurons and cortical GABAergic interneurons remain viable. To begin to test the hypothesis that abnormal protein quality control and degradation underlie cholinergic interneuron degeneration, we performed ubiquitin immunohistochemistry at the developmental time point marking the beginning of behavior onset and cell death. Surprisingly, cholinergic interneurons did not exhibit protein folding abnormalities, while forebrain GABAergic populations contained abnormal perinuclear accumulation of ubiquitinated proteins. We are currently examining whether changes in endoplasmic reticulum associated degradation or the unfolded protein response contribute to these waves of abnormal ubiquitination during forebrain development. These findings suggest that abnormal accumulation of ubiquitin is not limited to dying cells, and instead represents a more general consequence of torsinA loss-of-function that may disrupt motor circuit maturation.

Title: Resting state brain connectivity in musician's dystonia

Authors: *K. KITA[1], J. ROKICKI[2], S. FURUYA[3], L. M. LI[4], H. MATSUDA[2], T. SAKAMOTO[2], T. HANAKAWA[2];
[1]Chiba Univ., Chiba, Japan; [2]Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan; [3]Sophia Univ., Tokyo, Japan; [4]Imperial Col. London, London, United Kingdom

Abstract: Musician's dystonia (MD) is subtype of a focal task-specific dystonia (FTSD) characterized by abnormal posturing and loss of fine motor control. Pianists, guitarists, violinists etc. can develop MD in the hands. The affected fingers become uncontrollable whilst playing a specific musical instrument but may respond normally during other motor activities. Although the neurological origins of this disorder are not yet completely clarified, dysfunctional or maladaptive brain plasticity is thought to be associated with the MD.
In this study, we investigated resting state (rsfMRI) connectivity of MD subjects (3T Siemens MAGNETOM Verio MRI scanner). In total, 67 subjects participated in our study: 37 healthy

musicians (HM: 31 pianists, 3 violinists, 2 saxophonist, and 1 clarinetist, mean age 34.5±12.2, 2 left-handed); and 30 musicians with MD (24 pianists, 3 violinists, 2 saxophonist, and 1 clarinetist, mean age 38.5±10.3, 4 left-handed). 21 musicians with MD had dystonic symptoms in the right hand, and 9 had it in the left hand. We analyzed resting state fMRI data with the FSL analysis package using independent component decomposition (ICA), dual regression and permutation analysis of linear models (PALM).
We have selected 9 ICA networks of interest: default mode network, sensory-motor network, insula, two motor networks, basal ganglia, two cerebellum networks and thalamus. The general linear model used for analysis was: 3 groups (healthy musicians, right hand-affected MD [R-MD] and left hand-affected MD [L-MD]); we controlled for age, handedness and musical instrument. We found significant differences in rsfMRI connectivity for the basal ganglia network only. The R-MDs had higher functional connectivity within the putamen bilaterally relative to HM ($p<0.05$, corrected for multiple voxels using FWE). Moreover, R-MDs showed significantly higher connectivity in posterior parts of the putamen, as compared with L-MDs ($p<0.05$, FWE). There were no significant differences between HM and left-affected MDs. Our result is in line with previous writer's cramp study, which found dysfunction in the somotosensory cortex and putamen contralateral to symptomatic hand [1].
We report, for the first time to our knowledge, increased connectivity in rsfMRI putamen region for MD subjects. Even though symptoms of MD appear only during some specific tasks, there are functional abnormalities in the brains of MD subjects, which can be detected even in the resting state.

Title: Consequences of inducing acute endoplasmic reticulum stress in DYT1 rodent brain *In vivo*

Authors: *G. BEAUVAIS[1], J. L. WATSON[1], C. MELIS[2], M. E. EHRLICH[2], P. GONZALEZ-ALEGRE[1,3];

[1]Ctr. for Cell & Mol. Therapy, The Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Departments of Neurol. and Pediatrics & Genet. and Genomic Sci., Mount Sinai Sch. of Med., New York, NY; [3]Dept. of Neurol., Perelman Sch. of Med. at the Univ. of Pennsylvania, Philadelphia, PA

Abstract: DYT1 dystonia is an autosomal dominant disease, caused by a recurrent deletion mutation in the TOR1A gene. Biochemical, cell biological and animal-based studies suggest that the protein encoded by TOR1A, torsinA, participates in the neuronal response to endoplasmic reticulum (ER) stress and the DYT1 mutation would interfere with this function. Data from our laboratory using a murine chronic ER stress model supports this notion. However, whether mutant torsinA interferes with the normal response to acute ER-stress *in vivo* remains unknown. We hypothesize that the neuronal response to acute ER stress is abnormal in the mammalian DYT1 brain *in vivo*. To test this hypothesis, we used tunicamycin to induce acute ER stress in DYT1 transgenic rats and DYT1 knock-in mice. Tunicamycin inhibits N-linked glycosylation which causes an accumulation of misfolded ER-resident proteins. Five month-old DYT1 and control rats and mice received an intraperitoneal injection of 1 mg/kg of tunicamycin and were sacrificed 24 or 48 hours later. Whole cell striatal and cerebellar lysates were obtained and analyzed by western blotting. In both rats and mice, we found that this dose of tunicamycin triggers ER stress in brain tissue, present at 24 hrs and persisting 48 hrs after administration. The presence of mutant torsinA altered the neuronal ER stress response in the cerebellum and striatum of DYT1 rats and mice. In sum, these findings support previous reports from our laboratory and others suggesting that torsinA modulates the neuronal response to ER stress. Furthermore, they also provide us with a novel model in which to explore molecular pathways and potential therapeutic targets in DYT1 *in vivo*.

Title: Increase in the number of striatal cholinergic interneurons in a mouse model of DOPA-responsive dystonia

Authors: *G. YALCIN CAKMAKLI[1,2], R. M. VILLALBA[1,2], S. J. ROSE[3], E. J. HESS[4,5], Y. SMITH[1,2,5];
[1]Yerkes Natl. Primate Res. Ctr., Atlanta, GA; [2]Udall Ctr. of Excellence for Parkinson's Dis., Emory Univ., Atlanta, GA; [3]Cell Biol., Duke Univ., Durham, NC; [4]Deprtment of Pharmacol., [5]Dept. of Neurol., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Dystonia, which is the third most common movement disorder after tremor and Parkinson's disease, is characterized by involuntary twisting and patterned muscle movements. Despite a number of different mechanisms and pathways suggested as substrates for the pathophysiology of dystonia, there is still need for a more comprehensive and integrative explanation. Some evidence suggests that dysfunction of striatal cholinergic interneurons plays a critical role in the development of various forms of dystonia. The aim of this study was to evaluate potential changes in the number of striatal cholinergic interneurons in a recently developed knock-in mouse model of DOPA-responsive dystonia (DRD).
C57BL/6J mice were used to generate a knockin mouse model of DRD by introducing a mutation homologous to the DRD-causing c.1141C>A (p.381Q>K) mutation in the human tyrosine hydroxylase (TH) gene. Homozygous mice display the core features of the disorder including dystonia that worsens throughout the course of the day and response to L-DOPA (Rose et al, 2015, Brain 138: 2987).
Striatal brain sections from DRD (n=3, 2 females and 1 male) and wild-type (n=3, 2 females and 1 male) mice were immunostained with choline acetyltransferase (ChAT) and parvalbumin (PV) antibodies. Every 6th section, extending approximately from IA (interaural) 5.1 to IA 2.5 mm, was used for stereological counts of ChAT- and PV-positive neurons. Total numbers of neurons are estimated using a stereological approach. The striatum was divided into quadrants and rostrocaudal tiers to evaluate changes in the number of ChAT-containing neurons in specific functional territories of the striatum.
The number of striatal ChAT-immunopositive interneurons was 31.5 % higher in DRD mice (9238.1±1068.7) than in wild-type mice (6330.2±716.3). The largest increases were observed in the ventrolateral quadrant (43.3 %) and in the post-commissural tier (47.3 %) of the striatum. In contrast, the number of PV-positive interneuron was not significantly different between DRD mice (13812.4±1162.9) and wild-type mice (12395±1110.8), suggesting that the change in the number of interneurons is specific to cholinergic cells.
Our findings provide the first evidence for pathological increase in the number of intrastriatal cholinergic interneurons in the striatum of DRD mice. Future studies are needed to characterize the consequences of such neuronal increase on the intrastriatal cholinergic transmission and regulation of striatal outflow. It is noteworthy that these changes may be specific to DRD because they are not seen in the DYT1 knock-in mouse model of dystonia (Song et al, 2013, Neurobiol Dis 54: 362).

Title: Theta oscillations in the internal pallidum correlate with dystonic symptom severity in patients with cervical dystonia

Authors: *W.-J. NEUMANN[1,2], C. BRÜCKE[2], J. HUEBL[2], C. SLENTZ[2], G.-H. SCHNEIDER[3], A. A. KÜHN[2];
[2]Dept. of Neurol., [3]Dept. of Neurosurg., [1]Charité - Univ. Med. Berlin, Berlin, Germany

Abstract: Question: Theta oscillations in the internal pallidum has been shown to be correlated and coherent to dystonic muscle activity in patients with dystonia. Thus, pallidal theta oscillatory activity has been implicated in the pathophysiology of dystonia. We therefore aimed to investigate a potential association between pallidal theta activity recorded from deep brain stimulation electrodes with dystonic symptom severity as quantified by the Toronto Western Spasmodic Torticollis Rating Scale (TWSTRS) in patients with cervical dystonia.Methods: We included 27 patients (17 female; age: 50 ± 9.5 years, MEAN ± S.E.M) in our study. All patients underwent bilateral implantation of deep brain stimulation (DBS) electrodes in the internal pallidum (GPi). Pallidal local field potentials were recorded bilaterally from the DBS electrodes at rest from adjacent contact pairs (01,12,23), while the leads were still externalized. All data were analysed in the frequency domain using fourier transform based methods. The resulting power spectra were normalized and visually inspected for peaks in the low-frequency (θ: 4 - 12 Hz) and beta band (β: 13 - 30 Hz). Furthermore, inter-hemispheric coherence analysis has been conducted to investigate the spatial oscillatory connectivity. Spearman's correlations were used to investigate associations between coherence and peak amplitude and preoperative dystonic symptom severity (TWSTRS) for each frequency band.Results: Distinct peaks in the theta band (4 - 12 Hz, mean: 6.6 Hz ± 0.26 S.E.M.) and in the beta band (13 - 30 Hz, mean: 17 Hz ± 0.68 S.E.M.) were found in all patients. Significant correlations with dystonic symptom severity, as measured by preoperative TWSTRS were revealed for the theta, but not beta peak amplitude (N=27, Spearman's $\rho = 0.4$, $P = 0.009$) and interhemispheric coherence (n=26; Spearman's $\rho = 0.51$; $P = 0.0024$). Contact pairs with the highest theta peak power overlapped with the contact chosen for chronic stimulation in 94% (48/53 included contact pairs) and the correlation improved, when only these contact pairs were included ($N = 27$, Spearman's $\rho = 0.48$, $P = 0.005$).Conclusions: We have demonstrated that the amplitude of pallidal theta oscillations can

directly correlate with dystonic symptom severity in patients with cervical dystonia. Our results suggest that spectrally focal oscillations in the theta, but not beta band have a role in the pathophysiology of dystonia and may be a useful biomarker for dystonic symptom severity.

Title: The effects of motor gating on somatosensory induced beta oscillation in writer's cramp

Authors: *Y. TSENG[1], Y.-Y. LIN[2];
[1]Dept. of Med. Res., Mackay Mem. Hosp., Hsinchu City, Taiwan; [2]Lab. of Neurophysiol. and Dept. of Neurol., Taipei Veterans Gen. Hosp., Taipei, Taiwan

Abstract: Objective: To clarify the tuning effects of different sensoymotor circumstances on the somoatsensory evoked field (SEF) and sensory induced cortical beta synchronization (beta ERS) in patients with writer's cramp. **Methods:** We evaluated the neuromagnetic responses elicited by electrical median nerve stimulation at the wrist in 9 healthy subjects and 9 patients with writer's cramp during rest, imagery writing, and writing. **Results:** The N20m and P35m were attenuated during writing, but those were not changed during imagery writing. The beta ERS and SEFs components did not differ between groups after right median nerve stimulation. However, the beta ERS induced by left median nerve stimulation was significantly attenuated during writing in patients. **Conclusions:** The reduced beta ERS reflects abnormal inhibition of ipsilateral motor cortex during writing. A motor-task dependent dysregulation in the sensorimotor network might trigger the malfunction of motor control.

Title: Structural correlates of distinct clinical phenotypes and putative genotypes in spasmodic dysphonia

Authors: *S. BIANCHI[1], G. BATTISTELLA[1], H. P. HUDDLESTON[1], R. SCHARF[1], L. FLEYSHER[2], L. J. OZELIUS[4], K. SIMONYAN[1,3];
[1]Neurol., [2]Radiology, [3]Otolaryngology, Mount Sinai Icahn Sch. of Med., New York, NY;
[4]Neurol., Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Spasmodic dysphonia (SD) is a form of focal dystonia characterized by involuntary spasms in the laryngeal muscles during speaking. Most commonly, SD presents as an adductor type (ADSD) leading to voice breaks on vowels and harsh, strangled voice quality. Less commonly, SD patients are affected by the abductor type (ABSD), which leads to voice breaks on voiceless consonants, and breathy voice quality. While the causative pathophysiology of SD is unknown, about 16% of SD patients have a family history of dystonia, which suggests the presence of potential gene mutations with low penetrance.
Previous neuroimaging studies have shown several structural abnormalities in SD, including gray matter alterations in the laryngeal sensorimotor cortex, inferior frontal and superior and temporal gyrus, the cerebellum, as well as white matter changes in the internal capsule, basal ganglia, cerebellum, and temporal and parietal regions. Yet, little is known about the neural bases associated with SD putative genotypes and clinical phenotypes.
In this study, we acquired high-resolution MRI and diffusion-weighted images (DWI) in a large cohort of SD patients to examine abnormalities of cortical thickness and white matter integrity in association with distinct clinical phenotypes in 37 ADSD and 37 ABSD, and distinct genotypes in 29 familial and 30 sporadic cases. Following the standard processing pipelines, between-group differences in cortical thickness and fractional anisotropy were assessed using independent *t*-tests ($p_{corr} = 0.01$).
We found that genotype-specific alterations were characterized by cortical thickness changes in the left superior temporal gyrus and bilateral orbitofrontal regions, as well as by white matter

alterations in the arcuate portion of the left superior longitudinal fasciculus. Phenotype-specific cortical thickness abnormalities were found in the dorsal portion of the left central sulcus corresponding to the sensorimotor representation of the trunk and neck, the angular gyrus, whereas white matter alterations were observed in the superior corona radiata underlying the right precentral gyrus.
These findings suggest that SD genotypic pathophysiology may be associated with structural abnormalities in regions regulating phonological and sensory processing, while phenotypic differences may reflect dysfunction of primary and associative areas, underlying the sensorimotor control.

Title: Connectome-wide phenotypical and genotypical associations in laryngeal dystonia

Authors: *S. FUERTINGER[1], K. SIMONYAN[2];
[1]Dept. of Neurol., [2]Dept. of Neurol. and Otolaryngology, Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: Laryngeal dystonia (LD) is a focal dystonia of unknown pathophysiology characterized by involuntary spasms in the laryngeal muscles during speech production. An earlier study identified altered functional connectivity within sensorimotor brain regions in LD, whereas another combined study of LD and other focal dystonias suggested the presence of large-scale network abnormalities across different forms of this disorder. In this study, we used graph theoretical analysis of symptomatic speech production fMRI acquired from 90 LD patients (54.5±12.9 years; 73 females/17 males) and 32 healthy subjects (50.5±10.2 years; 21 females/12 males) to further characterize the LD functional connectome and its associations with distinct phenotypes and genotypes. We employed a community detection strategy to assess the formation of task-related LD genotype- and phenotype-specific functional modules and to contrast

pathological network topology with results obtained from healthy controls. Compared to healthy controls, the LD connectome was characterized by an overall abnormal pattern of hub formation particularly affecting regions in the parietal, primary motor and somatosensory cortices, and thalamus. We found that left thalamus formed a clearly delineated functional community in familial but not sporadic LD patients, while ADLD and ABLD showed marked differences in the topological organization of parietal regions during the production of meaningful speech. The interaction of sporadic genotype with adductor phenotype yielded four functional communities primarily governed by intra-modular hub regions, whereas familial abductor LD was associated with numerous long-range hub nodes distributed across five nodal groups characterized by abnormal functional integration of left thalamic and basal ganglia structures. Taken together, these results suggest that, on a connectome level, LD genotype-phenotype interactions are reflected by the interplay between global and local topological characteristics of functional communities. Our findings provide a comprehensive atlas of functional topology across different LD phenotypes and genotypes during symptomatic task production and thus may contribute to the development of neural imaging markers for this disorder.

Title: Symptoms and ketamine sensitivity in mouse models of dystonia: ATP1A3 and Lamb1

Authors: *K. J. SWEADNER[1], Y. B. LIU, 02114[1], M. V. SZABARI, 02114[1], A. SACINO[2], L. J. OZELIUS[1], J. B. LINGREL[3], K. LYKKE-HARTMANN[4], A. BRASHEAR[5];

Abstract: Paradoxical responses to drugs that are sometimes used as anesthetics were observed in two different mutant mouse dystonia models. In humans, mutations of *ATP1A3* (Na,K-ATPase alpha3) can have a variety of severe effects, and dystonia is a common (and often predominant) symptom. One mouse line was a hypomorph of the *Atp1a3* gene, and a second was a knock-in of a human mutation (D801Y) in the same gene. The third mouse line, lamb1t, was discovered by its dystonia-like symptoms, and has a mutation in the *Lamb1* (laminin beta1) gene (Liu et al. 2015 DOI: 10.7554/eLife.11102). All three mutations are lethal in homozygotes, and so symptoms were investigated in heterozygotes. The *Atp1a3* hypomorph (80% yield) exhibited no symptoms in motor skill tests, but the D801Y *Atp1a3* mutant (30% yield) showed baseline hyperactivity; hindlimb weakness; slow beam crossing; and interestingly, consistently-improved rotarod performance. The *Lamb1* mutant exhibited no baseline activity increase, but had hindlimb dystonic movements; many slips in beam crossing; and reduced rotarod performance. Histology did not detect spinal or sciatic nerve abnormalities in either symptomatic mouse. The *Atp1a3* D801Y mouse exhibited agitation and abnormal movements in response to ketamine, and could not be anesthetized with it. The response to ketamine in the *Atp1a3* hypomorph, in contrast, was the same as WT. The hypomorph was tested for potentiation of ketamine by repeated exposure: motor activity during recovery from the drug did increase, peaking at 3-4 days, but WT showed the same potentiation. In the lamb1t mouse, twitching of the hindlimbs is seen in sleep and in isoflurane anesthesia, and is caused by co-contraction of opposing muscles driven by abnormal activity in the spinal cord (Liu et al.). This twitching was exacerbated and prolonged by ketamine compared to isoflurane. Nitrous oxide, which overlaps with ketamine in inhibiting NMDA receptors, but which alone is not anesthetic in mice, also exacerbated twitching in lamb1t mice, and increased motor activity in *Atp1a3* D801Y mice compared to WT. In conclusion, the *Atp1a3* knock-in and lamb1t mice share exaggerated activating responses to certain drugs. We hypothesize that the drug sensitivity reflects an underlying imbalance of excitation-inhibition ratio due to mutation effects on synaptic activity (Na,K-ATPase) or synaptic plasticity (laminin); overflow of excitation is an endophenotype typical of dystonia and related disorders. Title: Acute cerebellar shRNA-mediated knockdown of sgce reproduces salient features of Myoclonus-Dystonia

Authors: *S. G. KEE, R. FREMONT, K. KHODAKHAH;
Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: Myoclonus dystonia (DYT11) is an inherited movement disorder caused by loss-of-function mutations in *SGCE* and characterized by involuntary jerking of the upper body (myoclonus) and sustained contraction of agonist and antagonist muscles that result in painful, twisted postures (dystonia). A striking feature of this disorder is that patients frequently report improvement of motor symptoms after consumption of alcohol. Unfortunately, the neural basis of DYT11 is unclear, although motor structures including the basal ganglia and cerebellum have been implicated. To better understand the neural causes of the symptoms in DYT11, we generated a mouse model of DYT11 using short hairpin RNA (shRNA) to knock down *sgce,* the mouse homolog of *SGCE*, in the adult mouse. We found, using two different shRNA sequences, that knockdown of *sgce* in the cerebellum, but not the basal ganglia, produced dystonia and repetitive jerk-like movements in mice. Furthermore, we showed that the motor symptoms of these mice improved after administration of ethanol. In contrast, the motor symptoms of a mouse model of a different hereditary dystonia which in patients is not responsive to ethanol, DYT1, did not lessen following ethanol administration. To test whether aberrant cerebellar activity underlies the motor symptoms in our mouse model of DYT11, we performed extracellular recordings from dystonic mice. We found that, compared to mice injected with a control shRNA that does not target any gene in the genome, both Purkinje cells and deep cerebellar nuclei (DCN) neurons fire aberrantly in dystonic mice. Future studies will seek to determine whether alcohol relieves symptoms in these mice by restoring the regular activity of the neurons. In addition, we will examine whether the irregular activity of Purkinje cells and DCN neurons is due to a change in the intrinsic activity of the neurons or whether it is caused by a change in their synaptic inputs.

Title: Immune system activation and neurodegenerative phenotypes in aged CIZ1 knock out mice

Authors: *M. KHAN[1], J. XIAO[2], M. LEDOUX[1];
[1]Neurol., Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN; [2]Neurol., Univ. of Tennessee Hlth. Sci. Ctr., Memphiis, TN

Abstract: CIZ1 is a $p21^{(Cip1/Waf1)}$ interacting zinc finger protein that plays an important role in DNA replication and cell cycle progression at the G1/S checkpoint. Germline or somatic variants in *CIZ1* have been associated with dystonia, Alzheimer disease and cancer. Recently, we have shown that germline knock-out of *Ciz1* is associated with mild motor, behavioral, and hematological abnormalities in young adult mice. However, the effects of CIZ1 deficiency in much older mice may be more relevant to the understanding of age-related neurological disorders such as isolated dystonia and Alzheimer disease. To this end, we have now characterized motor, cognitive and neuropathological phenotypes in 18-month old $Ciz1^{-/-}$ mice. Aged $Ciz1^{-/-}$ mice exhibited marked relative deficits in motor and cognitive functioning in comparison with WT littermates and younger $Ciz1^{-/-}$ mice. In particular, $Ciz1^{-/-}$ mice performed poorly on a crossmaze task, raised beam task, rotarod and open-field activity. Furthermore, $Ciz1^{-/-}$ mice exhibited increased inflammatory responses in brain as assessed by myeloperoxidase (MPO) activity, neutrophilic infiltration, reactive astrocytosis and activated microglia. TUNEL labeling showed that inflammatory and neurodegenerative markers were associated with significant increases in apoptotic cells. These findings suggest that the deleterious effects of CIZ1 deficiency become more pronounced with aging and CIZ1 knockout is associated with neurodegenerative behavioral and pathological phenotypes. Therefore, defective or deficient CIZ1 and closely related cell-cycle proteins could contribute to the pathogenesis of Alzheimer disease, isolated dystonia and age-related motor and cognitive decline in elderly human populations.

Title: DYT1 transgenic rats evolve dystonia after peripheral nerve injury

Authors: *S. KNORR[1], K. GRUNDMANN-HAUSER[2], J. VOLKMANN[1], C. IP[1];
[1]Dept. of Neurol., Univ. of Wuerzburg, Wuerzburg, Germany; [2]Inst. of Med. Genet. and Applied Genomics, Rare Dis. Ctr. Tuebingen, Univ. Tuebingen, Tuebingen, Germany

Abstract: DYT1 is the most common idiopathic torsion dystonia characterized by a typical limb-onset in childhood, followed by generalization of dystonic symptoms. However, although the GAG deletion of the *Tor1A* gene is known, the pathophysiology remains enigmatic. The reason for the markedly reduced disease penetrance of 30% is still unknown. We forward the hypothesis, that dystonia manifests in genetically predisposed individuals only after a "second hit" (e.g. abnormal sensory input) causing maladaptive plasticity of the basal ganglia-cortex network. To prove this hypothesis, we developed a novel dystonia scoring system to analyze dystonic symptoms after a traumatic injury in a transgenic DYT1 rat model (ΔETorA), that harbors the full human mutant *Tor1A* gene and does not show dystonia per se. Development of dystonia in wildtype (wt) and ΔETorA rats after sciatic nerve crush of the right hindlimb was observed by blinded scoring of videotapes taken during tail suspension. Dystonia of the hindlimbs was assessed by using a newly developed 0-5 point dystonia scoring system. Wt and ΔETorA rats were analyzed before (pre-OP) and after nerve injury (week 2, 5, 9 and 12). Control groups consisted of naive ΔETorA rats, naive wt rats, sham operated ΔETorA and wt rats. After nerve crush of the right hindlimb, wt and ΔETorA rats developed dystonic motor features. A maximum score of 5.0 ± 0.0 in ΔETorA rats and 4.8 ± 0.2 in wt rats was observed 2 weeks after surgery. After a slow decrease of the dystonia score in both groups, in nerve injured wt rats the dystonia score decreased to a minimum of 0.4 ± 0.3 on week 9 with a still constant low dystonia score at week 12 (0.6 ± 0.3). ΔETorA rats however demonstrated a significant higher dystonia score after crush injury at week 9 (1.9 ± 0.4) and week 12 (1.9 ± 0.4). All control groups stayed at a dystonia score level < 1 during the whole trial. A higher penetrance of dystonia in ΔETorA nerve injured rats (70%), compared to wt nerve injured rats (10%), was apparent by the dystonia scoring. Moreover, dystonic spreading to the contralateral hindlimb, indicative for a beginning

generalization, was observed in 35% of the nerve injured ΔETorA rats while none of the nerve injured wt rats developed signs for generalization.This newly established clinical dystonia scoring has the capability to reveal clinically apparent dystonia triggered by peripheral nerve injury in ΔETorA rats. We were able to calculate the penetrance of dystonia and distinguish between focal and beginning generalized dystonia by using this novel dystonia score. Our data indicate that peripheral nerve injury triggers dystonia in genetically predisposed animals supporting the "second hit" hypothesis.

Title: Deep brain stimulation evoked potentials reveal functional mechanisms of DBS treatment

Authors: *E. ARGUELLES, D. FERMAN, M. BERTUCCO, T. D. SANGER;
USC, Los Angeles, CA

Abstract: Dystonia is a movement disorder characterized by involuntary muscle contractions and abnormal postures. Dystonia can be considered as a disorder of aberrant plasticity, in which a complex set of physiological abnormalities leads to abnormal neural organization. Dystonic symptoms have been associated with basal ganglia dysfunction and increased cortical excitability. Deep brain stimulation of the internal segment of the globus pallidus (GPi DBS) is a common treatment for severe dystonia, despite an incomplete understanding of its mechanisms of action. Recently, we started to explore the effects of combined GPi and thalamic stimulation with more noticeable clinical improvement. We hypothesize that DBS disrupts the abnormal information flow through the pallidothalamocortical loop and reduces cortical excitability, leading to gradual brain reorganization. An essential component of this hypothesis is that DBS has an effect on cortex that could be mediated by anterograde trans-synaptic pathways from GPi and thalamus. We measure the effects of DBS on cortical activity by recording changes in scalp EEG evoked potentials by 15 Hz GPi and VL (ventrolateral thalamus) DBS. We collected data from 5 subjects implanted with GPi and VL DBS leads. We found that VL-DBS evoked potentials have an onset at ~15ms and peak at ~23ms, with higher amplitude in paracentral regions ipsilateral to stimulation side, and tend to be smaller for most distal stimulation contacts

(off target contacts). GPi DBS evoked potentials are less distinctive and are not always present. These results indicate that the effect of the stimulated GPi efferent axons do not necessarily reach cortex, instead, GPi DBS seems to have a regulatory effect on thalamus. The progressive time course of clinical improvement of dystonia and the absence of evoked potentials after GPi DBS reflect changes within the basal ganglia or thalamus that lead to gradual cortical reorganization. The clinical observations indicate that in some cases GPi DBS alleviates dystonic symptoms, whereas for most cases VL DBS improves tremor-like movements.

Title: Rs-fmri in cervical dystonia - associations between functional networks and temporal discrimination thresholds

Authors: S. NARASIMHAM[1], E. MCGOVERN[2], O. KILLIAN[1], B. QUINLIVAN[1], J. S. BUTLER[3], M. HUTCHINSON[2], *R. REILLY[4];
[1]Trinity Col. Dublin, Dublin, Ireland; [2]St. Vincent's Univ. Hosp., Dublin, Ireland; [3]Dublin Inst. of Technol., Dublin, Ireland; [4]Trinity College, Dublin|910004852|0, Dublin, Ireland

Abstract: Dystonia, a neurological disorder characterized by rigid body movements and abnormal postures, has till date, unknown pathophysiology. Previous literature reports impaired inhibition detected at various levels of the central nervous system with recent findings suggesting involvement of large-scale functional networks. The temporal discrimination threshold (TDT - shortest time interval at which two stimuli are detected to be asynchronous) has been shown to be abnormal in adult-onset primary torsion dystonia (AOPTD). Abnormal TDT values have been strongly correlated to AOPTD, eliciting its role as a possible endophenotype for Cervical Dystonia (CD). It has been postulated that abnormal TDT and CD result from disordered functioning of mid-brain network for covert attention (the Superior Colliculus (SC) being the primary node of dysfunction). Probing abnormal TDT in affected and unaffected first-degree

relatives would provide further information on the pathophysiology of dystonia and gene mutation carriage in families. Experimental evidence for this, as well as an investigation of the functional networks in this disorder remains to be explored.
To examine large-scale topology of functional brain networks in dystonia, we undertook a resting state-fMRI study. Resting state networks (RSNs) reflect the organization of structural and functional brain networks. It was employed to eliminate task performance related confounds across subjects. Our subjects (age and gender matched) were grouped as follows: a) 16 dystonia patients with abnormal TDT values, b) 16 relatives with normal TDT (unaffected relatives) and c) 16 relatives with abnormal TDT (affected relatives). It was hypothesised that the Default Mode Network and Salience Network would be the same across the cohorts, while there would be significant differences in the Frontoparietal Network (FPN), Visual Network (VN) and Basal Ganglia. We acquired data from these three cohorts, using a 3T Philips MRI Scanner. We implemented Independent Component Analysis to explore the different RSNs, compare the functional connectivity in each across the cohorts and correlate these with their TDT results. Preliminary statistical analysis (1-way ANOVA) with z-scores showed significant differences in functional connectivity in the FPN and VN ($p<0.05$, FWE corrected), consistent with previous findings. While the FPN plays a crucial role in attention, selection of relevant environmental information and sensory-motor processing, the SC is a chief node in the VN. These connectivity changes in the FPN and VN in affected relatives corroborates the mid-brain covert attention hypothesis of CD and abnormal TDT values.

Title: *In vivo* imaging reveals impaired connectivity across cortical and subcortical networks in a mouse model of DYT1 dystonia

Authors: *J. C. DESIMONE[1], M. FEBO[2], P. SHUKLA[1], E. OFORI[1], L. M. COLON-PEREZ[2], Y. LI[3], D. E. VAILLANCOURT[4];
[1]Dept. of Applied Physiol. and Kinesiology, [2]Psychiatry, [3]Neurol., [4]Dept. of Applied Physiol. and Kinesiology, Neurology, Biomed. Engin., Univ. of Florida, Gainesville, FL

Abstract: In humans, DYT1 dystonia represents the most common genetic form of the primary dystonias, and is caused by a trinucleotide (ΔGAG) deletion in one allele of the DYT1 (TOR1A) gene and subsequent removal of a single glutamic acid residue in the carboxyl terminal region of the torsinA protein. To advance our current understanding of the pathophysiology underlying human DYT1 dystonia, the current study examined *in vivo* functional connectivity of cortical, basal ganglia, and cerebellar networks in Tor1a (Dyt1) ΔGAG heterozygous knock-in (Dyt1 KI) mice using resting-state functional MRI and an independent component analysis. In addition, using diffusion MRI we examined how structural integrity across the basal ganglia and cerebellum directly relates to impairments in functional connectivity. Compared to wild-type (WT) control mice, Dyt1 KI mice exhibited increased functional connectivity in the striatum, thalamus, and somatosensory cortex - and reduced functional connectivity in the motor cortex and cerebellum. A support vector machine classification algorithm based on functional connectivity revealed a high area under the curve cross-validation in a testing cohort, and high genotype (Dyt1 KI, WT) prediction accuracy in an independent cohort. Further, Dyt1 KI mice demonstrated increased free-water in the striatum and cerebellum, and free-water values correlated with the degree of functional connectivity across cortical, basal ganglia, and cerebellar functional networks. The current study provides the first *in vivo* MRI-based assertion that the selective removal of a glutamic acid residue on the Tor1a protein produces network level functional abnormalities across cortical and subcortical brain regions. Moreover, our results show that free-water may serve as a sensitive marker of microstructural degeneration in mouse models of DYT1 dystonia.

Abstract: Pathogenic molecular mechanisms underlying the abnormal, painful muscle contractions characteristic of primary dystonia remain to be elucidated and current treatments are unsatisfactory. DYT6 dystonia is caused by mutations in THAP1 [Thanatos-associated (THAP) domain-containing apoptosis-associated protein] and is autosomal dominant and partially penetrant. The function of Thap1 in neurons is unknown, but there is a unique, neuronal 50-kDa Thap1-like immunoreactive species, and Thap1 levels are auto-regulated on the mRNA level. Neuroimaging in manifesting and non-manifesting carriers (NMCs) demonstrates abnormalities in the cerebello-thalamo-cortical and cortico-striato-pallido-thalamo-cortical pathways, similar to DYT1 dystonia. Prevalent theories on the pathophysiology of primary dystonias include developmental abnormalities of the cerebellum and striatal neurons and interneurons and their pathways, neurotransmitter and electrophysiological dysfunction, including monoamine neurotransmission and plasticity, and dysfunction of ion channels and intracellular signaling. We previously created two lines of mice with physiologic mutations, a Thap1^{C54Y} knockin (KI) mouse and a mouse with a null allele. The C54Y mutation prevents binding of Thap1 to DNA *in vitro*. In particular, we sought to determine the *in vivo* role of Thap1^{C54Y} and null alleles on the gene transcription signatures at postnatal day 1 (P1) in the mouse striatum and cerebellum in an attempt to correlate with specific genes and /or pathways with potential points of convergence on the pathogenesis of DYT6 dystonia. We performed RNAseq on P1 striata and cerebella from Thap1$^{C54Y/+}$, Thap1$^{+/-}$ and WT mice and pathway analysis revealed convergence with other forms of dystonia. We validated our findings by qPCR, Western Blotting and immunocytochemistry. Overall our findings may help to elucidate key pathways involved in the pathogenesis of DYT6 dystonia at an early time point.

Title: A circuit theory for the pathogenesis of blepharospasm

Authors: *D. A. PETERSON, T. J. SEJNOWSKI;
Salk Inst. CNL-S, La Jolla, CA

Abstract: Blepharospasm (BSP) is a focal dystonia that involves involuntary eyelid spasms, eye closure, and increased blinking. New treatment strategies could be developed if the pathophysiology that underlies BSP was better understood. The objective of this study was to develop a theoretical model of pathological circuits implicated in BSP. The model integrates three bodies of previous experimental and theoretical work: 1) an overarching theory for the multifactorial pathogenesis of isolated dystonias, in which we postulated that a combination of abnormal dopaminergic signaling in the striatum and abnormal patterns of sensorimotor state space utilization could induce pathological reinforcement learning that leads to dystonia (Peterson and Sejnowski 2010 Neurobiol Dis), 2) a two-hit rodent model specifically of BSP, demonstrating that the joint contribution of dopaminergic and ophthalmic factors could be critical in the pathogenesis of the disorder (Schicatano, Basso, and Evinger 1997 J Neurophysiol), and 3) a computational mean-field model of motor control circuits, including simulations of the impact of pathological dopaminergic signaling (van Albada and Robinson 2009 J Theor Biol). We incorporated three additional features critical to cranial motor control: 1) the joint influence of motor cortical regions and direct descending projections from the substantia nigra pars reticulata on brainstem motor nuclei, 2) nested loops composed of the trigeminal blink reflex arc and the long sensorimotor loop from trigeminal nucleus through thalamus to somatosensory cortex back through basal ganglia to the same brainstem nuclei modulating the reflex arc, and 3) abnormalities in the basal ganglia dopamine system that provide a sensorimotor learning substrate which, when combined with patterns of increased blinking induced by the orbicularis oculi lesion, leads to abnormal sensorimotor mappings

manifest as BSP. We use a biologically plausible computational rule for dopamine-mediated synaptic plasticity in the striatum, selective for D1- and D2-type dopamine receptors. The model reproduces the blink reflex physiology from Schicatano and is consistent with selective impairments in the D2-family of dopamine receptors reported from PET studies of BSP patients. The model also makes predictions that can be tested in new experimental animal models based on emerging genetics in dystonia, including the recently characterized striatal-specific D1R transduction alterations caused by the GNAL mutation. More broadly, the model will provide a platform for future studies mechanistically linking multiple factors in the pathogenesis of BSP.

Title: MR imaging following a single low dose of trihexyphenidyl in patients with cervical dystonia

Authors: *R. G. BURCIU[1], P. SHUKLA[1], E. OFORI[1], J. CHUNG[1], C. HESS[2,3], N. MCFARLAND[2,3], A. WAGLE SHUKLA[2,3], M. OKUN[2,3,4], D. VAILLANCOURT[1,2,5]; [1]Dept. of Applied Physiol. and Kinesiology, [2]Dept. of Neurol., [3]Ctr. for Movement Disorders and Neurorestoration, [4]Dept. of Neurosurg., [5]Dept. of Biomed. Engin., Univ. of Florida, Gainesville, FL

Abstract: Cervical dystonia (CD) is the most common type of primary dystonia, and is characterized by involuntary neck muscle contractions that cause abnormal movements of the neck and head. Oral pharmacological therapy for patients with dystonia often includes anticholinergic agents such as trihexyphenidyl. Although anticholinergic medication can provide symptomatic relief in CD, it is not entirely clear how it affects the brain. In the current study, we were interested in testing whether acute administration of a low dose of trihexyphenidyl has an effect on motor-related brain activity and/or water diffusion within brain tissue in patients with CD. To investigate underlying pathophysiology of CD and response to trihexyphenidyl, we chose a behavioral task that we did not expect to elicit a behavioral difference between CD and

controls. The task was a grip force hand task. A total of 16 patients with idiopathic CD completed two sessions of MR imaging: OFF medication, and average two hours following a single 2-mg dose of trihexyphenidyl (i.e., ON medication). On both occasions we collected fMRI scans while CD performed a visually-cued unimanual grip force task, and 64 direction diffusion MRI scans from which we calculated free-water and free-water corrected FA measures in several regions of interest across the basal ganglia, thalamus, cerebellum, brainstem, and corpus callosum. A group of age- and gender-matched healthy individuals who underwent the same scanning protocol as CD but not the pharmacological intervention was also included in the study. We found no differences in behavior during grip force between CD and controls, and task performance did not change with the administration of trihexyphenidyl. Symptom severity as assessed with the Burke-Fahn-Marsden Dystonia Rating Scale was slightly but not significantly reduced posttreatment. The fMRI data showed that when OFF medication CD had reduced activity in the sensorimotor cortex (bilaterally), and increased activity in the right dorsal premotor cortex, pre-supplementary motor area, and lobule VI of the cerebellum, as compared to controls. A single dose of trihexyphenidyl was associated with a bilateral increase in activity in the sensorimotor and ventral premotor cortices. We found no differences in free-water or free-water corrected FA measures between controls and CD, and no drug effect on these measures in CD. Together, results suggest a baseline disruption of sensorimotor processing in CD that is modulated acutely by administration of trihexyphenidyl, providing new leads for models of anticholinergic action in CD.

Abstract: Protein clearing pathways represent a powerful physiological mechanism to control homeostasis within eukaryotic cells, while their dysfunction is a key factor in the molecular mechanisms underlying neuronal degeneration. These clearing pathways remove misfolded proteins and altered organelles. Two main pathways named autophagy pathway and ubiquitin proteasome are considered to be prominent in eukaryotic cells. These pathways are commonly viewed as distinct biochemical cascades occurring within specific cytosolic compartments where pathway-specific enzymatic activity is believed to take place. The classic view considers these clearing pathways as distinct depending on various items: different compartmentalization, different substrates, different enzymatic activities, different roles in cell homeostasis. We just described the morphological convergency of autophagy (ATG) and ubiquitin proteasome (UP) pathway to form a novel organelle named autophagoproteasome. This is shown by confocal microscopy and immune-electron microscopy. Both ATG and UP are recruited robustly during methamphetamine exposure playing a pivotal role in methamphetamine toxicity. Methamphetamine dramatically alters autophagoproteasomes which play a critical role in counteracting methamphetamine toxicity. Despite being segregated within a single organelle ATG and UP components undergo a slight different pharmacological regulation. Both pathways are up-regulated along with autophagoproteasome following methamphetamine administration, but ATG prevails for low doses while UP takes over for higher doses of methamphetamine, which demonstrates a common, dopamine-dependent regulation with slight differences for these clearing pathways within a single organelle. ATG and UP component appear to be molecularly bound within autophagoproteasome depending on specific pharmacological stimulation as shown by western blotting of immunoprecipitates. The structure and function of the autophagoproteasome critically relies on mTOR activity for all its components. The fine tuning of mTOR activity is likely to impact significantly methamphetamine toxicity as well as dopamine-dependent pathological conditions.

Title: PACAP protects against toxicity induced by combination of low alcohol and nicotine in SH-SY5Y cells

Authors: *S. MANAVALAN[1,2], B. GETACHEW[3], K. F. MANAYE[4], S. J. KHUNDMIRI[4], A. B. CSOKA[5], A. TAMAS[1], D. REGLODI[1], Y. TIZABI[3];

Abstract: Pituitary adenylate cyclase-activating polypeptide (PACAP) is a neuroprotective endogenous 38 amino acid neuropeptide. *In-vitro* and *in-vivo* studies have demonstrated that PACAP protects against neuronal injury related to ischemia, trauma and various endogenous and exogenous toxic agents. We have previously reported that PACAP protects against toxicity induced by high concentrations of ethanol (e.g. 500 mM) in neuroblastoma-derived SH-SY5Y cells (Manavalan et al. SFN abst 2015). At very low concentrations (10 mM) ethanol has neuroprotective effects. Similarly, nicotine at very low concentrations (10 μM) may also be neuroprotective. Surprisingly, however, the combination of low concentrations of alcohol and nicotine results in significant toxicity in SH-SY5Y cells. The aim of this study was to determine the molecular mechanisms of PACAP-dependent protection against ethanol and nicotine-induced toxicity. Exposure of SH-SY5Y cells for 24 h to a combination of ethanol (10 mM) and nicotine (10 μM) resulted in approximately 50% cell death that was blunted by pretreatment with 100 nM PACAP. The protective effects of PACAP were inhibited by 1 μM PACAP antagonist (PACAP 6-38). These data suggest that PACAP prevents cell death by a combination of low dose alcohol and nicotine in a PAC1 receptor-dependent manner. Further studies are underway to elucidate intracellular mechanism(s) responsible for observed toxicity and protection by PACAP.

Title: Understanding the regeneration mechanisms in the hippocampus of control and fetal alcohol rats during the first two postnatal months

Authors: *B. ELIBOL[1], M. BEKER[1], U. KILIC[2], E. JAKUBOWSKA-DOGRU[3];
[1]Dept. of Med. Biol., Bezmialem Vakif Univ., Istanbul, Turkey; [2]Dept. of Med. Biol., Istanbul Medipol Univ., Istanbul, Turkey; [3]Dept. of Biol. Sci., Middle East Tech. Univ., Ankara, Turkey

Abstract: Ethanol, a powerful teratogen that leads to neuronal death during development, distorts motor and cognitive functions of the individuals subjected to alcohol in the perinatal period. However, these behavioral abnormalities were shown to be compensated in later times through the puberty by a recovery mechanism which hasn't been identified yet. In this study pups were treated with ethanol (6 gr/kg/day) by intragastric gavage between the 7^{th}-21^{th} gestational days. The hippocampal tissue of pups was collected at postnatal day (PD) 1, PD10, PD30, and PD60 for evaluation of regeneration process by western blot analysis of proteins which is found in the signaling pathways for survival, neurogenesis, angiogenesis and apoptosis. Firstly, at PD1, prenatal ethanol increased Akt which controls the cellular growth and survival, glucose metabolism and cellular migration, CREB which is a transcription factor regulated by Akt, neuronal precursor Nestin, neuronal migration marker Doublecortin (DCX), mature neuronal marker NeuN, pro-apoptotic Bax and anti-apoptotic Bcl-2 and Bcl-XL. At PD30 which is the age showing significant behavioral abnormalities, prenatal ethanol increased Akt and mitogen activated kinase kinase ERK suggesting the behavioral recovery observed at PD60 by activating survival kinases. In addition, prenatal alcohol induced a decrease in the number of mature neurons in PD30 and it approached to control levels in PD60. In fact alcohol causes an artificial impact by triggering neurogenesis, because it ends up with reduction in mature neuron number in adulthood. Angiogenesis marker PECAM also supports the results of neurogenesis. In conclusion, the effect of prenatal alcohol treatment on selected proteins can be observed at birth which disappears in the following periods of development. This action is the consequence of recovery mechanism created against inhibitory effects of alcohol. Survival protein Akt is possibly at an important position for this mechanism by regulating many other functions such as neurogenesis and angiogenesis.

Title: Exercise mitigates cognitive dysfunction through mitochondrial remodeling in alcohol administrated mice

Authors: A. K. GEORGE, 40202[1], Y. ZHAI[1], M. NURU[1], *N. TYAGI[2];
[1]Physiol., Univ. of Louisville, Louisville, KY; [2]Physiol., Univ. Of Louisville, Louisville, KY

Abstract: Alcohol consumption is a potent inducer of oxidative stress. Previous data indicate that alcohol consumption induces mitochondrial dysfunction and free radical production in mouse cerebral cortex. Exercise has been recommended by clinicians as a secondary protective therapy; however, its effect on brain functions through mitochondrial interventions has not been fully explored. Therefore, we hypothesized that exercise mitigates alcohol-induced neurodegeneration and decline in cognitive function through mitochondrial remodeling. To test this hypothesis, we selected 10-12 weeks old male wild-type mice (C57BL/6, WT), grouped as follows: 1) WT, 2) WT+ Alcohol, 3) WT+ Exercise, 4) WT+ Alcohol+ Exercise. Mice were given an intraperitoneal injection of EtOH (1.5g/kg BW) or saline solution every day for 12 weeks. The mice were exercised for 12 weeks on a treadmill with a controlled speed of 7 meters/min for the first week, the speed of 10 meters/min for the second week and 11 meters/min in the following weeks and a total of 330 meters every day. After each 110 meters mice were given rest of 10 minutes. Cognitive and behavior alterations were assessed by novel object recognition, Passive avoidance, and Y-maze tests. Mitochondrial membrane potential and mitochondrial permeability changes were evaluated by flow cytometry. Our results suggest significant improvement in cognitive functions in exercised alcohol administrated group, as compared to non-exercised alcohol administrated group. The involvement of mitochondrial remodeling in mice the following exercise was further confirmed and we found there was a significant increase in ATP production, membrane potential, oxygen consumption, copy- number as well as a decrease in reactive oxygen species when compared with non-exercised alcoholic mice. Furthermore, a considerable reduction in TUNEL reactivity was determined in intact mitochondria isolated from exercised group as compared to non-exercised alcoholic mice. In addition, the effect of exercise on neuronal survival in the alcoholic brain was confirmed by fluoro-jade C reactivity. Taken together, our results indicate a myriad of beneficiary effects of exercise over mitochondrial pathology during alcoholism. Furthermore, our findings suggest

exercise mitigates neurodegeneration and cognitive dysfunction and thereby improving total mitochondrial function. This work was supported by NIH grant HL107640-NT

Title: Alcohol exacerbates ketamine-induced neurotoxicity and the involvement of CREB pathway

Authors: *D. ZUO[1], Y. LIU[1], F. SUN[1], Z. LI[1], Y. SUN[2], Y. WU[1];
[1]Pharmacol., Shenyang Pharmaceut. Univ., Shenyang, China; [2]Jilin Provincial Inst. for Food and Drug Control, Changchun, China

Abstract: Ketamine, a noncompetitive antagonist of the *N*-methyl-D-aspartate (NMDA) receptor, has been used as an anesthetic in clinic. Recently, ketamine abuse or recreational use has been gaining increasing attention, especially the combined abuse of ketamine and alcohol in adolescents. However, the characteristic neurotoxicity and the underlying mechanism after ketamine and alcohol abuse are still not been fully understood. The aim of the present investigation was to explore the pattern of neurotoxicity and the underlying mechanism of ketamine and alcohol co-abuse *in vivo* and *in vitro*. Here, Sprague-Dawley rats were treated with ketamine and/or alcohol for continuous 14 days. Then, morphological changes, cell apoptosis and related protein expression were investigated. In addition, the detailed pattern of neurotoxicity and the mechanism after ketamine and/or alcohol treatment were also investigated in neuronal PC12 cells *in vitro*. Our results revealed that alcohol significantly increased ketamine induced neurotoxicity of rats manifested by severer morphological and apoptotic changes in the cortex and hippocampus. Western blotting studies showed that p-CREB, p-Akt, CAMK4 and PKA expression were obviously decreased and cleaved caspase-3 expression were significantly increased after ketamine and alcohol co-treatment. *In vitro* studies of PC12 cells further proved that alcohol aggravated ketamine induced decrease of cell viability and apoptotic changes. Immunofluorescence showed that the level of Ca^{2+} increased significantly. Western blotting

results further proved that the expression of p-AKT, p-CREB, CAMK4, PKA, Bcl-2 and BDNF were decreased, and cleaved caspase-3 expression was significantly increased after ketamine and alcohol co-treatment. CNQX, an AMPA/KA receptor antagonist, could partly cancel the change induced by alcohol and ketamine co-treatment, which indicates that AMPA/KA receptor activation, at least in part, are involved in the neurotoxicity of ketamine and alcohol co-administration and CREB signaling pathway might be significantly inhibited during these processes. Keywords: ketamine; alcohol; neurotoxicity

Title: Alcohol increases olfactory manganese uptake into the brain and exacerbates neurotoxicity

Authors: ***M. HAN**, J. KIM;
Northeastern Univ., Boston, MA

Abstract: Environmental and occupational exposure to heavy metals remains one of the major concerns in public health. Manganese (Mn) is a potential neurotoxicant that alters emotional behavior and motor function. Mn absorption is in part mediated by iron transporters whose expression is modified by alcohol treatment. However, it is largely unexplored whether alcohol exposure influences the pharmacokinetics and neurotoxicity of Mn. Thus, we investigated Mn deposition into the brain and behavioral and neurochemical functions in Mn-exposed mice upon alcohol consumption. Mice (mixed strain; 3-4 weeks old) were treated with 10%(v/v) alcohol by drinking water for a total of 4 weeks. Since the second week of alcohol treatment, $MnCl_2$ (5 mg/kg) or saline was intranasally instilled daily for 3 weeks. In saline-instilled groups, ethanol-exposed mice showed increased Mn levels by 15% ($p<0.001$) in the brain compared with water-drinking mice. Upon Mn instillation, alcohol exposure increased brain Mn levels by 38% ($p=0.004$). Furthermore, the divalent metal transporter 1 (DMT1), a major iron transporter that also transports Mn, was up-regulated in the brain upon ethanol consumption (90% increase,

p=0.002) as determined by western blot analysis. These results indicate that alcohol consumption increases Mn uptake into the brain, possibly through up-regulation of DMT1. In the elevated plus maze task, there was no significant difference in time spent in open arms between alcohol- and water-drinking mice in the absence of Mn exposure. Upon Mn instillation, alcohol-exposed mice spent less time in open arms (24% decrease; p=0.011) than water-drinking mice, indicating that alcohol exposure increases Mn-associated anxiety. Since Mn modifies dopamine signaling, which is involved in emotional behavior, we quantified dopamine-related protein expression in the brain by western blotting. After alcohol exposure, the dopamine transporter (DAT) showed a trend of up-regulation (124% increase; p=0.066), while the dopamine receptor 1 (D1DR) was down-regulated (28% decrease; p=0.034). Upon Mn instillation, DAT was up-regulated by 414% (p=0.001) and D1DR was decreased by 34% (p=0.040) in alcohol-exposed mice compared with water-drinking mice. These results suggest decreased dopamine signaling with alcohol consumption. Notably, Mn-instilled mice with alcohol drinking demonstrated decreased GABA levels by 30% (p=0.006) compared with Mn-instilled mice. Taken together, our results suggest that individuals drinking alcohol are more susceptible to increased olfactory uptake of Mn and metal-induced neurotoxicity, likely due to altered dopaminergic and GABAergic signaling pathways.

Title: The effects of alcohol on lipopolysaccharide-induced inflammatory response in rat mixed glial cultures

Authors: *J.-Y. WANG[1], C.-L. CHEN[2], S.-Y. CHEN[1];
[1]Dept Nursing (Basic Med. Sci), Hungkuang Univ., Taichung, Taiwan; [2]Li-Shin Hosp., Taoyuan, Taiwan

Abstract: Alzheimer's disease (AD) is the most common neurodegenerative disorder. It is associated with relevant neuroinflammatory response. The microglial cells, kind of glial cells, are the resident inflammatory cells in the brain that promote brain inflammation in response to

stimuli. Astrocytes, another kind of glia, also can produce mediators that involve in neuroinflammation. The processes accompany with inflammatory response are increasing in the expression of transcription factor NFκB, inducible nitric oxide synthase (iNOS) and the release of inflammatory mediators (ex. nitric oxide (NO) and cytokines). Ultimately, these events may create a vicious cycle to induce neuronal injury. Alcohol is considered to be one of the most commomly abused chemical. Alcohol consumption has various effects on various organs. Experimental evidence indicated that alcohol consumption can alter the inflammatory response. Furthermore, neuroinflammation is thought to be a factor in alcohol-induced neurodegeneration, and microglia activation may be a key role. It is known that ethanol exposure increased the level of iNOS and decreased the number of neurons in mice brain. However, some data indicated that the microglial activation was not equivalent to neuroinflammation in alcohol-induced neurodegeneration. Although there are many studies to investigate the effect of alcohol, but the role of alcohol in neurodegeneration has not consensus. In this study, we wanted to estimate the influence of alcohol on lipopolysaccharide (LPS)-induced neuroinflammation in mixed glial cells. The *in vitro* experiment: rat cortical mixed glial cultures will be subjected to (1) control; (2) LPS treated with 1, 10, 100, 500 or 1000 ng/ml; (3) Alcohol treated with 0.1, 0.5, 1 or 2 % ; (4) pretreatment of alcohol following LPS treatment; all of above were treated for 1, 3 or 5 days. Cell density and morphology will be observed by phase-contrast microscopy. Cell injury will be assessed by MTT reduction. The production of NO will be measured to estimate the inflammatory responses. The expression of NFκB and iNOS will be estimated by western blot analysis and immunohistochemical staining. Our data indicated that the cell viability significantly decreased in LPS treatment for 1 day, but the MTT reduction (% of control) was about 90 %. The accumulation of nitrite was significantly increasing in 1, 3 or 5 days. Both MTT reduction and nitrite accumulation in alcohol exposure were not significant difference. Pretreatment with alcohol with high doses (1 % and 2 %) significantly decreased the LPS-induced NO production. We suggested that alcohol can attenuate the LPS-induced inflammatory response.

Title: Transcriptomic immaturity of the hippocampus and prefrontal cortex in patients with alcoholism

Authors: *T. MURANO[1,2];
[1]Ctr. for Genet. Analysis of Behavior, Natl. Inst. For Physiological Sci., Aichi, Japan; [2]Fujita Hlth. Univ., Icms, Japan

Abstract: Alcoholism, which is defined as the recurring harmful use of alcohol despite its negative consequences, has a lifetime prevalence of 10%, and is a serious social problem. Accumulating evidence indicate that alcoholism is often comorbid with schizophrenia and these diseases have common genetic risk factors and pathophysiology, such as hypoglutamatergic and hyperdopaminergic activities in the brain.
By performing informatics analyses of genome-wide gene expression data, we previously revealed that the brains of patients with schizophrenia have significant similarities with those of infants in their gene expression patterns in the hippocampus and prefrontal cortex (PFC). Considering the similarities between alcoholism and schizophrenia, we hypothesized that the brain cells of patients with alcoholism also show pseudo-immature phenotypes. In this study, we compared the genome-wide gene expression patterns in the hippocampus and PFC of patients with alcoholism with those of normal infants. Our informatics analyses demonstrated that the gene expression patterns of patients with alcoholism were significantly similar to those of infants in both brain regions. Interestingly, the genes that were different in both groups significantly overlapped with the genes regulated in the developmental course of parvalbumin-positive neurons. These results suggest that the pseudo-immaturity of the hippocampus and PFC could be one of the endophenotypes of alcoholism underlying the brain dysfunctions and behaviors of alcoholism.

Title: Frequency-dependent changes of brain signal oscillations in alcoholism

Authors: J.-Y. HONG[1], E. M. MÜLLER-OEHRING[1,2], A. PFEFFERBAUM[1,2], E. V. SULLIVAN[2], D. KWON[1,2], *T. SCHULTE[1,3];
[1]Neurosci Program Ctr. Hlth. Sci., SRI Intl., Menlo Park, CA; [2]Dept. of Psychiatry & Behavioral Sci., Stanford Univ., Stanford, CA; [3]Pacific Grad. Sch. of Psychology, Palo Alto, CA

Abstract: Chronic alcoholism is associated with changes in brain activity and intrinsic connectivity subserving attention, salience, and executive control function. Most functional magnetic resonance imaging (fMRI) studies have examined brain signal fluctuations at a single, lower frequency oscillation band (0.01-0.08 Hz), thereby ignoring information from other frequencies. To measure resting-state fMRI activity in terms of amplitude of spontaneous blood-oxygen-level-dependent fluctuations across different frequency bandwidth, we implemented an amplitude of low frequency fluctuation (ALFF) quantification. The measure of frequency oscillation power has been linked to neuronal physiological properties. Oscillation power differs across frequency bandwidths, with power signatures regionally specific, where neocortical areas having greater power in lower frequency bands, whereas allocortical regions having greater power in higher frequency bands. We examined potential frequency-dependent differences using ALFF to analyze resting-state fMRI data in 56 sober, chronic alcoholics compared with 56 age- and sex- matched healthy controls (HCs). ALFF analysis was applied to the smoothed data to calculate the frequency power spectrum for each voxel across three frequency bandwidths: slow-5 (0.01-0.027 Hz), slow-4 (0.027-0.073 Hz) and slow-3 (0.073-0.198 Hz). Because ALFF values have been shown to differ across frequency bands, we specified contrasts between each pairing of the three frequency bands to examine differences in ALFF values across frequency bands. In addition, group-difference contrasts examined ALFF differences between alcoholics and HCs in each frequency band. A significant threshold was $p<0.05$. Regardless of diagnosis, higher ALFF values in the slow-3 band were observed in allocortical regions (limbic areas, cingulate cortex, insula), whereas higher ALFF values in the slow-4 and slow-5 bands were exhibited in neocortical regions (occipital, parietal, sensorimotor, medial frontal). Relative to HCs, alcoholics showed greater frequency oscillation power in the orbital frontal cortex across all frequency bands. In addition, group differences showed less ALFF power in alcoholics in the posterior insula within higher frequency bands and in the parietal cortex within slower frequency bands. Application of different distribution attributes within cortical executive control regions and sensorimotor regions enabled detection of frequency-specific power alterations in alcoholism that may reflect differences in the functional connectivity potentially underlying alcohol-related cognitive or motor deficits.

Title: Vitamin A deficiency affects the hippocampal molecular composition of the rats exposed to chronic ethanol intoxication and ethanol withdrawal- an FT-IR study

Authors: *I. DURSUN[1], B. ELIBOL[2], F. SEVERCAN[3], E. JAKUBOWSKA DOGRU[3]; [1]Dept. of Physiol., Istanbul Kemerburgaz University, Fac of Med., Istanbul, Turkey; [2]Dept. of Med. Biol., Bezmialem Vakif Univ., Istanbul, Turkey; [3]Dept. of Biol. Sci., Middle East Tech. Univ., Ankara, Turkey

Abstract: The numerous adverse effects of ethanol abuse and ethanol withdrawal on behaviour, brain morphology and physiology are well documented and commonly accepted. In contrast to this, the understanding of the molecular mechanisms underlying these pathological effects is still incomplete. The aim of the present study was to examine the effects of prolonged, lasting 3 months, ethanol intake by liquid diet and subsequent ethanol withdrawal on the molecular profiles of lipids, proteins and nucleic acids of rat hippocampus using FT-IR spectroscopy. A potential destructive effect of the vitamin A deficiency during ethanol intake and ethanol withdrawal was also investigated. In the present study, ethanol consumption and withdrawal produced some changes in proteins' structure having little effect on the lipids according to band frequency changes. On the other hand, dietary depletion of vitamin A had a strong effect on the molecular structure of the hippocampus. Vitamin A deficiency caused frequency shifts in protein bands suggesting protein denaturation and produced significant decrease in the frequencies of lipid bands (CH_2 asymmetric and symmetric) suggesting lipid ordering and thus a decrease in acyl chain flexibility. Interestingly, in both presence and absence of the vitamin A, a decrease in the membrane fluidity which was predicted from significant decrease in the bandwith of CH_2 asymmetric stretching band was observed due to ethanol intake. However, in parallel to lipid ordering, the decrease in the membrane fluidity was more dramatic in the absence of vitamin A. Vitamin A deficiency also showed additional negative effects on the lipid and nucleic acids by decreasing their concentrations and decreasing in the number of double bonds in fatty acids and thus decreasing the ratio of unsaturation to saturation. In conclusion, depletion of vitamin A aggrevated the effects of ethanol intake and withdrawal by decreasing lipid disordering and membrane fluidity and changing protein structure. Keywords: Ethanol, FT-IR spectroscopy, rat hippocampus, membrane fluidity, lipid disordering

Title: Neural and behavioural changes in periadolescent male mice after prolonged nicotine and MDMA treatment

Authors: *P. A. ADENIYI[1], P. D. SHALLIE[2], O. M. OGUNDELE[3];
[1]Afe Babalola Univ. Ado-Ekiti (ABUAD), Ado-Ekiti, Nigeria; [2]Dept. of Human Anat., Olabisi Onabanjo Univ., Ago – Iwoye, Nigeria; [3]Dept. of Human Anat., Afe Babalola Univ., Ado - Ekiti, Nigeria

Abstract: The interaction between MDMA and Nicotine affects multiple brain centers and neurotransmitter systems (serotonin, dopamine and glutamate) involved in motor coordination and cognition. In this study, we have elucidated the effect of prolonged (10 days) MDMA, nicotine and a combined Nicotine-MDMA treatment on motor-cognitive neural functions. In addition, we have shown the correlation between the observed behavioural change and neural structural changes induced by these treatments in BALB/c male mice. We observed that MDMA (2 mg/Kg body weight; subcutaneous) induced a decline in motor function, while Nicotine (2 mg/Kg body weight; subcutaneous) improved motor function in male periadolescent mice. In combined treatment, Nicotine reduced the motor function decline observed in MDMA treatment, thus no significant change in motor function for the combined treatment versus the control. Nicotine or MDMA treatment reduced memory function and altered hippocampal structure. Similarly, a combined Nicotine-MDMA treatment reduced memory function when compared with the control. It is noteworthy to mention that a combined treatment increased the rate of lipid peroxidation in brain tissue.

Title: Regulation of tyrosine hydroxylase in response to co-administration of nalbuphine in opiate dependent rats

Authors: *R. RAGHAV[1], R. JAIN[1], T. S. ROY[2], A. DHAWAN[1], P. KUMAR[2];
[1]NATIONAL DRUG DEPENDENCE TREATMENT CENTER, DEPARTMENT OF PSYCHIATRY, ALL INDIA INSTITUTE OF MEDICAL SCIENCES, NEW DELHI, India;
[2]Anat., All India Inst. of Med. Sci., New Delhi, India

Abstract: Background: Opiate dependence is associated with long term adaptive changes in brain that involve gene expressions. Chronic morphine administration increases dopamine levels in Ventral Tegmental Area (VTA). Such up-regulation of dopamine has been related to behavioral effects of drugs. Among the most consistent drug-induced adaptations in the VTA is induction of tyrosine hydroxylase (TH) the rate-limiting enzyme in the biosynthesis of dopamine. The mechanism underlying these adaptations has remained controversial. The present study evaluated the effects of Nalbuphine on opiate withdrawal and expressions of TH in rat brain. **Method:** Male adult Wistar albino rats were made physically dependent by administrating increasing dose of morphine and withdrawals were precipitated with naloxone. Somatic signs of withdrawals were scored by using Gellert-Holtzman rating scale. Nalbuphine was co-administered acutely and chronically in variable doses with morphine (0.1, 0.3, 1.0, 3.0 mg/kg, i.p.). Thereafter, blood was drawn from heart for corticosterone levels and brain was dissected out for estimating TH expressions. **Results:** Animals pretreated with acute dose of nalbuphine did not produce any effect on GH score, plasma corticosterone levels and TH expressions. At behavioral level, some symptoms of physical opiate withdrawal were reduced as well as significant decrease was observed on GH score, plasma corticosterone levels and TH expressions with chronic co-administration of nalbuphine at all doses. **Conclusion:** These findings suggest that withdrawal induced TH changes play a role in the behavioral expression of opiate withdrawal. These findings further supports that co-administration of nalbuphine with morphine may constitute a preferable superior approach to the treatment of opiate addiction. Title: Prolonged sedation with opioids and benzodiazepines in full-term infants is associated with decreased subcortical volumes: a pilot study

Authors: S. L. WILCOX[1], M. DROTTAR[2], J. SOLODIUK[1], R. W. JENNINGS[3], P. E. GRANT[2], *D. BAJIC[1];

Abstract: Prolonged administration of opioids and benzodiazepines used for pain and sedation management in the youngest of patients is associated with a high incidence of drug tolerance and dependence. Our understanding of potential immediate effects of such treatment on the developing brain is limited. We hypothesized that prolonged sedation associated with opioid and benzodiazepine dependence in full-term infants younger than 1-year of age would be associated with significant decrease in volumes of subcortical structures when compared to controls. We compared patients with healthy controls at two ages: <6 months (N=4 patients and 4 controls) and 6-12 months (N=3 patients and 1 control) as per IRB approval at Boston Children's Hospital. All participants were scanned on the same 3T MRI scanner. 3D T1 anatomical images were acquired using a 32-channel head coil (TR 2520ms; TE 1.75ms; FOV 180x180; slice thickness 1mm; voxel size 1.0x1.0x0.99 mm). Subcortical volumes were estimated using FSL's I*ntegrated Registration and Segmentation Tool* (FIRST). We present estimated and normalized bilateral volumes of forebrain subcortical structures (caudate, putamen, globus pallidus, n. accumbens, hippocampus, thalamus, and amygdala) and that of the brainstem. There are no differences between volumes of the left and right structures of the forebrain or the brainstem in either patients or controls. Estimated normalized volumes (presented as % of the whole brain volume) were smaller in older groups. In addition, estimated normalized volumes of all the structures in patients were about half those in controls at both ages. Future investigations of gray and white matter organization in at-risk full-term infants can provide crucial information of how prolonged sedation associated with development of opioid and benzodiazepine dependence can affect brain development and give rise to potential functional alterations later in life.

Title: The effects of commonly used opioids on neuronal cell cultures

Authors: *E. H. NYLANDER, A. GRÖNBLADH, E. FLAIEH, L. LEOSON, S. ZELLEROTH, M. HALLBERG;
Dept of pharmaceutical biosciences, Uppsala Univ., Uppsala, Sweden

Abstract: Introduction: Chronic non-medical use of opioids can cause cognitive dysfunction by inhibiting neurogenesis and inducing neuronal apoptosis. In the US, both frequency of use and opioid-related disorders are increasing and a similar trend has been observed in Scandinavia. Since these trends also involve young adults with still undergoing development of the central nervous system, the outcomes of these neurotoxic events must be further evaluated.
Aim: The aim of the current study was to examine the acute and long-term neurotoxic effects of different opioids on primary neuronal cell cultures.
Methods: Neuronal tissue was dissected from embryonic day 17 rats and was enzymatically digested and mechanically dissociated in order to acquire primary neuronal cell cultures. At day 7 *in vitro,* varying concentrations of opioids (oxycodone, ketobemidone, buprenorphine and fentanyl) were added to the cells for 24 hours or longer. Untreated cells were placed in serum-free media and served as controls. Cell viability was measured using the colometric MTT assay and cytotoxicity was assessed using the lactate dehydrogenase (LDH) assay.
Results: Each opioid induced neurotoxic effects. However, the lethal dose 50% (LD_{50}) varied between the drugs. Certain drugs, such as oxycodone, only demonstrated pronounced toxic effects after long-term treatment.
Conclusion: The present study suggests that both acute and long-term use of opioids may induce neurotoxic effects on primary neuronal cell cultures. The result further highlights the problems associated with opioids and can provide further insight on how to counteract these problems.

Title: Nrf2 activators with distinct mechanisms of action induce divergent pharmacodynamic and functional responses in primary human astrocytes

Authors: *K. E. RICHTER, M. S. BRENNAN, Z. XIN, E. Y.-. S. LIN, B. LUCAS, R. H. SCANNEVIN;
Biogen, Inc., Cambridge, MA

Abstract: Oxidative stress is thought to play a key role in several neurodegenerative diseases, and one potential therapeutic strategy is to activate endogenous cellular antioxidant responses. Nuclear factor-erythroid 2-related factor 2 (NRF2, NFE2L2) is a transcription factor expressed in astrocytes, microglia and many other cell types that regulates expression of the antioxidant response by binding the Antioxidant Response Element (ARE), regulating the transcription of many genes responsible for maintaining oxidative and inflammatory homeostasis and detoxifying xenobiotics. Under basal conditions, Nrf2 is maintained and constitutively degraded in the cytosol by interaction with the chaperone-like molecule, Kelch-like ECH associated protein 1 (KEAP1), resulting in low to no transcriptional activity. Certain modifications to Keap1, such as oxidation of cysteine residues, or inhibition of the binding between Keap1 and Nrf2, leads to the translocation of Nrf2 to the nucleus and subsequent activation of transcription. Here, we examined structurally diverse Nrf2 activating compounds either reacting with Keap cysteine residues or inhibiting Keap-Nrf2 binding for effects on primary cultures of human astrocytes. Test compounds included RTA-408, a prototypical triterpenoid that covalently modifies Keap1 cysteine resides, and a noncovalent Keap1-Nrf2 protein-protein interaction inhibitor, the benzene disulfonamide, BIO-0504885 (compound 16 of Marcotte et al., *Bioorg. Med. Chem* 21:4011,2013). We identified class effects of covalent vs. noncovalent Nrf2 activators in ARE-transcriptionally activated genes and correlated those effects with glutathione biosynthesis and protection against oxidation-dependent cell death induced by arsenite. Because the Nrf2 pathway in astrocytes affects astrocytic as well as neuronal glutathione, this has implications not only for astrocyte survival and oxidative homeostasis, but also for the neurons they support. These findings may help guide therapeutic strategies.

Title: Tocotrienols affect on the antioxidant enzyme protein expressions of high-fat diet-treated mice

Authors: *M. SHIRAI[1], K. FUKUI[2];
[1]Dep of Biosci. and Engin., Shibaura Inst. of Technol., Saitama/Saitama, Japan; [2]Dept. of Biosci. and Engin., Shibaura Inst. of Technol., Saitama, Japan

Abstract: The ratio of obesity is increasing in many developed countries, and the ratio of obesity-related severe diseases such as heart disease, diabetes and high blood pressure has been increased. Reactive oxygen species (ROS) which are generated from adipose tissue, accelerate oxidative damages in living tissues. However, the relationship between obesity-derived oxidative damage and brain function has not yet elucidated. We reported that tocotorienol (T3) which is one kind of vitamin E has a neuroprotective function, and the function of T3 was significantly higher than that of tocopherol (Toc). On the other hand, it has been reported about anti-obesity and cholesterol-lowing effect of T3. In the present study, we tried to clarification the mechanism of anti-obesity effect of T3 in high-fat diet-treated mice. Specifically, we focused on the relationship between high-fat diet-induced oxidative stress and brain antioxidant system. Before start of this project, we determined measurement condition of 8 isoforms of vitamin E using HPLC-ECD, and detected alpha-and gamma-T3 in normal mouse brains. However, these T3 values were much lower than the Toc. Next, we produced animal models of obesity by providing the animals with a high-fat diet (5.24kcal/g) starting at 1month of age. In order to effect of T3, we mixed 0.01% T3s in high-fat diet. C57BL/6 mice, which reached 3 month of age were used all experiments. We measured antioxidant enzyme activities and protein expressions of high-fat diet-treated mice in the presence or absence of T3. As a result, it was detected T3 from the brains of the T3 non-supplemented group. Although, antioxidant enzyme activities of high-fat diet-treated mice did not show significant difference among all samples, these protein expressions significantly changed in the presence or absence of T3. Lipid peroxidative products did not differ in the presence or absence of T3. These results indicate that obesity accelerates imbalance of brain antioxidant enzyme protein expressions, and treatment with T3 protects brain antioxidant

system via its neuroprotective effect. However, further investigation is needed to clarify the mechanism between obesity-related brain oxidation and its importance function of T3.

Abstract: Small conductance calcium-activated potassium (SK) channels provide protection in different paradigms of neuronal cell death. Recently, these channels were identified at the inner mitochondrial membrane, however, their particular role in neuroprotection remained unclear. Here, we sought to investigate the distinct role of mitochondrial SK2 channels in protection against glutamate toxicity, with particular focus on the potential role of SK2 channels in the regulation of mitochondrial metabolism and mitochondrial calcium uptake, two key players in neuronal cell death.
We show that overexpression of mitochondria-targeted SK2 channels enhanced CyPPA-mediated mitochondrial resilience in a paradigm of glutamate toxicity, as evaluated through measurements of the mitochondrial membrane potential, mitochondrial ROS formation and cellular ATP levels in the neuronal HT22 cell line. CyPPA-mediated restoration of cell viability and cellular ATP levels was inhibited by overexpression of a mitochondria-targeted dominant-negative SK2 channel mutant that suppresses the activity of the endogenous SK2 channels located at the mitochondrial membranes. Analysis of respiration in isolated mitochondria of

HT22 cells revealed that SK2 channel activation, and overexpression of mitochondrial SK2 channels, attenuated basal and maximal mitochondrial respiration. Further, real-time measurements of mitochondrial Ca^{2+} uptake in HT22 cells *via* mitochondrial aequorin and in primary cortical neurons *via* a FRET sensor further revealed that SK channel activation significantly reduced mitochondrial Ca^{2+} uptake in response to glutamate and ATP.
These findings strongly suggest that activation of mitochondrial SK2 channels mediated neuroprotection against glutamate toxicity by reducing mitochondrial respiration and mitochondrial calcium uptake.

Abstract: Chronic neurodegenerative disorders as well as acute CNS injury are directly linked to oxidative stress, characterized by a rapid and massive production of reactive oxygen species (ROS) and reactive nitrogen species (RNS). ROS and RNS are initiators of lipid peroxidation (LP) and the release of nitric oxide (NO), eventually contributing to propagation of neurodegeneration. The aim of this study was to characterize biological activities of a novel small molecule and functional mimetic of glutathione peroxidase 4 (GPx4), called ADA-409-052 (052). GPx4 catalyses the reduction of lipid hydroperoxides at the expense of glutathione. 052 was designed to exercise GPx4 function independent of glutathione. Here, we describe the effects of 052 to modulate neuroinflammation and neurodegeneration in different in vitro models

as well as in two in vivo models of Parkinson's disease (PD) and a mouse model of ischemic stroke.
The impact of 052 on cell viability and LP production was investigated using PC-12 cell models, and on ROS and RNS production using LPS exposed microglia. The neuroprotective potential of 052 was studied in a MPP^+-induced dopaminergic (DA) cell loss model in C. elegans. Additionally, we investigated the effects of repeated administration of 052 in a MPTP-mouse model of DA neurodegeneration by measuring the striatal content of dopamine. The neuroprotective effects of 052 during acute injury were validated by subjecting C57BL/6j mice to thromboembolic (TE) stroke, followed by oral administration of 052 or vehicle. Lesion sizes and the severity of edema were determined by MRI at 24 h post stroke.
Exposure of PC-12 cells to 052 dose-dependently increases cell viability and decreases LP and NO production under oxidative and/or nitrosative stress. Our results show that 052 diminishes MPP^+-driven DA cell loss in C. elegans. We determine that the MPTP-induced DA depletion in mouse striatum is significantly attenuated by 052 treatment. Finally, our data demonstrate that 052 administration significantly reduces both the lesion size and edema after TE stroke.
In conclusion, our study reveals potent lipid peroxidation and neuroinflammation mitigating effects in vitro and in vivo for a novel small molecule compound. ADA-409-052 may represent a new therapeutic strategy to alleviate neurodegeneration and neuroinflammation in the future.

Title: Neuroprotective effect of epigallocatechin-3-gallate on methamphetamine-induced glial activation and dopamine terminal damage in the mouse striatum

Authors: *A. L. PAN, J. A. ANGULO;
Biol. Sci., Hunter Col., New York, NY

Abstract: Methamphetamine (METH) is an illicit drug that can cause dopamine terminal damage and over- activation of glial cells in mouse striatum. It is believed that activation of glial cells, specifically microglial cells, could be one of the contributing factors to METH-induced neuronal damage. Although many studies have been done on METH-induced neurotoxic effect, there is still no therapeutic treatment on METH-induced neuronal damage. In the present study, we examined the neuroprotective effect of epigallocatechin-3-gallate (EGCG), the polyphenol found in green tea extract, on METH-induced glial activation and dopamine terminal damage. CD-1 mice received 2 mg/kg of EGCG via intraperitoneal injection (i.p.) 30 minutes prior to METH (30 mg/kg, i.p. injection) and sacrificed 24 hours or 72 hours after METH injection. Immunohistochemical methods and western blot analysis were used to evaluate the changes of microglia and astrocytes in the striatum. Quantitative analysis of reactive microglia revealed that injection of EGCG prior to METH administration significantly potentiated the METH-induced microglial activation in the striatum after 24 hours. Moreover, western blots demonstrated that EGCG did not have significant effect on METH-induced activation of astrocytes 3 days after METH administration, but prevented METH-induced tyrosine hydroxylase depletion. These observations raise the possibility that EGCG might contribute to the activation of microglia to ameliorate METH-induced dopamine terminal damage.

Title: A vital role of Kv2.1 somato-dendritic clusters in oxidative stress-induced apoptogenic trafficking of Kv2.1

Authors: *J. A. JUSTICE, A. SCHULIEN, K. HE, K. HARTNETT, E. AIZENMAN, N. SHAH;
Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: As the predominant mediator of the delayed rectifier current, I_{KDR}, Kv2.1 is an important regulator of neuronal intrinsic excitability. Kv2.1 also plays a well-established role in apoptotic cell death. Apoptogenic-stimuli induce syntaxin-dependent trafficking of Kv2.1, resulting in an augmented I_{KDR} that acts as a conduit for K+ efflux required for pro-apoptotic protease/nuclease activation. Recent evidence suggests that Kv2.1 somato-dendritic clusters regulate the formation of endoplasmic reticulum-plasma membrane (ER-PM) junctions that function as scaffolding sites for plasma membrane trafficking of ion channels, including Kv2.1. However, it is unknown whether Kv2.1-mediated ER-PM junctions are required for apoptogenic trafficking of Kv2.1. By overexpression of Kv2.2CT, a protein derived from the C-terminus of Kv2.2, we were able to induce calcineurin-independent disruption of Kv2.1 somato-dendritic clusters without significantly altering the electrophysiological properties of the channel, normally mutually inclusive events. In this study, we report that Kv2.2CT expressing neurons are specifically less susceptible to oxidative stress-induced apoptosis, as Kv2.2CT expressing neurons were not protected against non-apoptotic cell death generated by NMDA receptor-mediated excitotoxicity. Confocal imaging of Kv2.1 clusters revealed a zinc-dependent progressive disruption of Kv2.1 somato-dendritic clusters culminating, 3 hours following a brief exposure to the thiol oxidant DTDP, in an approximate twofold increase in current density of the I_{KDR}. Critically, expression of Kv2.2CT effectively blocked the increased current density of the I_{KDR} associated with DTDP-induced trafficking of Kv2.1, supporting a vital role of Kv2.1-mediated ER-PM junctions in apoptogenic trafficking of Kv2.1. Furthermore, Kv2.2CT-mediated neuroprotection is syntaxin binding domain-independent, differentiating this protein's neuroprotective mechanism from that of C1A, a Kv2.1 C-terminal, syntaxin binding domain-derived peptide that prevents syntaxin from interacting with Kv2.1, precluding Kv2.1 trafficking and subsequently preventing apoptosis. Combined, our data suggest a novel neuroprotective mechanism of Kv2.2CT, providing the impetus for further investigation.

Title: Regulatory effects of neuroinflammatory responses through bdnf-derived neurotrophic factor signaling in microglial cells

Authors: *S.-W. LAI[1], D.-Y. LU[2], H.-Y. LIN[2];
[1]Grad. Inst. of Basic Med. Sci., [2]China Med. Univ., Taichung, Taiwan

Abstract: In the central nervous system (CNS), microglia plays a crucial role in innate immune processes. The hallmark of neuroinflammation is considered to be microglial activation that leads to the production of excessive proinflammatory molecules. Hence, inhibitory effect on microglial over-activation is major strategy to balance inflammatory/anti-inflammatory homeostasis. Brain-derived neurotrophic factor (BDNF) is the one of major neurotrophic factors to maintenance of development and survival of neurons in the brain. However, whether BDNF signaling participates in neuroinflammatory response remains unknown. Numerous studies have shown that BDNF is produced by astrocyte to modulate several biological functions. We previously reported that the phosphorylated adenosine monophosphate-activated protein kinase (AMPK)-α mediates anti-neuroinflammatory responses. Here, we treatment with BDNF decreases cyclooxygenase-2 (COX-2) and proinflammatory cytokine expressions in microglia. In addition, minocycline also induced BDNF expression then further inhibited cytokines expression in microglial cells. BDNF
resulted in enhancement of erythropoietin (EPO) and sonic hedgehog (Shh) leading to inhibit inflammatory effects. In addition, astrocyte also acts on BDNF/EPO/Shh signaling to regulate microglial neuroinflammatory exerting neuroprotective function. In this study we provide a novel mechanism between astrocyte and microglia to exert anti-neuroinflammation via BDNF/EPO/Shh signaling pathway. **Keywords:** BDNF; COX-2; microglia; astroglia; neuroinflammation

Title: Protective effects of a multiple-ingredient supplement from gamma-irradiation induced chemofog

Authors: *S. THARMALINGAM[1], J. A. LEMON[2], F. SOLEIMANI[1], S. JOUET[1], K. MONSTER[2], D. C. ROLLO[2], T. C. TAI[1], D. R. BOREHAM[1];

Abstract: Chemofog refers to radiation induced cognitive impairment that result from medical radiation treatments. Radiation induced neurological symptoms include difficulty concentrating, impaired recall memory, changes in verbal working memory, and diminished smell acuity. Currently there is no known intervention to protect or restore cognitive function in patients undergoing radiation treatments. Here we report that an in-house developed multiple ingredient dietary supplement (MDS) consisting of 30 compounds protects from radiation induced cognitive impairment in C57BL/6J wild-type mice. The MDS was designed to offset five mechanisms involved in radiation induced cellular damage including oxidative damage, inflammation, impaired glucose metabolism, mitochondrial dysfunction and membrane deterioration. Gene expression analysis of the right caudal cerebral hemisphere at 30 days post-irradiation revealed that daily MDS administration 30 days prior to irradiation protected 10 gray head-only irradiated mice from oxidative stress, DNA damage and neuroinflammation. MDS treatment also protected the cerebral hemisphere from radiation induced apoptosis and subsequent neuronal loss. Furthermore, assessment of olfactory function revealed that head-only irradiated mice lost the ability to detect odors while MDS treatment prevented the radiation induced anosmia. Similar MDS mediated protective effects were observed in hippocampus dependent memory tests. Interestingly, the neuroprotective effects of daily MDS administration 30 days prior to irradiation were also achieved when MDS was given 30 days post-irradiation. Taken together, these results demonstrate that MDS protects individuals undergoing medical radiation treatment from developing neuronal cellular stress and cognitive impairment, and can also be administered to protect against cellular damage after accidental radiation exposures. This study also emphasizes that daily exogenous administration of antioxidants may help to improve the therapeutic index of radiation treatments by protecting normal tissue from reactive oxygen

species. Therefore the MDS provides a non-invasive therapy to mitigate risk and decrease radiation induced chemofog due to diagnostic imaging and cancer therapy.

Title: A systems biology view of the neuroprotection from oxidative stress induced ferroptosis by HDAC inhibition

Authors: *M. BOURASSA[1], S. S. KARUPPAGOUNDER[1], Y. CHEN[1], F. DUENDAR[2], P. ZUMBO[2], L. SKRABANEK[2], G. COPPOLA[3], R. R. RATAN[1];
[1]Burke-Cornell Med. Res. Inst., White Plains, NY; [2]Weill Cornell Med. Col., New York, NY; [3]Univ. of California Los Angeles, Los Angeles, CA

Abstract: Histone deacetylase inhibitors have been shown to be effective in reducing damage in rodent models of a broad array of acute and chronic neurological conditions, including stroke and Alzheimer's disease. By inhibiting HDACs, the deacetylation of histones is blocked, allowing acetylated regions of the genome to remain transcriptionally active. HDAC inhibitors have the putative advantage over other potential drugs in their ability to affect the transcription of a large cassette of adaptive genes. Our aim is to optimize their protective and restorative properties and reduce or eliminate their side effects. Accordingly, we have used Scriptaid, an HDAC inhibitor and its pharmacological negative control, Nullscript that does not significantly inhibit HDACs, as a chemical pair to understand the direct effect of HDAC inhibition on the adaptive genetic response. In an established model of oxidative stress-induced ferroptotic death, neurons pretreated with a pulse of Scriptaid for 8 hours are fully protected from ferroptosis 24 hours following Scriptaid removal suggesting a transcriptional, preconditioning mechanism. Using transcriptomics, we have found that Scriptaid, but not Nullscript, affects the expression of nearly 4000 genes. Thus the protective effect of HDAC inhibitors is unlikely due to a single gene but may be attributed to one of the HDACs inhibited by Scriptaid. We will present multilevel bioinformatics analyses including network analyses combined with experimental validation via molecular manipulation of specific HDACs. These studies provide a framework to understand

the broad salutary effects of HDAC inhibitors on oxidative stress as well as plasticity and regeneration.

Title: Reactive oxygen species induce axonal degeneration via microtubule-associated protein alterations and its prevention by tocotrienols.

Authors: *K. FUKUI;
Shibaura Inst. Technol., Saitama, Japan

Abstract: Reactive oxygen species (ROS) may attack several living organs and induce cell death. Accumulation of oxidative damage increases the risks of several severe diseases. Specifically, brain is susceptible against ROS. In order to prevent development or progression of ROS-related diseases, it is important to find an early change before induction of cell death. Hydrogen peroxide, which is one kind of oxidative stress induces neuronal cell death in a concentration- and time-dependent manner in cultured model. However, treatment of neuronal cells with a low concentration of hydrogen peroxide induces axonal degeneration. The axons showed abnormal morphologies including beads formation, shrinkage and fragmentation. Treatment with tocotrienol significantly inhibited hydrogen peroxide-induced axonal injury. The neuroprotective effect of tocotrienol was significantly higher than that of tocopherol. Furthermore, we also found these abnormal morphologies in hippocampal slices of normal aged- and vitamin E-deficient mice. CRMP2, which is one microtubule-related protein significantly phosphorylated in normal aged- and vitamin E-deficient mouse brains. It is well known that pCRMP2 loses binding ability with tubulin, and induces microtubule disability. Finally, we isolated microtubules from the brains of mice, and measured tyrosinated- and acetylated-tubulins by western blotting. The ratio of tyrosinated-tubulins tended to increase in normal aged-mice. These results indicate that axonal degeneration induces before induction of cell death, and the reason of it may be related to ROS-derived microtubule disruption. Cognitive dysfunction during aging may be associated with ROS induced axonal dysfunction. Tocotrienols were supplied from Eisai Food Chemical Co. Ltd. Tokyo, Japan.

Title: ApoE isoforms differentially regulate vascular stabilization in pericytes

Authors: *Y. YAMAZAKI, T. KANEKIYO, G. BU;
Dept. of Neurosci., Mayo Clin., Jacksonville, FL

Abstract: Since the discovery of *APOE4* as the strongest genetic risk factor for late-onset Alzheimer's disease (LOAD), it becomes increasingly evident that apolipoprotein E (apoE) plays critical roles in multiple biological processes necessary for maintaining the homeostasis of the central nervous system (CNS). ApoE4, when compared to the "neutral" isoform apoE3, is less efficient in carrying out CNS functions and consequently subjects brain environment more susceptible to AD development. In addition to astrocytes, vascular mural cells (*i.e.* vascular smooth muscle cells and pericytes) abundantly express and secrete apoE in the CNS. Pericytes, the mural cells of brain microvessels, have recently come into focus as regulators of vascular morphogenesis and cerebrovascular homeostasis. Consistently, dysfunction of these cells has been shown to cause blood-brain barrier (BBB) disruption, reduced cerebral blood flow, and altered functions of endothelial cells (ECs) and other cell types in the neurovascular unit. These alterations in the cerebrovasculature, more frequently seen in *APOE4* carriers, are often involved

in the pathogenesis of LOAD; however, the relationship between apoE isoforms and the pericyte functions is poorly understood. Using primary pericytes from the brains of apoE3-targeted replacement (TR) or apoE4-TR mice, we show that apoE4-pericytes are significantly inferior in vasculogenic and vascular stabilizing abilities to those carrying apoE3. In 3-D co-culture models of pericytes and ECs, the formation of vascular tunnels and the induction of extracellular matrices in endothelial cells were significantly impaired in ECs/apoE4-pericytes co-cultures compared to ECs/apoE3-pericytes co-cultures. Consistently, in the *in vitro* BBB models composed of pericytes and ECs, the barrier integrities were lower in the presence of apoE4-pericytes than apoE3-pericytes. Notably, this effect requires a direct contact interaction between co-cultured ECs and pericytes. Together, our results demonstrate an inferior function of apoE4-pericytes in vascular stabilization compared to apoE3-pericytes and may explain, in part, the contribution of *APOE4* as a risk factor for LOAD.

Title: Corticosterone and exogenous glucose alter blood glucose levels, neurotoxicity and vascular toxicity produced by methamphetamine

Authors: *J. F. BOWYER[1], K. M. TRANTER[1], S. SARKAR[1], N. I. GEORGE[2], J. P. HANIG[3], K. A. KELLY[4], L. T. LINDSAY[4], D. B. MILLER[4], J. P. O'CALLAGHAN[4];
[1]Neurotoxicology, [2]Bioinformatics and Biostatistics, NCTR/FDA, Jefferson, AR; [3]Ctr. for Drug Evaluation and Research/FDA, Silver Spring, MD; [4]Hlth. Effects Lab. Div., CDC/ NIOSH, Morgantown, WV

Abstract: Our previous studies have raised the possibility that altered blood glucose levels may influence and/ or be predictive of methamphetamine (METH) and amphetamine (AMPH) induced neurotoxicity. This study evaluated the effects of exogenous glucose and corticosterone (CORT) pretreatment on blood glucose levels and the neuro and vascular toxicity produced by METH in rat. METH exposure consisted of four sequential injections of 5, 7.5, 10 and 10 mg/kg (2h between injections) D-METH. Pretreatment with 2 X 20 mg/ kg of CORT 1 d prior to METH initially significantly increased blood glucose levels during METH dosing to a peak of about

170% (170 to 180 mg/ dL) of the saline controls but by 1 h after the last METH injection the levels returned to near control. Administration of 1 g/ kg of D-glucose 1 min prior to each injection of METH initially raised blood glucose but by the final METH dose this group paradoxically had lower levels than control. The groups given either CORT pretreatment or four glucose injections (no METH) had slight increases in blood glucose, relative to saline control, that did not reach significance. The METH only group had slightly higher glucose levels than controls during the initial phase but significantly lower levels after the 4th injection of METH. Despite cooling to prevent METH-induced lethal hyperthermia, METH+CORT (>40%) and METH+glucose (>40%) had significantly higher mortality rates than the METH (< 10%) only group. There were no differences in the hyperthermic profiles in between any of the METH groups. CORT pretreatment prior to METH increased neurodegeneration approximately 2-fold in the parietal cortex and thalamic regions. Thus, maintaining elevated to normal levels of glucose during METH exposure increases lethality and may exacerbate neurodegeneration. The adverse effects seen only in the METH+CORT group indicated that CORT enhances vascular leakage/ blood-brain barrier disruption that is unrelated to elevated blood glucose. These effects may be related to changes in ferritin labeling of cells associated with vasculature in the dorsomedial hippocampus (medial to CA1).

Title: Time-dependent vascular remodeling and inflammation following decompression in cervical myelopathy

Authors: *W.-R. YU[1], A. BADNER[2], T.-R. KIEHL[3], M. G. FEHLINGS[2];
[1]Genet and Develop, U of Toronto, Krembil Institute, Univ. Hlth. Network, Toronto, ON, Canada; [2]Divisions of Genet. & Develop. and Neurosurgery,, [3]Divisions of Genet. & Develop. and Neurosurg., Krembil institute, Toronto Western Hospital, Univ. Hlth. Network, Toronto, ON, Canada

Abstract: Cervical spondylotic myelopathy (CSM) results from progressive spinal cord compression by the degenerating cervical spine. Although CSM is currently treated with

decompression, little is known of the vascular and inflammatory response under chronic compression and the subsequent decompression of the cervical spinal cord. Here, we examined the role of inflammation and vascular remodeling in a mouse model of progressive compression and decompression. Moreover, using human samples, we demonstrated the clinical relevance of our CSM mouse model and the complex processes involved in inflammation and ischemia.
A synthetic polyether material was implanted under the C5-C6 lamina of mice for 6 or 16 weeks to model moderate and severe CSM, respectively. The animals were subsequently followed for short-term (4 weeks) and long-term (3 months) periods after decompression. We investigated the inflammatory response, blood vessel changes and neurobehavioral outcomes in detail. The animal data was complemented by immunohistochemical analysis of human post-mortem spinal cord tissue from individuals with CSM. Comparing human CSM tissue with that of controls, we found significant up-regulation of the inflammatory response, including human leukocyte antigen, Iba1 and CD68 positive macroglia/macrophages; and increased anti-inflammatory M2 positive cells. The results also showed a significant increase in blood vessel density and the increased expression of fibronectin, PDGFR-B and Von Willebrand Factor in human CSM cases. Our CSM mouse model also displayed neuronal loss, inflammation and gliosis with reduced blood flow to the spinal cord and increased vascular density. In moderate CSM followed by a short-term (4 week) period post-decompression, we found an increased inflammatory response (Iba1, glectin-3 and GFAP expression) and vessels reperfusion compared to the CSM at 10 weeks. Interestingly, at 3 months after decompression in severe CSM, the mice had significantly increased blood flow support to spinal cord as measured by Power Doppler, a reduced inflammatory response and increased number of neurons as well as vessels. These animals also had an increased spinal cord size and improve functional recovery, determined by the rotarod test.
As a result, we report novel evidence that inflammation and ischemia are critical to inducing neural degeneration in the setting of progressive CSM. As decompression induces early ischemia and an inflammatory response, mice require 2 to 3 months to recover their spinal cord size and functional vasculature. Taken together, this supports the clinical results that demonstrate decompression is beneficial for CSM.

Title: Exploring the transcriptional response of hippocampal vasculature to focused ultrasound-mediated blood-brain barrier opening

Authors: *D. MCMAHON, K. HYNYNEN;
Sunnybrook Res. Inst., Toronto, ON, Canada

Abstract: While the development of agents with therapeutic potential is necessary for the treatment neurological disorders, this is effort is for not if these agents cannot reach their intended target. The protective nature of the blood-brain barrier (BBB) is vital in shielding the central nervous system (CNS) from harmful molecules; however, it also severely hinders the entry of substances with the potential for treating neuropathologies. Extensive research has demonstrated the utility of focused ultrasound (FUS), in combination with circulating microbubbles, to create temporary, localized increases in BBB permeability, permitting the movement of therapeutics into the brain parenchyma. While this technique has the potential to revolutionize the way neuropathologies, such as Alzheimer's disease, are treated, questions regarding the biological events that follow BBB opening remain to be answered before its clinical potential can be fully realized. Currently, our view of the driving mechanisms behind FUS-mediated BBB opening, as well as the series of events that result in the restoration of normal barrier function, are poorly understood. This information is not only critical to understanding the basic science behind the technique, but may also have value in revealing biological targets for controlling the duration and degree of BBB opening, further evaluating safety, and discovering potential applications of FUS, independent of therapeutic agent delivery. The overarching goal of this research is to characterize the transcriptional response of hippocampal vasculature to FUS-mediated BBB opening. To this end, microarray analysis of laser captured microvessels from the hippocampi of male rats has been performed at 6 and 24 hours following sonication. Of particular interest, a significant downregulation of Oat 1 and 3 mRNA was detected at 6 hours following FUS compared to non-sonicated controls. The proteins encoded by these transcripts have been implicated in the transport of a variety of therapeutic agents. A downregulation of these proteins may contribute to reduced drug efflux following FUS-mediated BBB opening, allowing for drugs to remain in the target area for longer. Thus, in addition to allowing therapeutic agents to permeate the BBB, FUS may contribute to enhanced therapeutic effects by reducing drug efflux.

Title: Blood brain barrier disruption during viral encephalitis is associated with endothelial-mesenchymal transition in the neurovasculature

Authors: *S. BONNEY[1], S. SEITZ[2], K. TYLER[2], J. SIEGENTHALER[1];
[1]Pediatrics, [2]Neurol., Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: Blood vessels in the brain provide oxygen, nutrients, and establish the blood brain barrier (BBB). Loss of vascular integrity is a consequence of many central nervous system (CNS) diseases, like encephalitis, which is acute inflammation of the brain leading to extensive neuronal damage and death. Vascular instability can exacerbate encephalitis therefore identifying mechanisms underlying BBB breakdown is an important area of research. To study vascular instability in encephalitis we utilized the classical viral-induced encephalitis mouse model in which perinatal mice are exposed to reovirus. Even though endothelial cells are not infected by reovirus we found that the vasculature is becoming dysmorphic early in infection and this is followed by leakage of fibrinogen, a serum protein, into the neural parenchyma. This indicates that the vasculature is disrupted and there is a loss of BBB properties during reovirus-induced encephalitis. To determine how vascular instability arises we first looked at the Wnt signaling pathway which is essential for establishing and maintaining the BBB. We found, however, that Wnt signaling and Wnt driven BBB targets were not altered in reovirus infected mice. Recent studies suggest that endothelial-mesenchymal transition (EndoMT) can contribute to vascular instability. Surprisingly, we found loss of endothelial markers like Erg1 and up-regulation of mesenchymal transcripts like S100a4, Klf4, Id1, and Snail1 in whole brains during reovirus infection. Immunohistochemical analysis verified expression of mesenchymal proteins within the vasculature at late stages of reovirus infection. This correlates with ectopic TGFβ signaling in the vasculature during reovirus infection which is an EndoMT effector pathway. This data suggests that TGFβ-mediated EndoMT causes vascular instability during reovirus-induced encephalitis. Future experiments will determine if EndoMT initiates loss of vascular integrity and BBB properties during encephalitis and if it is mediated by TGFβ signaling.

Title: Epidermal growth factor prevents amyloid-β induced angiogenesis deficits and cognitive deficits *In vivo*

Authors: *R. R. THOMAS, K. P. KOSTER, F. M. MAROTTOLI, A. W. J. MORRIS, L. M. TAI;
Anat. and Cell Biol., Univ. of Illinois At Chicago, Chicago, IL

Abstract: Cerebrovascular (CV) dysfunction is emerging as a critical component of Alzheimer's disease (AD) progression. However, the role of known AD risk factors in CV dysfunction is unclear. *APOE4* is the greatest genetic risk factor for sporadic AD, increasing risk up to 12-fold compared to *APOE3*. Our preliminary data demonstrate that *APOE4* and amyloid beta (Aβ) induce cognitive deficits and increase global CV leakiness in female mice at 8 months, using a novel transgenic model that express human *APOE3* (E3FAD) or *APOE4* (E4FAD) and overproduce Aβ. The *APOE4*-induced cognitive and CV deficits correlate with vessel degeneration, an indication of disrupted angiogenic signaling. Angiogenic signaling in brain endothelial cells (BEC) is crucial for regulating total vessel length and transport, signaling, and metabolic functions of the CV. Therefore angiogenic growth factors (GFs) may improve CV dysfunction in AD. Our comparison of the main angiogenic GFs demonstrate that EGF protects against Aβ-induced disruption of vessel formation and vessel degeneration *in vitro*. Based on the *in vitro* findings, we treated female E4FAD mice with EGF (300μg/kg/week) from 6-8 months in a prevention paradigm. EGF treatment prevented the age-dependent cognitive decline as assessed by spontaneous alternation (Y-maze), novel object recognition, platform latency (Morris water maze), with no effects on anxiety-related behavior (open field, light/dark box test, and marble burying test). Further EGF had effects on CV leakiness, cerebral angiogenesis, and vessel degeneration. Therefore, this proof of concept study demonstrates that targeting angiogenic pathways, principally those involving EGF, is a potential therapeutic strategy for the treatment of AD and CV dysfunction.

Title: Lifespan of one focused ultrasound mediated blood-brain barrier opening treatment in a mouse model of Alzheimer's disease

Authors: *C. POON[1,2], K. HYNYNEN[1,3];
[1]Sunnybrook Hlth. Sci. Ctr., Toronto, ON, Canada; [2]Inst. of Biomaterials and Biomed. Engin., [3]Med. Biophysics, Univ. of Toronto, Toronto, ON, Canada

Abstract: Background: Alzheimer's disease (AD) is a neurodegenerative disease that affects approximately 35.6 million people worldwide. A major limiting factor to pharmacologically treating AD is delivering drugs from the systemic circulation into the brain through the blood-brain barrier (BBB). Approximately 2% of small-molecule drugs can cross the BBB. Current methods of circumventing the BBB are either highly invasive (intracranial injection), or difficult to control (vasodilating agents). Focused ultrasound (FUS)-mediated blood-brain barrier opening (BBBO) is a noninvasive and targetable method to cause transient BBBO by increasing transcellular and paracellular transport. Anti-Aβ antibodies have been successfully delivered using FUS-mediated BBBO to the hippocampi in a mouse model of AD. Surprisingly, FUS-mediated BBBO without therapeutics also resulted in a significant decrease in Aβ plaque load. A follow-up study showed that three weekly treatments of FUS-mediated BBBO targeted to the bilateral hippocampus restored spatial memory performance in AD mice to the levels of non-transgenic controls. However, five biweekly (once every two weeks) FUS treatments did not yield the same behavioural benefits. Based on the cumulative behavioural data, the lifespan of one FUS-mediated BBBO treatment in AD mice appears to be between one to two weeks. Objective: The objective of this study is to determine the lifespan of one FUS-mediated BBBO treatment by quantifying levels of insoluble Aβ species in the TgCRND8 AD mouse model using two-photon microscopy. Methods: Six-month-old TgCRND8 AD mice will be used, at which time Aβ deposits and cognitive impairments are present. A cranial window will be installed for longitudinal imaging. Insoluble Aβ plaques will be tracked *in vivo* using two-photon microscopy every day for two weeks after FUS treatment. Aβ plaques will be fluorescently labelled with methoxy X-04. Two measurements will be made: 1) Plaque area and volume using Imaris software, and 2) Plaque number using stereology. Preliminary results: Plaque area appears to decrease from the onset of BBBO until 1.5 weeks, upon which it plateaus and begins to rise

again. Plaque volume measurements are more varied. Significance: FUS is a safe and effective method of bypassing the BBB in selected brain regions, and has been shown to result in functional benefits in AD animals. The lifespan of this treatment must be evaluated to discern its use in conjunction with AD therapeutics, as well as its potential use in clinical studies.

Title: Optogenetic regulation of pericytes

Authors: *A. R. NELSON, Z. ZHAO, B. V. ZLOKOVIC;
Zilkha Neurogenetic Inst., USC, Los Angeles, CA

Abstract: Pericytes are integral to proper blood-brain barrier (BBB) formation/maintenance and perform multiple roles at the neurovascular unit including regulation of 1) BBB permeability and bulk flow fluid transcytosis, 2) capillary diameter, 3) cerebral blood flow (CBF) velocity, 4) angiogenesis and subsequent microvascular stability and network architecture, 5) phagocytic clearance of toxic metabolites from the central nervous system (CNS), 6) pro-inflammatory responses, e.g., leukocyte trafficking, and 7) multipotent stem cell activity. However, whether or not pericytes are contractile cells has been a continuous debate dating back to 1873 when they were first described by Rouget as regularly arranged longitudinal amoeboid cells on capillaries that have a muscular coat. Here, we test the hypothesis that capillary level pericytes are contractile cells. To test this hypothesis, we developed a novel inducible pericyte-specific Cre (*pericyte-CreER)* mouse using a double-promoter approach with both the *Pdgfrβ* and *Cspg4* promoters. This *pericyte-CreER* mouse was then crossed to a Cre-dependent channelrhodopsin (ChR2) mouse with a YFP reporter gene, named *pericyte-ChR2*. Using these mice, we first confirmed that ChR2 is only expressed in pericytes by performing immunofluorescent staining with anti-CD13 antibody which colocalized with the YFP reporter gene. Using the *pericyte-ChR2* mice, we performed optogenetics experiments in acute brain slices to test pericyte

contractility upon light stimulus using a Mightex's Polygon400 Patterned Illuminator. Discovering the functional role of pericytes will have important implications for pathological conditions and neurodegenerative diseases in which pericytes degenerate including stroke, Alzheimer's disease, amyotrophic lateral sclerosis, Parkinson's disease and Huntington's disease.

Title: Study of the anatomical basis for a volume transmission mechanism on the melanin-concentrating hormone (MCH) peptidergic system

Authors: *G. B. DINIZ[1], C. A. S. HAEMMERLE[1], F. PRESSE[2,3], J.-L. NAHON[2,3,4], J. C. BITTENCOURT[1,5];
[1]Dept. of Anat., Inst. of Biomed. Sci. of the Univ., Sao Paulo, Brazil; [2]Inst. de Pharmacologie Moléculaire et Cellulaire, Valbonne, France; [3]Univ. of Nice Sophia Antipolis, Nice, France; [4]Station de Primatologie, UPS 846, Rousset sur Arc, France; [5]Ctr. for Neurosci. and Behavior, Inst. of Psychology, São Paulo, Brazil

Abstract: In the volume transmission paradigm (VT), neurons can release messenger substances in their immediate vicinity, into the extracellular fluid (ECF) or in the cerebrospinal fluid (CSF) to influence the behavior of other neurons either near or far from its release. A growing number of authors have suggested that the VT paradigm is a possible mechanism of action in different peptidergic systems. In an effort to establish if the same occurs in the melanin-concentrating hormone (MCH) system, we set to further characterize the anatomical aspects of MCH and its receptors in rodents, with special attention to its relationship with the CSF. To achieve this, three sets of experiments were designed: the distribution of MCH-immunoreactive (MCH-ir) fibers and its receptor (MCHR1) was mapped in the CNS of the mouse using immunohistochemistry (IHC) combined with confocal microscopy; the ultrastructural relationship between MCH-ir fibers, MCHR1-ir elements and the ependymal layer of the brain ventricles was probed using

IHC coupled to transmission electron microscopy (TEM); and the direct communication between MCH-ir neurons and the CSF was evaluated through retrograde tracer injections directly in the CSF. Regarding the MCH pattern innervation, a large number of fibers was detected in the vicinity of the ventricles, mainly in the medial wall of the lateral ventricles, the dorsal third ventricle and the floor of the fourth ventricle. Through TEM it was possible to detect sparse MCH immunoreactivity in ependymal cells, including putative axons coursing through the interventricular space. The MCHR1 IHC results revealed that MCHR1 is mainly present in the primary cilia of neurons, and this pattern of immunoreactivity could be found across all the CNS. The tracer study revealed that subpopulations in the three main MCH-producing areas of the diencephalon (incerto-hypothalamic area, zona incerta and lateral hypothalamic area) are in contact with either the CSF or the periventricular ECF. Our results indicate that there is a strong anatomical basis for a VT mechanism in the MCH peptidergic system. The contact of MCH-ir neurons with the CSF and the periventricular ECF could be a route of release and transport of MCH to distant sites, and the presence of MCHR1 in the primary cilia of neurons makes this receptor ideally suited to detect free MCH transported through these media. Our results also fit well with other works in the literature, since the MCH-induced increase of ciliary beating reported elsewhere could be a mechanism to further increase the reach of released MCH in the CSF.

Title: Synthesis and deposition of basement membrane proteins by primary brain capillary endothelial cells in a murine model of the blood-brain barrier

Authors: *T. MOOS, L. ROUTHE, S. BIRKELUND, A. BURKHART, A. STEENSBALLE, M. THOMSEN;
Aalborg Univ., Aalborg East, Denmark

Abstract: Neurodegenerative disorders are accompanied by changes in the composition of the brain vascular basement membrane, and the contribution hereto from brain capillary endothelial

cells (BCECs), pericytes, and astrocytes of the blood-brain barrier (BBB) is probably significant. The aim of the present study was to analyse four different *in vitro* models of the murine BBB for expression and possible secretion of major basement membrane proteins from murine BCECs (mBCECs). The mBCECs and pericytes were isolated from brains of adult C57BL/6 mice, and glial cells (mainly astrocytes and microglia) were prepared from cerebral cortices of newborn C57BL/6 mice. The mBCECs were grown as mono-culture, in co-culture with pericytes or mixed glial cells, or as a triple-culture with both pericytes and mixed glial cells. The integrity of the BBB models was validated by measures of transendothelial electrical resistance (TEER) and passive permeability to mannitol. The expression of basement membrane proteins was analysed using RT-qPCR, mass spectrometry, and immunocytochemistry. Co-culturing mBCECs with pericytes, mixed glial cells, or both significantly increased the TEER compared to the mono-culture, and a low passive permeability was correlated with high TEER. The mBCECs expressed major basement membrane proteins *in vitro.* Increased expression of laminin α5 correlated to the addition of BBB inducing factors (hydrocortisone, Ro 20-1724, and pCPT-cAMP), whereas increased expression of collagen IV α1 primarily correlated to increased levels of cAMP. In conclusion, BCECs cultured *in vitro* coherently form a BBB and express basement membrane proteins as a stage of maturation.

Title: Soluble Gas1 is present in the cerebrospinal fluid and it is expressed in the stroma of the choroid plexus of the adult rat brain

Authors: *E. AYALA, E. ESTUDILLO, G. PEREZ-SANCHEZ, A. SIERRA-SANCHEZ, L. GONZALEZ-MARISCAL, D. MARTINEZ-FONG, J. SEGOVIA-VILA;
fisiologia y neurociencias, CINVESTAV, Ciudad DE Mexico, Mexico

Abstract: Growth arrest specific 1 (Gas1) is a GPI-anchored protein that inhibits cell proliferation in tumors, while during the development of different organs and tissues Gas1 promotes cell survival and proliferation. This dual capacity responds respectively, to Gas1

inhibition of the glial cell-line derived neurotrophic factor (GDNF) signaling, and to the promotion of the activity of sonic hedgehog (Shh) pathway. GPI-anchored proteins are present as membrane bound and soluble forms. Gas1 in different organs is membrane bound, and only one report has described a soluble form of Gas1 in urine, likely secreted from podocytes and/or glomerular mesangial cells. In the developing central nervous system (CNS), Gas1 is found in neural progenitors; however, it continues to be expressed in the adult brain. Here, we demonstrate that in adult rats, soluble Gas1 is present in both the cerebrospinal fluid (CSF) and blood plasma. The most abundant proteins in the CSF are derived from plasma and are transported across the choroid plexus (CP), however this structure also produces other proteins that are directly delivered into the CSF. Hence, we analyzed the CP and found Gas1 expression in the stroma. Additionally, we confirmed Gas1 expression in the liver, the main producer of blood plasma proteins. The pattern of expression of Gas1 is perivascular in both the CP and the liver. In vitro studies show that fibroblast cell line NIH/3T3 expresses one form of Gas1 and releases two soluble forms, one of 37 kDa and another of 34 kDa, into the supernatant. In summary, in the present work, we demonstrate in adult rats the presence of Gas1 in the CSF and the CP, and reveal that soluble Gas1 exists as two different isoforms.

Title: Anatomical basis for interstitial fluid transport through the cribriform plate

Authors: *J. N. NORWOOD[1], D. CARD[2], A. CRAINE[3], P. J. DREW[4,5,3];
[1]Cell. and Developmental Biol., [2]Physics, [3]Biomed. Engin., [4]Engin. Sci. and Mechanics, [5]Neurosurg., Pennsylvania State Univ., University Park, PA

Abstract: Cerebrospinal fluid (CSF) is thought to be transported into and out of the brain via the glymphatic system. However, the pathways by which CSF and interstitial fluid leave the brain

are poorly understood, though there is evidence that the CSF may exit into the nasal epithelium via the cribriform plate. To better understand the anatomical substrate of this transport, we used CT imaging to visualize the cribriform plate, the bone structure that separates the olfactory bulbs from the nasal turbinates. The cribriform plate was highly porous, with four major foramina located laterally from the crista galli, the ridge of bone along the midline of the plate. Multiple, smaller foramina, lined with Aquaporin-1, concentrated mostly along the crista galli were also observed. We then tested whether interstitial fluid exits the brain along the olfactory nerve axons by injecting FITC albumin into the olfactory bulb. FITC albumin accumulated in the olfactory nerve layer and exited the brain compartment along axon bundles and vessels through the cribriform plate. Axon bundles localized to the four major foramina laterally from the crista galli co-stained with the outflow of the FITC albumin injected dye while the smaller holes observed along the crista galli did not correspond to outflow of FITC albumin. These data suggest an anatomically defined pathway for the clearance of interstitial fluid in the olfactory bulb.

Title: Targeting immunoliposomes to transferrin receptors on brain capillary endothelial cells as a mean for cargo transport across the blood-brain barrier

Authors: T. MOOS[1], K. JOHNSEN[1], A. BURKHART[1], J. BRUUN[2], P. SIUPKA[3], *M. S. NIELSEN[3], T. ANDRESEN[2];
[1]Aalborg Univ., Aalborg East, Denmark; [2]Tech. Univ. of Denmark, Copenhagen, Denmark; [3]Univ. of AARHUS, Aarhus, Denmark

Abstract: Brain capillary endothelial cells (BCECs) express transferrin receptors as opposed to endothelial cells of any organ in the remaining body, suggestive of targeting to these transferrin receptors as a reasonable strategy for delivering drugs to the CNS. As the intracellular trafficking of transferrin receptor however does not suggest transcytosis through BCECs of ligands and antibodies bound to this receptor, another strategy for transport through the BBB is to target nanocarriers, e.g. liposomes, to BCEC, which may allow the carriers to release their content within the BCECs with a subsequent transport further into the CNS. We studied transferrin

receptor-targeted (OX26) immunoliposomes containing oxaliplatin with the aim of quantifying the uptake of OX26, liposomes and oxaliplatin in BCECs and the remaining CNS. The uptake of the immunoliposomes and their cargo was studied in 18-day-old rats in which the expression of transferrin receptors by BCECs is almost twice as high as in the adult rat. For mechanistic purposes additional uptake studies were performed in primary rat BBB cultures consisting of BCECs and astrocytes. The uptake and transport of OX26-conjugated immunoliposomes by BCECs were significantly higher both *in vitro* and *in vivo* when compared to isotypic IgG-conjugated liposomes. Quantitative analyses after capillary depletion revealed cargo transport from BCECs to the remaining CNS. Pharmacokinetic analyses were performed to verify cargo transport through BCECs using OX26-targeted immunoliposomes as opposed to isotypic IgG control-conjugated liposomes. OX26-targeted immunoliposomes are suitable for uptake by BCECs.

Group, Helmholtz Ctr. for Infection Res., Braunschweig, Germany; [5]Inst. of Physiological Chem., Hannover Med. Sch., Hannover, Germany; [6]Vascular Neurosurg., Intl. Neurosci. Inst. GmbH, Hannover, Germany

Abstract: Background: Cerebral cavernous malformations (CCM) are vascular lesions, principally of the central nervous system that predispose to headaches, seizures and fatal hemorrhagic stroke. Currently, the only curative approach is neurosurgery and understanding of the molecular mechanisms leading to CCM development is limited. MicroRNAs are short non-coding RNAs that post-transcriptionally regulate gene expression and mounting evidence

suggests their imbalance in many diseases including loss of tight junctions and vascular permeability during endothelial dysfunction. Since, the role of miRNAs in CCM vascular pathophysiology has not been well elucidated, our goal was to identify miRNA-mRNA expression networks associated with CCM. **Methods and Results:** Total RNA was extracted and sequenced on Illumina HiSeq2500 sequencer using the small RNA preparation kit (Illumina). The miRNA sequencing identified 764 microRNAs that were differentially expressed in brain stem CCM resections (n=3) compared to normal brain autopsy controls (n=3) and the expression of a large set of miRNAs was similar in all three CCM patients. Further, 327 miRNAs with high abundance (having RPM values ≥ 30 in at least 2 of the 6 libraries studied) were selected and were subsequently filtered to a subset of 52, based on false discovery rate (FDR) correction by Benjamini-Hochberg method ($p \leq 0.05$). Application of additional stringency (Bonferroni correction) yielded five miRNAs (miR-95-3p, miR-370-3p, let-7b-5p, miR-181a-2-3p and miR-361-5p) which were significantly downregulated in CCM patients. The expression of five selected miRNA was validated by qPCR, where the results were consistent with the sequencing data. Additionally, using *in silico* target prediction tools, we determined for the five downregulated miRNAs a total of 1894 and 1080 putative and experimentally verified mRNA targets. Further analysis of the validated target mRNAs revealed a panel of CCM-specific genes regulated by let-7b-5p, miR-361-5p and miR-370-3p. **Conclusion:** Our study provides the first evidence of miRNAs which are differentially expressed in CCM. These findings are pivotal to understand the role of miRNAs in CCM pathogenesis and considering miRNA antagonism or overexpression as a therapeutic intervention, in addition to identification of specific miRNAs as potential biomarkers for diagnosis in CCM patients.

Title: Capillary ischemia produces MMP-9 dependent blood-brain barrier degeneration localized to cerebral pericyte somata

Authors: *R. G. UNDERLY, M. LEVY, D. A. HARTMANN, R. I. GRANT, A. N. WATSON, A. Y. SHIH;
Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: Pathological changes to cerebral capillaries, including reduced capillary density, increased tortuosity, and intravascular blockages, are common in the aging and diseased human brain (Girouard et al, 2006). The adverse effects of these changes are involved in the progression of tissue injury during stroke (Ostergaard et. al., 2000), traumatic brain injury (Dietrich et. al., 1994), vascular cognitive impairment (Gorelick et al, 2011), and Alzheimer's disease (Bailey et. al., 2004). One important facet of capillary dysfunction is the activation of matrix metalloproteinases (MMP) by cells of the neurovascular unit, which diminishes the integrity of the blood-brain barrier (BBB) and contributes to neurodegeneration.
One cell type in particular, the cerebral pericyte, plays an integral role in maintaining normal capillary function and has been shown to be susceptible to microvascular ischemia (Yemisci et al. 2009; Hall et al. 2014). Recent studies have also linked pericytes to MMP-2/9 production *in vitro* (Thanabalasundaram et. al., 2010; Takahashi et. al., 2014; Machida et. al., 2015). However, information about the spatiotemporal dynamics of MMP activation during capillary ischemia *in vivo* remains limited. In the current study we used *in vivo* two-photon microscopy to study the relationship between pericytes and BBB degeneration during photothrombotically-induced ischemia in capillaries. We imaged transgenic mouse lines expressing fluorescent reporters specifically in pericytes to unambiguously identify these structurally elaborate cells and their protruding ovoid-shaped somata within the capillary beds of the somatosensory cortex. We also utilized a FITC-bound gelatin probe to image MMP-2/9 activity *in vivo* in a spatially and temporally specific manner. We found that ischemia within the capillaries produced plasma leakage preferentially where pericyte somata adjoin the vessel wall, and that these events were associated with rapid (tens of minutes) and localized activation of MMPs following complete cessation of flow within the capillary branch. While their extensive processes cover the majority of capillaries, pericyte somata cover only 7%. As a result, a disproportionate amount of leakage occurred within a restricted fraction of the capillary bed. These localized leakage events could be significantly reduced with an MMP-9 inhibitor, but not an MMP-2 inhibitor. Our results suggest that pericytes may contribute either directly or indirectly to blood-brain barrier breakdown during diseases involving microvascular flow impairment.

Title: Construction of a new *In vitro* blood-brain barrier (BBB) model that incorporates triple culturing system of BBB components

Authors: *Y. TAKESHITA, Y. TOMOE, H. NISHIHARA, T. MAEDA, Y. SANO, T. KANDA;
Neurosci., Yamaguchi Univ. Grad. Sch. of Med., Ube, Japan

Abstract: [Background] The blood-brain barrier (BBB) is composed of brain-microvascular endothelial cells, pericytes and astrocyte. Pericytes and astrocytes endfeet, which are close contact with the endothelial cells, regulate the barrier function and play a key role in the pathogenesis of inflammatory neurological disorders including multiple sclerosis (MS) and neuromyelitis optica (NMO). However these regulations still remain unknown because there are no appropriate *in vitro* BBB models that enable us to closely mimic endothelium -interaction of pericytes and end-feet. [Aim] We construct an new *in vitro* BBB model incorporating three layer structure (endothelial cell, pericytes and end-feet of astrocytes) on the insert membrane using the UpCell technology of Nunc^{TM}. [Method] We utilized the conditionally immortalized human endothelial cell line (EC), pericyte cell line (PCT) and astrocyte cell line (AST). AST were co-cultured on abluminal side of insert membranes having 3 μm pores with PCT on luminal side. Then EC were cultured on UpCell^{TM} dish coated with Temperature-responsive polymer. After incubation at 20°C, sheet-like detachment of EC were transferred onto the PCT layer of the insert. They are tri-cultured at 37°C for one day to differentiate into mature cells (EC/PCT/AST). As control condition, we prepared traditional tri-cultured inserts with (EC/PCT-AST) or without (EC/PCT) AST-culture on the lower well surface. Solute permeability with 10k dextran with FITC were measured among them. [Result] Confocal 3D analysis with living cell staining revealed that triple cultured insert constitute a four-layer structure (EC, PCT, astrocyte endfeet protruded through membrane pores, and AST). Some astrocyte endfeet terminated in proximity to the EC and PCT layer. The values of permeability were significantly low in the order EC/PCT/AST, EC/PCT-AST, EC/PCT and EC. [Conclusions] Our model is the first BBB triple-cultured model incorporating the direct EC-interaction with pericytes and end-feet of astrocytes. This model provides reproducible assays for barrier regulations in MS or NMO with robust results, which will enable further defining the relationships between EC and the cellular elements of the BBB.

Title: Elevation of extracellular glycine levels leads to NMDAR internalization *In vitro* and ameliorates stroke outcomes *In vivo*

Authors: *A. SOKOLOVSKI, N. AHLSKOG, S. MORUZ, A. WONG, R. BERGERON; Neurosci., Ottawa Hosp. Res. Inst., Ottawa, ON, Canada

Abstract: Background: It has been suggested that cell death induced by ischemic stroke is the result of glutamate accumulation in the extracellular space and over-activation of ionotropic *N*-methyl-D-aspartate receptors (NMDARs). This leads to cell death *via* excitotoxicity, making blockade of NMDARs an attractive therapeutic target. However, large-scale multicenter clinical trials using NMDAR antagonists have failed to demonstrate satisfactory neuroprotective effects, suggesting a new approach is required. Glycine, a co-agonist of NMDARs with a bell-shaped dose-response curve, potentiates NMDARs at low doses while high doses induce NMDAR internalization. **Objective:** The goal of our investigation was to ascertain if glycine release was sufficient to cause NMDAR internalization in an *in vitro* stroke model (oxygen glucose deprivation: OGD) and to convey neuroprotection in an *in vivo* stroke model (photothrombosis: PT). **Preliminary Data:** Robust glycine release was observed using the sniffer patch technique during OGD. This was accompanied by a decrease in NMDA EPSC amplitude, which was abolished by blockers of dynamin-dependent internalization and exogenous application of the enzyme glycine oxidase. These *in vitro* data suggest that elevation of glycine during OGD may result in neuroprotection *via* NMDAR internalization during ischemic stroke. Consistent with this idea, glycine transporter-1 ($GlyT1^{+/-}$) transgenic mice, which have chronically saturating levels of glycine, showed a decreased stroke volume relative to wildtype (WT) mice. This was recapitulated *via* pharmacological blockade of GlyT1 in WT mice. In addition, a significant attenuation in post-PT sensorimotor deficits was observed in these mice, when assayed using the adhesive removal, horizontal ladder, and cylinder tests. **Conclusion**: Increased extracellular

glycine levels during ischemic events lead to NMDAR internalization, suggestive of a neuroprotective mechanism. Indeed, pharmacological elevation of glycine in WT mice, prior to PT, resulted in smaller stroke volumes and attenuated sensorimotor deficits. Thus, strategies aimed at maximizing extracellular glycine may be a novel therapeutic avenue in the treatment of stroke.

Title: The curcumin analog CNB-001 promotes clinical improvement in a rabbit embolic stroke model by down-regulating inflammatory markers and enhancing brain-derived neurotrophic factor.

Authors: *P. A. LAPCHAK[1], P. BOITANO[2], D. SCHUBERT[3];
[1]Dept. of Neurol. & Neurosurg., [2]Dept. of Neurol., Cedars-Sinai Med. Ctr., Los Angeles, CA;
[3]Salk Inst., La Jolla, CA

Abstract: We studied the pharmacokinetics and neuroprotective effects of intravenously administered [4-((1E)-2-(5-(4-hydroxy-3-methoxystyryl-)-1-phenyl-1H-pyrazoyl-3-yl)vinyl)-2-methoxy-phenol)] (i.e.: CNB-001), a pleiotropic molecule in a rabbit embolic stroke model. Since we have previously found that CNB-001 can potently and significantly reduce cell death mediated by glutamate, iodoacetic acid, ATP depletion, and oxidative stress (glutathione depletion), we tested the hypothesis that the in vitro neuroprotective effects of CNB-001 would translate in vivo and attenuate ischemia-induced behavioral deficits using the rabbit small clot embolic stroke model (RSCEM). **Pharmacokinetic Analysis**: For this study we used 2-3 month old male New Zealand white rabbits. In normal male New Zealand white rabbits, the t1/2 for IV administered CNB-001 (10mg/kg) was 3.37 ± 0.52 hours and clearance rate was 44.2 ml/min/kg. **Behavioral Analysis**: For this translational study, we used the standard RSCEM (Lapchak Translational Stroke Res. 2015 Apr;6(2):99-103. doi: 10.1007/s12975-015-0386-x.). A single dose of CNB-001(1-50mg/kg) was injected intravenously (IV) 1 hour post-embolization and behavioral function was measured 2 days post-embolization. Using quantal analysis, an effective

stroke clot dose (P_{50} in mg) producing neurological deficits in 50% of embolized rabbits was determined. Vehicle control and positive-control drugs were both included and studied in parallel; all studies were conducted blinded and randomized. In the RSCEM, 10mg/kg CNB-001 significantly improved behavior and increased P_{50} to 2.15 ± 0.09 mg (n=18, $p<0.05$) compared to vehicle 1.11± 0.08 mg (n=20), when the drug was administered 1 hour after embolization; the positive control group treated with tissue plasminogen activator (IV 3.3mg/kg) had a measured P_{50} of 2.69 ± 0.29mg (n=20). Dose-response analysis indicated that the minimal statistically effective dose was 5 mg/kg IV; and 50mg/kg significantly improved P_{50} by 125-150%. **Mechanism Studies**: In cortical tissue removed from naïve, vehicle- or CNB-001-treated embolized rabbits, using Western blot analysis, we measured and quantified inflammatory markers and BDNF levels. In embolized rabbits, CNB-001 attenuated COX-2 and 5-LOX expression and increased both pro-BDNF and BDNF expression. **Conclusions**: CNB-001 can significantly reduce behavioral deficits associated with brain ischemia when given after an embolic stroke; attenuation of deficits is produced by anti-inflammatory actions and enhanced neurotrophic factor mechanisms. (PAL was partially funded by NIH U01 NS060685).

Title: Early post treatment with (+) phenserine reduces ischemic brain injury in stroke rats

Authors: *Y. WANG, S. YU, E. BAE, K.-J. WU;
Natl. Hlth. Res. Inst., Zhunan, Taiwan

Abstract: (-) Phenserine, an acetylcholinesterase (AChE) inhibitor, has been used to improve cognitive function in patients with Alzheimer's disease (AD). (+) phenserine or posiphen, a stereoisomer of (-) phenserine, has been shown to possess neuroprotective effects in animal models of AD. Its mechanism of action is still not clear as (+) phenserine has no anti- AChE activity. The purpose of this study is to examine the neuroprotective effect of (+) phenserine against stroke. Primary cortical neurons were prepared from rat embryonic cortical tissues. (+) Phenserine significantly attenuated glutamate -mediated loss of MAP2 immunoreactivity. These data suggest that (+) phenserine has a neuroprotective action against excitatory amino acid-

induced neurotoxicity in culture. The protective effect of (+) phenserine was further examined in an animal model of stroke. Adult male rats were subjected to transient (60 min) middle cerebral artery occlusion (MCAo). (+) Phenserine or vehicle was given systemically after MCAo. Stroke animals receiving (+) phenserine showed a significant reduction in neurological scores and infarct volume. Post-treatment with (+) phenserine also reduced IBA1 immunoreactivity in the perilesioned area, suggesting (+) phenserine attenuated microglia activation in stroke brain. Taken together, our data support that early post-treatment with (+) phenserine reduced behavioral deficits, inflammation, and brain infarction in stroke animals.

Title: Sodium transport through the cerebral sodium-glucose transporter exacerbates the development of cerebral ischemic neuronal damage.

Authors: *Y. YAMAZAKI, S. HARADA, S. TOKUYAMA;
Kobe Gakuin Univ., Kobe, Hyogo, Japan

Abstract: Sodium-glucose transporter (SGLT) transports glucose into the cell, together with sodium ion. We recently demonstrated that the cerebral SGLT is involved in post-ischemic hyperglycemia-induced exacerbation of the development of cerebral ischemic neuronal damage. However, the associated SGLT-mediated mechanisms remain unclear. Thus, we examined the involvement of cerebral SGLT-induced excessive sodium ion influx in the development of cerebral ischemic neuronal damage. SGLT-specific sodium ion influx was induced using α-methyl-D-glucopyranoside (α-MG) treatments which is a non-metabolic glucose analog and a specific substrate for SGLT. In *in vitro* study, primary cortical neurons were cultured for five days before each treatment with reagents, and these survival rates were assessed using biochemical assays. A mouse model of focal ischemia was generated using a middle cerebral artery occlusion (MCAO). Mice were administered an intracerebroventricular (i.c.v.) injection of

regents at immediately and 6 h after reperfusion. Neuronal damage was assessed with histological and behavioral analyses. In *in vitro* study, at concentrations of greater than 0.1 mM, α-MG induced significant concentration-dependent decreases in neuronal survival compared with the control group without α-MG treatment. In contrast, 0.01 mM α-MG had no effect on neuronal survival rates. An SGLT family specific inhibitor, phlorizin (100.0 μM) significantly suppressed 100.0 mM α-MG-induced neuronal cell death. Moreover, 100.0 μM H_2O_2 significantly decreased neuronal survival rates compared with control group, and exacerbation of H_2O_2-induced neuronal cell death by 0.01 mM α-MG was suppressed by 50.0 μM phlorizin. In *in vivo* study, i.c.v. administration of α-MG (2.5, 5.0 μg/mouse) exacerbated the development of infarction and neurological abnormalities in a dose-dependent manner, and 5.0 μg of α-MG significantly exacerbated the development of infarction and neurological abnormalities compared with the vehicle-treated MCAO group. Under these conditions, phlorizin was protective against the development of infarction and neurological abnormalities. Therefore, excessive influx of sodium ion into neuronal cells through cerebral SGLT may exacerbate the development of cerebral ischemic neuronal damage.

Title: Anti-Nogo-A immunotherapy does not alter hippocampal neurogenesis after stroke in adult rats

Authors: D. SHEPHERD[1], S.-Y. TSAI[2], R. FARRER[2], *G. KARTJE[2,1];
[1]Loyola Univ. Chicago Hlth. Sci. Div., Maywood, IL; [2]Edward Hines Junior VA Hosp., Hines, IL

Abstract: Ischemic stroke is a leading cause of adult disability, including cognitive impairment. Our laboratory has shown that treatment with function-blocking antibodies against the neurite growth inhibitory protein Nogo-A promotes functional recovery after stroke in adult and aged rats, including enhancing spatial memory performance, for which the hippocampus is critically

important. Since spatial memory has been linked to hippocampal neurogenesis, we investigated whether anti-Nogo-A treatment increases hippocampal neurogenesis after stroke. After inducing permanent middle cerebral artery occlusion in adult rats, we measured cellular proliferation in the dentate gyrus at 5, 10, 14, and 21 days post-stroke, as well as the number of newborn neurons at 8 weeks post-stroke in untreated, control antibody-treated, and anti-Nogo-A-treated groups. We found that stroke alone transiently increased cellular proliferation and increased neurogenesis in the ipsilesional granule cell layer of the dentate gyrus. Treatment with both anti-Nogo-A and control antibodies increased the accumulation of new microglia/macrophages in the dentate granule cell layer, but neither treatment increased cellular proliferation or the number of newborn neurons above stroke-only levels. These results suggest that enhanced neurogenesis is not a key determinant of spatial memory recovery after stroke and anti-Nogo-A immunotherapy.

Title: Triiodothyronine neuroprotection after ischemia is mediated by astrocyte fatty acid oxidation

Authors: *M. M. SIFUENTES[1], N. SAYRE[2], D. HOLSTEIN[3], J. D. LECHLEITER[3]; [1]Cell. & Structural Biol., [2]Neurosurg., [3]Cell. and Structural Biol., Univ. of Texas Hlth. Sci. Ctr. At San Antonio, San Antonio, TX

Abstract: Stroke is a leading cause of death and disability in the United States, however few treatments options exist for patients. Thyroid hormone is observed to reduce stroke lesion size in mice, but the mechanism for this neuroprotection is still unknown. Astrocytes are critical support cells in the brain that our lab has shown readily respond to thyroid hormone by increasing energy production through the mitochondrial trifunctional protein (MTP), a protein complex that facilitates fatty acid oxidation (FAO). As increased energy metabolism is protective against brain injury, we hypothesized that thyroid hormone reduces lesion size by stimulating astrocyte MTP.

We observe that treatment with the active form of thyroid hormone (T3) stimulates an increase in ATP production in human astrocytes, which can be blocked by pretreatment with an irreversible FAO inhibitor. Astrocytes in the presence of T3 exhibit increased survival under in vitro stroke conditions, while this effect is not seen in astrocytes lacking MTP. Pharmacological and genetic inhibition of MTP in vivo also reduces thyroid hormone reduction of lesion size, suggesting that MTP activity is a critical component in brain damage from focal ischemia. Finally, we demonstrate that thyroid hormone protection against ischemia is attenuated in the presence of low concentrations of fluoroacetate, an astrocyte-specific mitochondrial inhibitor. Taken together, our research indicates that thyroid hormone reduces stroke damage by stimulating astrocyte metabolism in an MTP-dependent manner.

Title: The effect of extracellular zinc on the blood clot lysis induced by thrombolytic agents, streptokinase(SK) and tissue plasminogen activator(tPA)

Authors: *Z. WANG, X. YU, Y. LI;
Biomed. Sci., Ohio Univ. Dept. of Biomed. Sci., Athens, OH

Abstract: Thrombotic ischemic stroke occurs when the local blood clot obstructs an artery to the brain, causing affected brain tissue to lose function and die. It is one of the leading causes of mortality and a major cause of disability. Thrombolytic therapy is an approach to recover the impaired tissue function caused by stroke through I.V. administration of thrombolytic agents. Streptokinase (SK) and tissue plasminogen activator (tPA) are two such thrombolytic agents, which are widely used in the treatment of thromboembolism in the blood vessels. However, there are many safety concerns that arise from the usage of the thrombolytic agents. The most critical concern is their dosages applied during treatment, which heightens the risk of hemorrhagic transformation. In our present study, we studied the effect of different thrombolytic agents on blood clot lysis and how zinc affects thrombolysis induced by agents *in vitro*. We proposed a strategy to improve their effectiveness in thrombolysis in a low-dose regimen. The mice whole blood was used to produce blood clot *in vitro*. Thrombolytic agents, SK and tPA were used for inducing thrombolysis. Zinc and its chelator, CaEDTA, were applied with thrombolytic agents. Spectrophotometer was used to measure thrombolysis effect at 580 nm wavelength. Results

showed that both tPA and SK induced thrombolysis in a dose-dependent manner. Zinc inhibited thrombolysis effects of tPA and SK in a dose-dependent manner. Zinc chelator, CaEDTA, significantly increased the effects of both tPA- and SK-induced thrombolysis. We concluded that zinc inhibits thrombolytic effect *in vitro*. Chelation of zinc improves the effectiveness and safety of thrombolytic agents (tPA and SK) in thrombolysis.

Title: Preservation of neurological function by 4R-cembranoid following an ischemic stroke.

Authors: *W. CASTRO[1], H. MARTINS[2], B. CUADRADO[3], Y. FERRER[3], G. GRUDZIAK[4], P. FERCHMIN[3], V. ETEROVIC[3];
[1]Univ. Central Del Caribe, Cayey, PR; [2]Biochem., [3]Univ. Central del Caribe, Bayamon, PR; [4]Bromedicon, Yardley, PA

Abstract: 4R-cembranoid (4R) is a non-toxic, brain permeable compound that decreases the infarct volume caused by middle cerebral artery occlusion (MCAO) in rats and mice (Martins et al, 2015). This work addresses two questions: 1) Does 4R preserve neurological function after an ischemic stroke? 2) Can somatosensory evoked potentials (SSEP's), measured during occlusion and reperfusion, predict the infarct volume observed 24 hours after the MCAO? To answer these questions, rats were subjected to 1 hour of MCAO and 1 hour of reperfusion, followed by a subcutaneous injection of vehicle or 4R (6mg/kg). To answer the first question, SSEP's were evaluated throughout the experiment, and behavior was measured using the Neurological Severity Score (NNS) 24 hours after occlusion. Rats treated with 4R, but not with the vehicle, exhibited reemergence of SSEP's 15 to 30 min after administration ($p<0.01$) and showed an increased neurological function, measured 24 hours after the initial occlusion ($p<0.05$). Rats treated with 4R also exhibited decreased astrocyte reactivity around the infarction area, as measured by GFAP staining ($p<0.05$). These results suggest that one of the mechanisms by which 4R helps preserve neurological function is by decreasing astrocyte reactivity. To address the second question, a scoring system for the SSEP's amplitude measured during the occlusion and reperfusion was created. These scores were then evaluated and compared to the resulting

infarct volume measured by TTC. A negative correlation was obtained when comparing the SSEP score and the infarction volume (r^2, 0.85; $p<0.001$). These results confirm that 4R not only decreased the tissue damage caused by ischemic stroke, but also promoted a fast re-emergence of neurophysiological function that translated in an increase in neurological function. Our results also confirm that the SSEP score system we developed, used during occlusion and reperfusion, offers a novel tool to predict tissue damage outcome 24 hours after the initial occlusion.

Title: A novel therapeutic target for stroke by inhibition of GAPDH aggregation

Authors: *M. ITAKURA[1], T. KUBO[1], A. KANESHIGE[1], Y.-T. AZUMA[1], T. HIKIDA[2], T. TAKEUCHI[1], H. NAKAJIMA[1];

Abstract: Glycolytic enzyme glyceraldehyde-3-phosphate dehydrogenase (GAPDH) is a homotetrameric protein that also mediates cell death under oxidative/nitrosative stress. We previously reported that intermolecular disulfide-bonding of GAPDH aggregates through oxidation of the active site cysteine (Cys-152) participates in oxidative/nitrosative stress-induced cell death. Our recent findings also revealed that the active site cysteine-null GAPDH (C152A-GAPDH) rescues oxidative/nitrosative stress-induced neuronal cell death *in vitro* in a dominant negative manner via the formation of hybrid tetramer. Here we report that this dominant negative

C152A-GAPDH mutant against endogenous GAPDH aggregation in response to oxidative/nitrosative stress induced by an ischemia-reperfusion *in vivo* ameliorated neuronal cell death caused by mitochondrial dysfunction in a middle cerebral article occlusion (MCAO) stroke model using its conditional transgenic mice, and a specific inhibitor of GAPDH aggregation exerted decrease of infarction and neurological deficits These findings provide a therapeutic avenue of new drug target for the stroke brain damage.

Title: Effects of pomegranate supplementation on recovery following ischemic stroke: a randomized, placebo-controlled, double-blind trial.

Authors: *J. R. MURRAY[1], J. A. BELLONE[2], P. JORGE[3], T. G. FOGEL[4], M. KIM[4], D. WALLACE[4], R. E. HARTMAN[2];
[1]Psychology, Loma Linda Univ., Riverside, CA; [2]Loma Linda Univ., Loma Linda, CA; [3]Physical Med. and Rehabil., [4]Loma Linda Univ. Med. Ctr., Loma Linda, CA

Abstract: Motor and cognitive deficits are commonly observed following stroke, and individuals with these symptoms often experience difficulty with activities of daily living. Furthermore, these individuals typically have prolonged rates of recovery and are placed at greater risk for additional complications such as lower quality of life, fatigue, depression, and suicide. Our laboratory has shown that pomegranate supplementation can protect against Alzheimer's-like neuropathology and irradiation in mice and post-operative cognitive deficits following open heart surgery in humans. Other studies have reported increased muscle strength and decreased muscle pain among healthy individuals, and beneficial properties have been demonstrated in numerous disease states. Therefore, we sought to determine whether dietary supplementation with pomegranate polyphenols could enhance physical and/or cognitive recovery in individuals who recently suffered an ischemic stroke. We administered pills containing pomegranate polyphenols (n = 8), or placebo (n = 8) every day for one week to acute post-stroke inpatients. Cognitive changes were assessed with baseline and post-treatment Repeatable Battery for the Assessment of Neuropsychological Status (RBANS) tests, and physical recovery was measured pre- and post-treatment using a global relative Functional Independent Measure (FIM) score. The

pomegranate treatment group demonstrated significant cognitive improvement on the RBANS ($p<.05$), whereas the control group did not improve over the 1 week period. The pomegranate group also demonstrated significant improvement on the global FIM score relative to the placebo group ($p<.01$). Within the FIM, the pomegranate group demonstrated specific improvement compared to the placebo group in the Self-Care ($p<.05$) and Locomotion ($p<.01$) domains. Findings from this randomized, double-blind, placebo-controlled clinical trial suggest that pomegranate polyphenols may be effective at enhancing cognitive and physical recovery after ischemic stroke.

Title: Xo along with Xd might be important regulative enzymes for recovery and regeneration after stroke in rats

Authors: *K. DANIELYAN, A. A. SIMONYAN;
H. Buniatian Inst. of Biochem., Yerevan, Armenia

Abstract: Background. Xanthine Oxidase (XO; EC 1.1.3.22) along with Xanthine Dehydrogenase (XD; EC 1.17.1.4) are two enzymatic faces of Xanthine Oxidoreductase (XOR; EC 1.17.3.2), responsible for the last steps of purine catabolism, which might be converted into the oxidase form due to the limited proteolysis. Our investigations evidence, this enzyme might serve as a regulative compound for purine catabolism pathway and act by feed-back mechanism; inhibition of it stimulates the increase of the human embryo brain derived cells' number and prevents them from death. We also found out new inhibiting compound for XO, pyridoxine (Danielya, K.E., 2014). Methods. For flow cytometry analysis we used APC anti-human Ki-67. Cells were cultured by Mattson M. 1990, method. Cell culture waas treated with 3% H_2O_2 for one hour. Hydrogen peroxide after limited craniotomy was injected into the brain parenchyma. BBB disruption was evaluated spectrophotometrically (λ=550 nm). Results were evidencing, the cells proliferation might be stimulated after treatment with allopurinol, classical inhibitor of XO, and pyridoxine from days 1-6 as well as 1-12th. Also. in comparison with the control

(2680.00±45.34) in the peroxide treated cell culture group (1631.89±111.77) the number of the cells was dramatically decreased in contrast to allopurinol treated group 15 minutes before (1852.38±94.79) and 15 minutes after (1950.38±33.67) addition of H_2O_2. In pyridoxine group the number of the cells in statistically significant way were increased before (2106.88±79.64) and after (2392.38±104.01) H_2O_2 addition ($p<0.05$). For exclusion of experimental errors of Evans Blue extraction after animals' perfusion we have extracted from ipsilateral hemispheres the values of the contralaterals (that is the reason for the negative number appearance). Conclusion. Protective, regenerative abilities of pyridoxine and allopurinol, as XO inhibitors, are proposed.

Title: Hydrogen peroxide acts as an endogenous regulating factor for phagocytotic function of microglia: role of nrf2

Authors: *X. ZHAO, G. SUN, S.-M. TING, J. ARONOWSKI;
Neurol., UT Med. Sch., Houston, TX

Abstract: Red blood cells (**RBC**) and other components of the blood, deposited within brain parenchyma during intracerebral hemorrhage (**ICH**), are the source of cytotoxicity and inflammation, and the cause of secondary brain injury. Therefore, it is assumed that fast and efficient removal of the hematoma components from the brain could be essential for reducing the damage and improving functional recovery and brain repair. Microglia/macrophage (**MΦ**)-mediated phagocytosis represents an endogenous mechanism involved in the hematoma clearance after I**CH**. However, the high levels of pro-oxidative molecules (including hydrogen peroxide, **H_2O_2**) normally generated by MΦ during phagocytosis and phagosome-mediated catabolic processes, could be cytotoxic not only to brain cells but also to the function of MΦ themselves. Therefore, an efficient coupling between phagocytosis-mediated cleanup and the endogenous anti-oxidative processes within the phagocytes, could be required for the safe and efficient cleanup. Nuclear factor-erythroid 2 p45-related factor 2 (**Nrf2**) is a basic leucine zipper (bZIP) transcription factor that acts as a key regulator of the expression of antioxidant proteins as means of protection against oxidative damage fallowing injury and inflammation. In agreement with this notion, we established that the Nrf2-deficient MΦ are more susceptible to "ICH-like" injury and H_2O_2-mediated oxidative damage. And the Nrf2-KO mice subjected to ICH experienced more severe brain edema and delayed hematoma resolution. In addition, the phagocytosis of red blood cells (**RBC**) by cultured MΦ (model of hematoma cleanup process) was significantly inhibited by Nrf2 decoy and in MΦ harvested from Nrf2 knockout mice. On the other hand, pharmacologic activation of Nrf2 leads to improved phagocytosis function, suggesting that Nrf2 activation may be a potential therapeutic target for improving hematoma and inflammation resolution after ICH. Hydrogen peroxide (**H_2O_2**) is a reactive molecule produced by MΦ during phagocytosis process, which at higher concentrations is known to be toxic to neurons. In our studies, we find that **H_2O_2** at lower (sub-micromolar) concentrations serves also as a pro-survival factor for MΦ by activating Nrf2. Low levels of H_2O_2 protects MΦ

from ICH-like injury and similar to Nrf2 activators improves phagocytic function of MΦ toward RBC. We propose that H_2O_2 in MΦ functions as a double-edged sword, also having pro-survival and cleanup facilitating effects that could benefit ICH-mediated damage.

Title: MicroRNA-103-1 is involved in the pathogenesis of ischemic brain damage and may represent a stroke peripheral diagnostic marker

Authors: P. CEPPARULO, *F. MICELI, A. VINCIGUERRA, O. CUOMO, G. DI RENZO, G. PIGNATARO, L. ANNUNZIATO;
Fac. of Medicine, Univ. of Naples Federico II, Naples, Italy

Abstract: Ischemic stroke is a multi-faced pathology that involves gene reprogramming. Among those genes whose expression is influenced by cerebral ischemia can be included the plasmamembrane protein sodium-calcium exchanger-1 (NCX1), that, by controlling Ca^{2+} and Na^{+} fluxes in a bidirectional way across the synaptic plasma membrane, plays a pivotal role in the regulation of ionic homeostasis in physiological and pathophysiological conditions such as brain ischemia. We have recently identified a microRNA, miR-103-1, able to selectively modulate NCX1 expression in the brain during stroke, whose inhibition by anti-mir-103-1, intracerebroventicularly infused in ischemic rats, causes NCX1 upregulation in brain cortex and striatum accompanied by brain damage reduction. Since it has been established that microRNAs (miRNAs) can be included in microvesicles called exosomes and released in the blood, it has been hypothesized a potential use of these non-coding RNAs as biomarkers for neurological disorders. In this work, we firstly investigated the expression of miRNA-103-1 in the ischemic penumbra of animals subjected to brain ischemia or to the neuroprotective protocol called "Remote Postconditioning" (RemPost), a strategy in which a subliminal ischemia applied to a "distant" organ is able to protect the brain from a previous harmful ischemic insult. As expected,

the expression of miRNA103-1 increased after harmful brain ischemia and was dramatically reduced after remote postconditioning. More interestingly, we were able to demonstrate that miR-103-1 may serve as peripheral prognostic/diagnostic marker of stroke, since its expression level in plasma samples of rats subjected to brain ischemia is proportionate to brain ischemic damage. These results suggest that miRNA103-1 expression may be used as marker of ischemic brain damage and, more intriguingly, it is released in the blood in a manner proportionate to brain damage, thus representing a good candidate for stroke diagnosis and prognosis.

Title: Role of β-adrenoreceptor partial agonist in pathophysiology and recovery of ischemic stroke

Authors: K. RAVINA, Z. WARRAICH, S. KISLAL, *M. SHAMLOO;
Stanford Behavioral and Functional Neurosci. Lab., Stanford Univ. Sch. of Med., Palo Alto, CA

Abstract: Noradrenaline plays significant role in modulating metabolic and inflammatory activity within the brain by activating receptors on glial cells and neurons. Xamoterol is a selective β1-adrenoreceptor partial agonist. Our laboratory has shown that chronic treatment with β1-adrenoreceptor agonist, xamoterol, significantly enhances cognitive function and reduces inflammation and levels of pro-inflammatory markers in mouse models of Alzheimer's disease. We therefore investigated the effect of chronic xamoterol dosing on stroke recovery by implementing intraluminal filament method of transient middle cerebral artery occlusion in male Sprague-Dawley rats. Starting 24h post-stroke, animals received vehicle or 0.1, 1 or 3 mg/kg dose of xamoterol subcutaneously for 21 days. Brain tissue immunohistochemical assessment of neuronal loss displayed smaller infarction in animals treated with 1 and 3 mg/kg of xamoterol daily in comparison to the other treatment groups.
To evaluate whether the effect of 1 mg/kg dose on post-stroke functional recovery is treatment time-dependent, we initiated xamoterol treatment at 24 or 72 h after the onset of ischemia. In Garcia neurological scoring test and vibrissae elicited forelimb placement (paw-whisker) test the 72h post-stroke treatment group showed improved recovery in comparison to 24h post-stroke group.

Our results suggest that mild activation of β1-adrenoreceptors during early phase post-stroke (24-72 hours) exerts neuroprotective properties and can also enhance the recovery of function. Further research is granted to investigate molecular and cellular aspects of adrenergic stimulation in the pathophysiology of stroke.

Title: Procognitive property and antischemic effect of S 44819 a novel promising candidate drug for stroke therapy

Authors: I. GACSÁLYI[1], G. GIGLER[1], K. MORICZ[1], J. WELLMANN[1], *E. MOCAER[2], P. MACHADO[2], F. ANTONI[1];
[1]EGIS PHARMACEUTICALS, BUDAPEST, Hungary; [2]I.R.I.S., SURESNES, France

Abstract: S 44819 is a novel alpha 5 GABAA receptor competitive antagonist. S 44819 showed potential procognitive efficacy in different rodent models of cognition. In the object recognition (OR) model in naive mice and rats, S 44819 (0.3-10 mg/kg *i.p.*) significantly increased the time spent with novel object. The ketamine induced memory loss (reference and working memory), measured in radial maze in rats, was blocked by S 44819 (3 mg/kg *p.o.*) as well. Ischemic stroke causes a hypoexcitability in the peri-infarct motor cortex that stems from increased tonic GABA activity onto neurons. Whereas this chronically elevated inhibition in the peri-infarct region is useful to protect tissues in the excitotoxic phase of stroke, it may antagonize the neuronal plasticity phenomena responsible in a later phase for functional recovery after stroke. S 44819 by antagonizing this elevated GABA inhibition may accelerate the more rapid functional recovery after stroke. S 44819 proved to be effective in numerous animal models of stroke and vascular dementia. It antagonized the unilateral carotid occlusion induced memory deficits in mice 30 days after the occlusion in a working memory paradigm in T-maze (1-3 mg/kg *p.o.*). In the widely used stroke model, transient middle cerebral artery occlusion (tMCAO) model, the recognition memory deficit (NOR test) was reversed by acute and chronic 8 days administration (2x 15 mg/kg *p.o.*) of S 44819 in rats. The effect was still observed even after 7 days washout

period. Besides the cognitive decline, tMCAO surgery caused long lasting sensorimotor deficit in rat. The motor deficit assessed in the adhesive removal test was significantly improved by S 44819 (2x 15 mg/kg *p.o.*) during the 18 days treatment period. These results suggest that S 44819 is a promising candidate drug for improving recovery post-stroke.

Title: The neuroprotective capabilities of glial-derived neurotrophic factor following intraluminal filament middle cerebral artery occlusion in mice

Authors: *G. P. MORRIS[1,2], A. L. WRIGHT[1], S. STAYTE[1], R. ZINN[1,3], R. P. TAN[1,4], B. VISSEL[1,3,5];
[1]Neurosci., Garvan Inst. of Med. Res., Sydney, Australia; [2]Fac. of Med., [3]Univ. of New South Wales, Sydney, Australia; [4]Heart Res. Inst., Sydney, Australia; [5]Fac. of Sci., Univ. of Technol., Sydney, Australia

Abstract: Glial-derived neurotrophic factor (GDNF) is a highly conserved endogenously produced neurotrophic, neuroprotective and neurogenic factor that has been investigated as a treatment for a variety of acute and chronic neurodegenerative disorders including Parkinson's disease, Alzheimer's disease, traumatic brain injury and stroke. Characterised initially as a potent survival factor for midbrain dopaminergic neurons, GDNF is protective for a variety of neuronal populations. In this study we aimed to determine the neuroprotective capabilities of GDNF following ischemic injury, induced by intraluminal filament middle cerebral artery occlusion (MCAO) in mice. Further, we assessed whether GDNF may exert its neuroprotective effects by dampening widespread inflammatory responses following MCAO. Using 2,3,5-

Triphenyltetrazolium chloride (TTC), Cresyl Violet staining and immunohistochemistry (IHC) against NeuN, we first determined the magnitude and patterns of reproducible ischemic injuries following 0 - 60 min of occlusion at 0.5 - 72h post-reperfusion in C57BL/6 mice. We also assessed neurological scores, behavioural deficits (Open Field, Rotarod and Wire hang), weight loss, cerebral blood flow (CBF) and IHC staining of IBA1+ and GFAP+ microglia and astrocytes, respectively. Once reproducibly established, we administered GDNF to C57BL/6 mice via osmotic mini-pumps attached to cannula implanted in the lateral ventricle (+1.0 ML, -0.2 AP, 2.8 DV) and compared the impact of GDNF treatment on the magnitude of ischemic neuronal injury, neurological scores, motor behaviour, CBF, weight loss, IBA1+ microglia and GFAP+ astrocytes, to ACSF vehicle controls. We established a large reproducible ischemic injury, the magnitude of which could be manipulated by altering the period of MCAO. We also observed significant neurological and behavioural deficits following MCAO. In addition there were profound increases in IBA1 and GFAP staining after occlusion, with clear morphological alterations in IBA1+ and GFAP+ cells, extending through most of the ipsilateral cortex, compared with sham controls. Our present findings suggest GDNF treatment markedly decreases the magnitude of ischemic injury at 24h post-MCAO and improves neurological scores, compared to vehicle treated controls.

Title: Tissue plasminogen activator is essential for functional recovery after stroke by promoting axonal outgrowth

Authors: *S. MA, H. PU, L. ZHANG, C. WEI, Z. LU, X. HU, J. CHEN;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Objectives: Stroke is a neurological disorder that leads to long term motor and cognitive dysfunction. Human recombinant tissue plasminogen activator (tPA) is the only FDA approved drug for the thrombolytic treatment of ischemic stroke. Interestingly, accumulating evidence reveals that the effects of tPA in ischemic brain may extend beyond its thrombolytic

activity. So far, the function of endogenous tPA in injured brain is still unclear. In this study, we sought to elucidate the function of endogenous tPA in long term recovery after stroke.
Methods: Cerebral ischemia was induced by distal middle cerebral artery occlusion (MCAO) in tPA knockout (KO) mice and the wild type littermates. For tPA treatment, tPA (2mg/kg) were delivered intranasally to tPA KO mice for 14 days starting 6h after dMCAO. For outcome assessments, sensorimotor deficits (rotarod test, cylinder test, foot fault test, adhesive remove test) were determined at 3-35 days after stroke; cognitive deficits (water maze test) was determined at 22-27 days after stroke. The axonal damage were assessed by expression of non-phosphorylated neurofilament (SMI32). The neuronal tracer biotinylated dextran amine (BDA) was injected into the uninjured left motor cortex(M1, 21 day after stroke) to anterogradely label the corticorubral tract and the corticospinal tract . The effect of tPA on axonal outgrowth were also investigated in vitro in cortical neuronal cultures.
Results: Lack of tPA exacerbates sensorimotor deficits for at least 35 days after dMCAO. The tPA KO mice also exhibited significantly worsened performance in water maze after dMCAO compared to wild type mice, suggesting a deteriorated cognitive functions with tPA deficiency. The functional exacerbation in tPA KO mice is accompanied by enhanced axonal injury and poorer axonal sprouting at 35 days after stroke. In contrast, intranasal delivery of tPA after dMCAO improves long-term neurological functions as compare to vehicle-treated KO mice. TTC or MAP2 staining of coronal sections at different time points after dMCAO showed comparable infarct volume or tissue loss between KO and wild type mice. In vitro study demonstrated that tPA at nanomolar concentrations potently promotes the axonal growth under physiological condition or after oxygen and glucose deprivation (OGD).
Conclusion: Endogenous tPA is essential for functional recovery after stroke through, at least partially promoting axonal regrowth. These observations promote clinical investigations on tPA as a potential therapeutic agent for stroke patient.
Keywords: dMCAO**;** axonal sprouting; tPA.

Title: Mesenchymal stem cell transplantation affords therapeutic benefits against retinal ganglion cell death in adult rats with experimentally induced ischemic stroke

Authors: *J.-Y. LEE, H. NGUYEN, S. ACOSTA, C. V. BORLONGAN;
Neurosurg. Brain Repair, Univ. of South Florida, Tampa, FL

Abstract: The occurrence of retinal ischemia in animals subjected to middle cerebral artery occlusion (MCAO) has been recently suggested owing in part to the circulatory juxtaposition of the ophthalmic artery to the MCA. In this study, we examined laser Doppler to evaluate the hemodynamic in the eye of MCAO-induced stroke and MSC treatment rats. Brain and retinal perfusion was evaluated by laser Doppler at 0 days (after MCAO), 3 days and 14 days. Retina - relevant behavioral and histological outcomes were performed at 3 days and 14 days post-MCAO. We also studied the retina-sensitive task performance and the density of retinal ganglion cell after MSC treatment. Laser Doppler revealed typical reduction in cerebral blood flow in the ipsilateral front parietal cortical area of at least 80% decrement during MCAO compared to baseline, which returned to near baseline levels after MCAO. A significant defect in the retinal perfusion in the ipsilateral eye was detected with at least 30% reduction in blood flow during MCAO compared to baseline, which was also restored to near baseline levels during reperfusion. Behavioral performance in light stimulus-mediated place preference was significantly impaired in MCAO rats compared to control animals. Retinal ganglion cell density were significantly decreased in ipsilateral eye. After MSC treatment, cerebral blood flow were fast restored to near baseline levels in ipsilateral brain and eye during 3days and 14 days. Also, Behavioral test were significantly recovered in MSC treatment rats compared stroke animals. Interestingly, Immunohistochemistry for retinal ganglion cell were increased cell counting and brain infarct area were decreased during 14 days. In summary, stroke may present with visual deficits, which can be detected by retinal perfusion using laser Doppler measurements, complementing the diagnosis of stroke onset and progression. Stem cell transplantation may provide relief from such stroke-induced retinal dysfunctions.

Chiao-Tung Univ., Hsinchu, Taiwan; [5]Brain Res. Center, Natl. Chiao-Tung Univ., Hsinchu, Taiwan

Abstract: Neurorehabilitation is aiming to aid recovery the nervous injury from either the central nervous system or the peripheral nervous system, and to minimize and/or compensate for any functional alterations resulting from the injury. It is a complex medical process, especially for the stroke, epilepsy, brain trauma patients and so on. The main neural mechanism of the injury is still unknown and attractive for many researchers devote to investigate the neural plasticity. For example, stroke patients often experience muscle spasticity affecting upper limb function or gait performance, which will be seriously affected their daily life quality. So far, there were still no comprehensive treatment strategy which can integrate brain and peripheral system to enhance neural plasticity and improve motor functional performance.
Virtual reality recently has become a popular topic in the neurorehabilitation field. Stroke patients perform motor imagery-based training in virtual environment has evidenced a promising stagey to add to the motor rehabilitation. In addition, botulinum toxin (BTX) treatment can relieve spasticity after stroke, "likely acting at several hierarchical levels of the motor system" (Kanovsky, 2013). The goal of this study is to investigate the brain dynamics associate with the improvement of training upper limb function after BTX treatment through our developed virtual reality based neurorehabilitation training environment.
Fifteen stroke patients in different damage level performed three virtual reality based tasks, included forearm rotation, flexion and extension of elbow and fingers, before and after BTX injection. Each patient will take around one hour to perform two sessions, which comprise the proposed three tasks of each session in this study. We use Neuroscan System to record 32-channel electroencephalography (EEG) signals, and then decode EEG signals to investigate brain neural network changes after receiving BTX treatment.
We intend to observe the brain dynamics of the patients' motor cortex in comparison with the BTX injection or not for evaluating their upper limbs training performance. Brain activity changes reveal the recovery efficacy to inspire stroke patients perform the rehabilitation task with the BTX treatment, which will provide a points of view toward treatment of stroke patients. EEG signals can not only be a potential assessment in stroke patients, but also be used as a feature to develop a new rehabilitation treatment approaches. Furthermore, we will develop a treatment strategy including brain-computer interface and virtual reality training combined BTX treatment to assist neurorehabilitation effectiveness.

Title: Thyroid hormones effect in mice experimental MCAO brain stroke model

Authors: *A. MDZINARISHVILI[1], W. GELDENHUYS[2], P. SADANA[3], V. SUTARIYA[4]; [1]Dept. of Rehabil. Sci., Univ. of Oklahoma, Col. of Allied Hlth., Oklahoma City, OK; [2]Dept. of Pharmaceut. Sci., Sch. of Pharmacy, Univ. of South Florida, Tampa, FL

Abstract: Brain stroke is a devastating brain injury and is a leading cause of adult disability. The primary pathological complication and a significant reason for mortality in brain stroke is cerebral edema. Accumulation of fluid in the intracellular or extracellular spaces of the brain increases intracranial pressure which endangers the survival of the patients. **Currently, there is no effective neuroprotective agent for acute ischemic stroke in clinical practice.** Quests for salubrious and effective neuroprotective agents have led to increased interest in use of endogenous hormones as neuroprotectants. It has been shown that neuroendocrine profile is significantly altered in ischemic brain stroke. We have turned our attention to thyroid hormones and their potential use in brain ischemic stroke. In this work possible neuroprotective involvement of thyroid hormones was investigated using experimental brain stroke model – middle cerebral artery occlusion (MCAO). T2 is an active metabolite of T3, a key hormone secreted by the thyroid gland. It has been found that T2 has a much more rapid stimulation of metabolic rate than T3. Encapsulating T3 brain-targeted nanoparticles (PLGA-b-PEG) could have greater ability to permeate biological membranes and afford protection in the brain infarct areas. In our study we tested potential neuroprotective effects of thyroid hormones (T3, T2 and encapsulating T3 in brain-targeted nanoparticles) *in vivo* using the mice model of transient (1h) middle cerebral artery occlusion (t-MCAO). For drug treatment, CD-1 mice (25-30g) were treated with T3 and T2 (25 μg/kg) injected i.v. through the jugular vein. Equivalent dose of T3 nanoparticles in same volume were administered to respective mice group. T3, T2, T3 nanoparticles or vehicle were injected 30 min before brain stroke induction. Vehicle (PBS) treated animals served as controls. Animals were sacrificed after 24h, 1mm coronal brain slices

were prepared and stained with 1% TTC. Volumes of brain ischemia and edema formation were evaluated. *In vivo* results showed that T3 (25 μg/kg) reduced brain infarct volume by 37% ($p<0.005$), and edema formation by 60% ($p<0.001$).*In vivo* results showed that T2 (25 μg/kg) reduced brain infarct volume by 42% ($p<0.005$), and edema formation by 65% ($p<0.001$). *In vivo* results showed that encapsulating T3 in brain-targeted nanoparticles (25 μg/kg) reduced brain infarct volume by 58% ($p<0.005$), and edema formation by 75% ($p<0.001$). Positive effects of thyroid hormones in t-MCAO brain stroke model determined the ideal usage parameters for thyroid hormones (T3, T2 and encapsulating T3 brain-targeted nanoparticles) as a therapeutic agents in ischemic brain stroke.

Title: Elucidating the molecular mechanisms behind the long-term cerebral ischemic tolerance mediated by resveratrol preconditioning.

Authors: *N. KHOURY[1], K. B. KORONOWSKI[1], I. SAUL[1], K. R. DAVE[1], J. I. YOUNG[2], M. A. PEREZ-PINZON[1];
[1]Dept. of Neurol. and Neurosci. Program, Cerebral Vascular Dis. Rese, [2]Dr. John T. Macdonald Fndn. Dept. of Human Genet., Miller Sch. of Medicine, Univ. of Miami, Miami, FL

Abstract: In the absence of effective neuroprotective agents in the clinic, ischemic and pharmacological preconditioning are gaining increased interest in the field of cerebral ischemia. Our lab recently demonstrated that resveratrol preconditioning (RPC) affords tolerance against cerebral ischemia that lasts for at least 2 weeks *in vivo*, making it the longest window of ischemic tolerance discovered to date by pharmacological preconditioning. We conjectured that this window may be mediated by genomic reprogramming events that occur in the brain after preconditioning. Thus the goal of this study is to identify the epigenetic and transcriptional alterations which are induced in the brain after RPC that could mediate this long-term window of

ischemic tolerance. In order to identify the transcriptomic modifications, we injected 10 week old C57Bl6 male mice with either Vehicle or Resveratrol (10mg/kg) intraperitoneally (n=3 per group). Two weeks post the single injection we collected the cortex of these mice, isolated the RNA, and performed an RNA-seq experiment using the Illumina HiSeq 2500. Using a cut-off value of 0.1 for the false discovery rate and 1.5 for the fold change, we identified 85 differentially expressed genes. Interestingly 70 out of the 85 differentially expressed genes were downregulated after RPC compared to only 15 genes being upregulated. We randomly chose 10 genes having an FDR<0.1 and designed SYBR green primers to validate the relative expression of these genes compared to β-actin using real-time PCR analysis. The results obtained correlate well with our RNA-seq data. Pathway analysis using the Functional Annotation Clustering tool from DAVID Bioinformatics Resources, revealed 10 clusters for the differentially expressed genes. The clusters were enriched for the following gene ontology terms: dendrites, ribosome, translation, mitochondria, cytoplasmic vesicles, plasma membrane and synapses, ion transport, transcription among others. The downregulation in these cellular activities is reminiscent of the phenomenon of metabolic depression which is an adaptive mechanism observed in hibernating animals that allow them to tolerate extreme hypoxic and ischemic conditions experienced during torpor. In conclusion this study reveals that RPC induces a global downregulation in gene expression in the brain of preconditioned mice. Ongoing studies in the lab will reveal whether this mechanism is behind the long-term tolerance to cerebral ischemic insults observed after resveratrol preconditioning

Title: Anti-inflammatory effects of the AVP receptor blocker conivaptan

Authors: *S. M. JONES[1], E. ZEYNALOV[1], J. ELLIOTT[2];
[1]Neurotrauma Res., Swedish Med. Ctr., Englewood, CO; [2]Colorado Brain and Spine Inst., Englewood, CO

Abstract: Cerebral edema is a common complication of ischemic stroke, which can lead to increased intracranial pressure and secondary injury following reperfusion. In some cases, cerebral edema is due to disruption of arginine vasopressin (AVP), as in the syndrome of inappropriate diuretic hormone (SIADH). Multiple studies have shown that AVP exacerbates edema and promotes blood brain barrier breakdown and neural damage following injury or ischemia.

We have shown that the V1/V2 receptor blocker conivaptan prevents edema and blood brain barrier (BBB) breakdown in a mouse model of stroke. Previous studies have shown that AVP deficient rats have a reduced inflammatory response to traumatic brain injury (Szmydynger-Chodobska et al. 2010), including expression of chemokines and influx of neutrophils and monocytes. Overexpression of CXC and CC chemokines augment recruitment of inflammatory cells, which have been linked to cerebral edema, BBB disruption and neural damage. This study was designed to determine whether treatment with conivaptan reduces stroke-induced neuro-inflammation in mice.

Animal care and use were conducted according to guidelines and approval of Swedish Medical Center IACUC. Mice (C57/Bl6) were subjected to 60-minute focal middle cerebral artery occlusion (MCAO) followed by reperfusion. Treatment with conivaptan or saline (continuous infusion via jugular vein, 0.2 mg/mouse/day) was initiated immediately after reperfusion. After 5 hr survival, mice were sacrificed and brain tissue harvested for qPCR analysis TNFα, CXCL1 and CCL2 and the V1a receptor (AVPR1α).

In the ipsilateral cortex, MCAO induced the expression of AVPR1α five-fold compared to levels detected in sham animals. Conivaptan treatment prevented the induction of AVPR1α almost completely. The expression of TNFα, CXCL1 and CCL2 were also induced dramatically (30-120 fold) following MCAO. Treatment with conivaptan reduced the expression of TNFα and CXCL1, but had no effect on the expression of CCL2 which was highly variable between subjects. Similar to MCAO, oxygen glucose deprivation (OGD) induced the expression of AVPR1α in cultures of primary astrocytes. However, neither OGD nor AVP treatment had any effect on TNFα, CXCL1 or CCL2 in astrocyte cultures.

These data indicate that conivaptan reduces the induction of an early inflammatory response following stroke. The activation of these early cellular responses to injury initiate cascade of processes leading to secondary inflammation and the infiltration of neutrophils and monocytes, which have been shown to contribute to edema, BBB disruption and cellular damage.

Title: Neurotrophin regulation of neuronal death after injury

Authors: *L. E. MONTROULL[1], D. ROTHBARD[2], J. P. ZANIN[1], S. W. LEVISON[2], W. J. FRIEDMAN[1];
[1]Dept. of Biol. Sci., Rutgers University, Life Sci. Ctr., Newark, NJ; [2]Dept. of Pharmacology, Physiol. and Neurosci., Rutgers Univ., Newark, NJ

Abstract: The neurotrophin family of growth factors regulates neuronal growth, differentiation and survival during development by activating signaling via the Trk family of receptor tyrosine kinases. However, the neurotrophin precursors, or proneurotrophins, are potent ligands for the p75 neurotrophin receptor ($p75^{NTR}$)-sortilin complex that can induce apoptosis, especially after injury. We have previously demonstrated that $p75^{NTR}$ is induced after injury induced either by seizures or by contusion in a model of traumatic brain injury. Moreover, blocking either the p75 receptor, or the proNGF ligand, can attenuate neuronal death. To test the hypothesis that $p75^{NTR}$ promotes secondary cell death, we provided a $p75^{NTR}$ siRNA intranasally immediately following a controlled cortical injury administered to adult C57/Bl/6 mice. Data obtained are in agreement with our previous findings that $p75^{NTR}$ KO mice demonstrated 2-fold fewer apoptotic neurons 3 DPI. Furthermore, knockdown of $p75^{NTR}$ improved overall neurological function and in particular improved sensorimotor performance on beam walking tests. In addition to promoting neuronal apoptosis, we are also investigating a role for $p75^{NTR}$ in regulating axonal degeneration, and determining whether this is independent of neuronal death, or part of a continuum leading to neuronal death. We are studying the mechanisms governing the process of neuronal apoptosis and axonal degeneration.We previously demonstrated that p75NTR-mediated apoptotic signaling requires activation of the intrinsic caspase pathway, involving caspases-9, -6 and -3, and simultaneous induction of PTEN to suppress Akt activation. ProNGF induction of PTEN occurred at the translational level, and we are currently investigating mechanisms by which this is regulated. We are also determining the effectiveness of inhibiting the receptor compared with preventing downstream signaling.

Title: BLM-l, an isoform of BLM as a BH3-only protein of the BCL-2 superfamily, plays a role in regulating neuronal survival in stroke

Authors: C.-T. HO[1], *P.-H. HUANG[2];
[1]Col. of Medicine, Natl. Taiwan Univ., [2]Grad. Inst. of Pathology, Taipei, Taiwan

Abstract: Stroke is a devastating neurological condition and is one of the leading causes for death and disability in adults. Current therapeutics focuses on the restoration of brain circulation such as usage of thrombolytic drug tPA, but complimentary neuroprotective treatment should provide beneficial effect. Mitochondria-mediated apoptotic pathway is a major contributing factor to neuronal cell death in stroke. Apoptosis appears sequentially and broadly in both the infarcted area and the penumbra region, with concomitant regulated expression of the pro- and anti-apoptotic members of the BCL-2 family members. Control of apoptosis by inhibiting proapoptotic BAX protects neurons from ischemic insults. Nevertheless, enhancing pro-survival BCL-2 or MCL-1 has little protective effect, suggesting other BCL-2 members that antagonize BAX might be more critical in neuronal ischemic events.
We have identified and characterized a novel BCL-2 family member, BLM, of which the transcript expression level in the brain is temporally and spatially regulated in an isoform-specific manner. *Blm* is predicted to have more than 20 transcript isoforms. Previously, we have uncovered that the short 1.1-kb isoform-*Blm-s* is enriched in postmitotic migrating neurons of the developing cortex and functions as a BH3-only apoptosis sensitizer/derepresser in response to DNA double strand break via ATM/p53 and JNK/AP1 signaling pathways. Here, we report that the 4.0-kb transcript of BLM, designated as BLM-l for its longest transcript isoform, is expressed in the developing forebrain at constant moderate amount of protein from E10.5 to E17.5, which is then decreased to a barely detectable level in new-born and is re-expressed in adult brains. Specifically, both BLM-l transcript and protein are up-regulated in adult cortical and hippocampal neurons after hypoxia/ischemia insult, as evidenced by immunoblot analysis of cultured cortical neurons treated by oxygen glucose deprivation (OGD) and in a model of stroke in rat/mice receiving transient middle cerebral artery occlusion. Overexpression of BLM-l in cultured neurons prevents neuronal apoptosis induced by OGD. Furthermore, via immunohistochemical analysis of human brain tissues with hemorrhagic stroke, we demonstrate the BLM-l is detected in penumbra area but not in infarcted area. Biochemical analysis further

shows that BLM-l functions as a pro-survival protein by antagonizing pro-apoptotic BAX and BLM-s. These data altogether suggest that BLM-l could play a role in regulating neuronal cell survival in the adult brain after ischemia/hypoxia insult.

Title: Neuroinflammation and free-radical damage after hemorrhagic stroke in streptozotocin/nod mouse models of type-i diabetes

Authors: *K. M. NASH[1], Q. M. ALHADIDI[2], Z. A. SHAH[2];
[1]Pharmacol. and Exptl. Therapeut., [2]Medicinal and Biol. Chem., The Univ. of Toledo, Toledo, OH

Abstract: The etiology of type-I diabetes is still unclear, but is thought to be due to auto-immune mediated inflammatory damage to insulin-producing β-cells leading to chronic hyperglycemia. Various animal models have been used to study type-I diabetes, including streptozotocin (STZ) administration, which causes β-cell death through over-activation of poly-ADP ribosome polymerase (PARP), and Non-obese Diabetic (NOD) strain animals that spontaneously develop diabetes through luekocytic infiltration of pancreatic islets. Individuals with type-I diabetes have a markedly increased risk of suffering from stroke as well as a susceptibility to a more disabling or fatal stroke, and a poor prognosis for recurrent stroke. Hemorrhagic stroke is due to the rupturing of cerebral arteries, and accounts for nearly 13% of all stroke occurrences, yet the impact of type-I diabetes on the outcome and underlying mechanisms of hemorrhagic stroke are poorly understood. Both STZ and NOD mouse models were used to study the effects of type-I diabetes on hemorrhagic stroke induced by intrastriatal injection of collagenase. Grip strength analysis and neurological deficit scoring (NDS) were used to measure the functional outcomes of the animals, while brain tissues were collected and analyzed by immunofluorescence of inflammatory and free-radical markers. STZ-treated and diabetic NOD mice had significantly reduced grip strength 72 hours after intracerebral hemorrhage (ICH) as compared to baseline, whereas non-diabetic mice showed a slight decrease but improvement after 72 hours. Immunohistochemistry showed a difference between the models

of diabetes following ICH. Glial cells were found to be activated around the hemorrhagic area in all non-diabetic mice, however, the intensity of activation defined by the number of GFAP and Iba1 positive cells was higher in the STZ diabetic group, and reduced in the NOD diabetic group compared to their respective non-diabetic controls. 3-nitrotyrosine (3-NT) was observed to be present in high levels in tissue within the hematoma, while the inflammatory protein inducible nitric oxide synthase (iNOS) was localized at the border. As with GFAP and Iba1, iNOS was found to be decreased in both diabetic groups compared to their respective controls. A marked increase in 3-NT staining in diabetic brains suggests a substantial production of peroxynitrite ($ONOO^-$) leading to oxidative and nitrosative damage as compared to the control groups. 3-NT was also found to surround blood vessels in STZ diabetic groups, but not in NOD diabetic or control groups, suggesting a damaged and possibly compromised blood brain barrier (BBB) resulting from STZ treatment.

Title: Inhibition of the integrated stress response restores cognition after brain injury

Authors: *E. HENNESSY[1,2], A. CHOU[1,3], T. JOPSON[1,2], K. KRUKOWSKI[1,2], C. SIDRAUSKI[4,5], P. WALTER[5,6], S. ROSI[1,2,3,4];

Abstract: The integrated stress response (ISR) controls mRNA translation by phosphorylation of the translation initiation factor eIF2α. ISRIB is a drug-like small-molecule ISR inhibitor (in-cell EC_{50}=5nM) that enhances memory consolidation in normal animals. Loss of cognitive functions and sustained ISR are associated with numerous neurological conditions, including traumatic brain injury (TBI). We investigated the efficacy of ISRIB on the cognitive deficits induced by TBI using two different animal models tested in two different cognitive tasks. Firstly, focal contusion injury was induced by controlled cortical impact (CCI) in C57BL/6 mice. Spatial learning and memory retention were measured in the radial arm water maze starting 28 days after injury. Either ISRIB (2.5mg/kg) or vehicle were administered intraperitoneally the day prior to

and at the end of each training day for a total of 3 injections. In agreement with previous reports, TBI animals receiving vehicle failed to learn the location of the escape platform. In striking contrast, ISRIB-treated TBI animals learned as well as the non-injured animals. Memory consolidation was measured 24 hours and 7 days after training in the absence of any additional treatment. At both times, ISRIB-treated TBI animals remembered the location of the hidden platform indistinguishable from non-injured controls. Thus, ISRIB completely restored the ability of the injured animals to learn and remember a new task. Most importantly, this memory was fully consolidated, as it could be recalled without further treatment. Secondly, diffuse TBI was modeled by closed-head injury (CHI) in C57BL/6 mice and the delayed-matching-to-place paradigm was used in a dry maze (modified Barnes maze) to assess working/episodic-like learning and memory. Fourteen days after injury either ISRIB (2.5mg/kg) or vehicle were administered intraperitoneally prior to and then again at the end of each training day for a total of 4 injections. As in the CCI experiments, ISRIB treated animals performance was indistinguishable from uninjured controls, indicating that ISRIB treatment completely reversed the deficits induced by CHI. We conclude that in these models targeting the ISR at time points late after injury can completely reverse chronic loss of cognitive functions induced by head trauma.

Title: Antiparkinsonian evaluation of neuroprotective peptide Fraternina, isolated from the venom of social wasp Parachartergus fraternus, in murine model for Parkinson's Disease.

Authors: *A. B. MAYER;
Univ. of Brasília, Brasilia, Brazil

Abstract: Parkinson's Disease (PD) is the most common neurodegenerative disease related to movement, and currently affects about 1% of the population over 60 years old, and its prevalence increases over the years. The chronic use of dopamine precursors causes strong side-effects (dyskinesias), moreover the drugs used in the treatment are incapable of modifying disease progression. Thus, the development of new and more effective drugs with lower side-effects is extremely important. Wasp venoms is formed by cocktail of the bioactive molecules that present high molecular variability. Interestingly, same compounds show selectivity for the Central Nervous System of mammals. Therefore, the objective of this study was to assess the neuroprotective activity of Fraternina peptide, isolated from the venom of social wasp *Parachartergus fraternus,* in a murine model of Parkinson's Disease. **animal handling followed the ethical principles from the National Council for the Control of Animal Experimentation (CONCEA) and the Arouca Law (Law nº 11.794/2008). Study procedures were approved by the University of Brasília Ethical Committee on the Use of Animals.** For the experimental model, mice were divided into 3 groups (n=8): saline, group with injury by 6-hidroxidopamine (6-OHDA) and the group treated with Fraternina after injury by 6-OHDA. The peptide was injected one hour after lesion and during the next two days, always at the same time. Dopaminergic neurons from the *Substantia nigra* were unilaterally damaged by stereotaxic injection of 6-OHDA (60 µg/animal) into the striatum of adult Swiss male mice. To evaluate the neuroprotective effect, animals were euthanized andbrains were sliced (50 µm) using a vibration microtome and assessed through immunofluorescence. For the immunofluorescence, we used polyclonal primary antibody against tyrosine hydroxylase (TH), produced in rabbits (Abcam) and polyclonal secondary antibody (Abcam) produced in goat against IgG-H&L rabbit with the fluorophore Alexa Fluor-488. Quantification of reactive dopaminergic neurons was done using TH enzyme in the of *substantia nigra*. Dose of 3.6 mM was able to inhibit neuronal loss when compared to the other doses and group with 6-OHDA injury. Data from this study showed that Fraternina prevented the death of dopaminergic neurons in the *substantia nigra* ($p < 0.05$)This study revealed a promising peptide, obtained from a social wasp venom, that was able to prevent the progression of the neuronal loss in a murine model of PD.

Title: Intranasal orexin-A treatment to boost arousal in an asphyxial cardiac arrest rodent model.

Authors: *D. GARIKAPATI[1], H. R. MODI[1], Q. WANG[1], D. SHERMAN[1], E. GREENWALD[1], R. G. GEOCADIN[2], N. V. THAKOR[1];
[1]Biomed. Engin., Johns Hopkins Univ., Baltimore, MD; [2]Neurol. and Anesthesiology/Critical Care Med., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Introduction: Resuscitation post cardiac arrest (CA) leads to poor neurological outcome accompanied by a significant risk of coma. Since the hypothalamic orexinergic pathway is responsible for arousal in general, we hypothesized that targeting the orexinergic pathway via intranasal Orexin-A treatment may improve arousal. **Methods**: Male wistar rats (300-350g) were implanted with epidural electroencephalography (EEG) screw electrodes prior to insult. Two electrodes (EEGA, EEGB) were placed at 2 mm anterior to the left and right of the bregma, corresponding to the M1 regions of the frontal cortex. Another two electrodes (EEGC, EEGD) were placed at 6mm posterior and 4 mm to the right and left of the bregma, corresponding to the V1 regions of the occipital cortex. The EEG was monitored at baseline for 10 minutes followed by 7 minutes of asphyxia induced CA. All animals received either intranasal vehicle or Orexin-A treatment at 30 minutes post-resuscitation. EEG recording and physiological monitoring continued for up to 4 hours post CA. **Results**: Gamma fraction (GF) derived from the EEG is a critical parameter that indicates recovery and thereby substitutes for neurological outcome. At 60-70 minutes post ROSC, the vehicle animal shows a stationary GF (0.14 ± 0.02), while the Orexin-A treated animal displays a surge in GF (0.32 ± 0.23) in EEGA. Additionally, Orexin-A treated animals show a faster recovery in EEGA relative to EEGC. Concurrent with the increase in gamma fraction is the rise in Neuro deficit score (NDS) with intranasal orexin-A treatment. **Conclusion**: These results indicate that targeting the arousal pathway via intranasal orexin-A leads to enhanced coma recovery as measured by both behavioral (NDS) and electrophysiological parameters (EEG).

Title: Effect of antihypertensive drugs on learning, memory and neuronal morphology in Prefrontal Cortex and Hippocampus in Spontaneously Hypertensive Rats.

Authors: *H. COATL CUAYA, L. M. DE JESÚS VASQUEZ, M. GÓMEZ-VILLALOBOS, G. FLORES ALVARES;
Inst. de Fisiología, Benemerita Univ. Atonoma De Puebla, Puebla, Mexico

Abstract: Dementia is characterized by the development of cognitive impairment that is related with loss of memory, increasing disorientation in space, time and loss of autonomy. Recently studies have been showed that the arterial hypertension (AHT) is a major risk factor for development vascular dementia (VD). Besides, several researches suggests that prefrontal cortex (PFC) and hippocampus (Hp) play an important role in the development of the processes of learning and memory. Interestingly, spontaneously hypertensive (SH) rat an animal model of VD also shows alterations in the dendritic morphology of those areas. The aim of this study was to evaluate the effect of antihypertensive drugs on locomotor activity, learning, memory and neural morphology of PFC (layers III and V) and CA 1 of dorsal Hp of SH rats. We used male SH and WKY rats of two months of age, which were administered orally during 8 weeks with metoprolol and losartan (10mg/Kg/day) and amlodipine (1mg/Kg/day). After to performance the behavioral measurements, the brains were processed by Golgi-Cox staining. Pyramidal neurons of PFC and CA1 of dorsal Hp were drawn and processed through Sholl's analyses. The results suggested that losartan shows the best antihypertensive effect in SH group, decreasing its blood pressure (145.5±6.3 mmHg) more than metoprolol (171.9±4.2 mmHg) and amlodipine (174.5±4.8 mmHg) compared to SH vehicle group (196.8±4.9), whereas WKY groups did not show statistical significances among them. Also, SH treated group, showed improving in long term memory measured by novel object recognition test, index of discrimination: metoprolol (0.75±0.02), losartan ((0.71±0.02) and amlodipine (0.68±0.01) regarding vehicle SH group (0.67±0.04). Whereas index of discrimination in short term memory were higher in metoprolol (0.73±0.06) and losartan (0.66±0.07) of WKY groups than its vehicle group (0.51±0.1). Moreover the antihypertensive drugs administration did not show statistically differences in the short term memory on SH strain. Finally there is no effect on locomotor activity in WKY groups, but hyperactivity of SH rats was diminished by metoprolol (830.7±57.5), losartan (925.5±57.3) and amlodipine (942.8±57.4) compared to SH vehicle group. Therefore, administration of antihypertensive drugs in early stage of AHT prevents cognitive impairment by keeping the cellular integrity of the pyramidal neurons of the PFC and CA1 of dorsal hippocampus.

Title: Linking development with regeneration: ephrin-A1 attenuates glial scarring after adulthood stroke

Authors: *L. TEO, J. HOMMAN-LUDIYE, J. A. BOURNE;
AUSTRALIAN REGENERATIVE MEDICINE INSTITUTE, CLAYTON, Australia

Abstract: Glial scarring and astrogliosis after stroke are major impediments to neuroregeneration. Furthermore, chronic scarring in the infant primate neocortex is less severe compared to adults, allowing greater permissiveness towards regeneration after perinatal injuries. Paradoxically, acute genetic ablation of astrogliosis and scarring after injury is detrimental to wound healing and functional recovery. This is most likely because reactive astrocytes play neuroprotective roles in the acute periods following injury, prior to the formation of the glial scar. EphA4 was identified as a major modulator of astrogliosis and scarring after CNS injuries; however, the ephrin ligands involved in the injured infant and adult brain remains unknown.
A clinically translatable nonhuman primate (NHP) model of stroke in the infant and adult neocortex was utilised in this study. Thymidine analogues revealed that the chronic glial scar is formed by an acute wave of reactive astrocytes, which establishes a discrete boundary proximal to the ischemic core at 1-3days post-stroke. This is followed by a sub-acute wave of reactive astrocytes recruited/ generated 2-3weeks post-stroke, which results the dense, widespread chronic scar.
Furthermore, using *in vivo* and *in vitro* analyses, we demonstrate that the infant and adult primate brain regulates astrogliosis through separate Eph/ephrin-mediated pathways. In infants ephrin-A1 induced astrocyte repulsion, reduced proliferation and reactivity resulting in small, discrete scar. In Adults, ephrin-A2 and -A5 induced astrocyte attraction, increased proliferation and reactivity resulting in dense, widespread scarring. Ephrin-A1 treatment was able to inhibit NHP astrocyte reactivity induced by ephrin-A2/ -A5 signalling *in vitro*. Most importantly, *delayed* administration of ephrin-A1 in the sub-acute period post-stroke, prior to the peak of astrogliosis, in rodent and NHP successfully suppressed astrocyte reactivity resulting in a ~50% ($p<0.05$) reduction in glial scar volume and density, as well as a significant suppression of secondary astrocyte recruitment ($p<0.05$).
We demonstrated that the formation of the primate glial scar comprises an acute, neuroprotective wave and a sub-acute scar-forming wave of astrogliosis. Moreover, the primate brain undergoes

differential Eph/ephrin mediated astrogliotic responses depending on the age at which stroke occurred. Lastly, attenuation of the sub-acute astrogliotic wave through ephrin-A1 treatment results in the generation of an 'infant-like' glial scar that may be more permissible towards regeneration and functional recovery after stroke.

Title: Expression and role of IL-12 and IL-23 in spinal cord injury

Authors: *A. KRONER-MILSCH[1], B. APERI[1], K. STEHLIK[1], S. DAVID[2];
[1]Neurosurg., Med. Col. of Wisconsin, Milwaukee, WI; [2]Neurol., Ctr. for Res. in Neuroscience, McGill, Montreal, QC, Canada

Abstract: Spinal cord injury (SCI) is a frequent and severe condition with far reaching effects on health and quality of life for affected persons and their families. The primary tissue damage after SCI is caused by the mechanical trauma, while the secondary damage is caused by subsequent events, including hemorrhage and inflammation. These events contribute significantly to the pathology and thereby to the extent of the functional deficits. Inflammation after SCI is exacerbated and prolonged. Activated microglia and blood-derived macrophages are among the main immune cell types present after SCI. Previous work has shown that macrophages which phagocytose red blood cells (RBCs) develop a pro-inflammatory phenotype. RBCs are present at the site of SCI due to trauma-induced hemorrhage. One of the proinflammatory cytokines upregulated in macrophages by RBC phagocytosis is TNF. In TNF knockout mice, locomotor recovery after SCI is significantly improved. Additional cytokines and other factors are also likely to be involved. Interestingly, *Il12b*, which codes for the shared p40 subunit of the pro-inflammatory cytokines IL-12 and IL-23, is also strongly upregulated by RBC phagocytosis. Both IL-12 and IL-23 are expressed by a variety of immune cell types and can induce the production of other pro-inflammatory cytokines. We are investigating and dissecting the

expression and roles of IL-12 and IL-23 after SCI in female C57BL/6 mice, using a model of moderate contusion injury. Preliminary results show that IL-12 is upregulated 24 hours after SCI. Furthermore, IL-12 is expressed by CD11b+ macrophages/microglia in the injured tissue 3 days after injury. We are also assessing the time course of expression and the cell types expressing IL-12 and IL-23 in the injured spinal cord, in addition to the roles of IL-12 and IL-23 in vitro. Our preliminary data suggest a potential role of IL-12 and/ or IL-23 in SCI.

Title: The molecular mechanism underlying pruning of collaterals in the compensatory neural pathway after incomplete spinal cord injury

Authors: *T. NAKANISHI, Y. FUJITA, T. YAMASHITA;
Dept Mol Neurosci, Grad Sch. Med, Osaka Univ., Osaka, Japan

Abstract: Spinal cord injury (SCI) is one of the most devastating neurological injuries that elicit motor and sensory dysfunctions. Recently, it has been found that the some spontaneous recovery occurring after incomplete SCI is caused by the formation of the compensatory neural pathway. This pathway is composed of collaterals sprouted from the corticospinal tract (CST), propriospinal neurons and motor neurons. Moreover, these collaterals first start sprouting randomly and then the excess collaterals are eliminated, a process called axon pruning. The axon pruning is considered as an important process to elaborate the neural pathway, however the underlying molecular mechanism is still unknown. To address this issue, we focused on Semaphorin-Neuropilin signaling, which is responsible for the axon pruning occurring in developing CST. First, we made incomplete SCI model mice by dorsal hemisection at T8 level. By in situ hybridization, we found that Neuropilin-1 (Nrp-1) was upregulated in layer 5 pyramidal neurons especially in motor cortex 14 days after SCI, when the pruning of collaterals occurs. Then we generated adeno associated virus (AAV) vector expressing Nrp-1 small hairpin RNA (shRNA) or control shRNA and RFP, and injected the AAV vector into hindlimb motor area. As a result, the number of collaterals labeled by RFP was increased in Nrp-1 knocked-down mice compared to control mice 28 days after SCI. Finally, we injected retrograde tracer

into the lumbar cord in order to label the propriospinal neurons located in cervical cords, and conducted immunostaining. As a result, Smaphorin3A (Sema3A), which is the ligand for Nrp-1, was expressed in the propriospinal neuron. These results suggest that Sema3A-Nrp-1 signaling is probably involved in the pruning of collaterals from CST after incomplete SCI.

Title: Neuregulin-1 signalling controls an endogenous repair mechanism after spinal cord injury

Authors: *K. BARTUS[1], J. GALINO[2], N. D. JAMES[1], C. BIRCHMEIER[3], D. L. H. BENNETT[2], E. J. BRADBURY[1];
[1]King's Col. London, London, United Kingdom; [2]Univ. of Oxford, Oxford, United Kingdom; [3]Max Delbrück Ctr. for Mol. Med., Berlin, Germany

Abstract: The injured spinal cord maintains some capacity for spontaneous repair, although this is suboptimal. Understanding the cellular and molecular mechanisms underlying endogenous repair may provide a route to exploit and enhance these processes in order to improve functional outcome after spinal cord injury (SCI). We have identified neuregulin-1 (Nrg1) to be essential for Schwann cell-mediated spontaneous remyelination of injured spinal axons within the dorsal columns and to be a significant contributor to spontaneous locomotor recovery. We found that Nrg1 ablation in adult mice leads to complete failure of Schwann cell-mediated remyelination after contusive SCI. The type III isoform appears to be critical for this process, while other Nrg1 isoforms regulate different repair mechanisms. Importantly, we found that conditional Nrg1 ablation leads to chronic demyelination and conduction failure in dorsal column axons and worse functional outcome in mice with clinically relevant spinal contusion injuries. Finally, although some remyelinating Schwann cells are likely to be infiltrating the injured spinal cord from the periphery, we have evidence that at least a large proportion of centrally remyelinating Schwann cells are derived from precursor cells present in the spinal cord and that Nrg1 serves as a

molecular switch that influences the differentiation fate of centrally derived precursor cells. Through a genetic fate mapping approach that assesses both the infiltrating and the de novo-produced central Schwann cell lineages, we show direct evidence that ErbB receptor activation on oligodendrocyte precursor cells is required for their transformation into remyelinating Schwann cells after SCI. Moreover, we found that specific ablation of ErbB receptors on these central precursor cells in contused mice not only prevents a large part of Schwann cell-mediated remyelination, but also worsens spontaneous locomotor recovery, further highlighting the significance of this spontaneous repair response. Our data provide novel mechanistic insight into endogenous regenerative processes after SCI. These findings could lead to the design and development of combinations of effective and safe target-specific therapies for improving spontaneous repair and functional recovery after SCI. Title: Targeting TRPV4 to attenuate systemic and spinal immune activation in a mouse model of SCI

Authors: *R. J. GRILL[1], K. R. CLARK[1], H. HU[2];
[1]Neurobio. and Anatom. Sci., Univ. of Mississippi Med. Ctr., Jackson, MS; [2]Anesthesiol., Washington Univ. Sch. of Med. in St. Louis, St. Louis, MO

Abstract: Trauma to the spinal cord elicits a profound inflammatory response both within the damaged cord as well as throughout the rest of the body. This inflammatory response is further characterized by the activation and mobilization of systemic as well as CNS immune cells that are thought to provide both beneficial as well as pathological aspects to the healing process. Mechanisms underlying the activation and progression of this immune/inflammatory activation

continue to be unveiled. The Transient Receptor Potential channel, subfamily V, member 4 (TRPV4) is a calcium-permeable, non-selective cation channel expressed throughout the body and serves as a molecular and mechanical sensor to detect alterations in temperature, osmolality, and blood pressure, etc. Due to TRPV4's association with endothelial cells and role as a regulator of vascular tone, we hypothesized that aberrant activation of TRPV4 via mechanical insult may worsen spinal vascular leakage produced by contusion injury. We determined that blood-spinal cord-barrier (BSCB) breakdown was reduced in TRPV4-null mice compared to wild type (WT) when assessed 48 hours post-spinal contusion injury. Utilizing additional mutant mice in which TRPV4 is linked to GFP, we observed strong co-association of GFP with both spinal microglia as well as splenic macrophages. This led us to hypothesize that TRPV4 activation following spinal cord injury (SCI) may contribute to systemic immune activation/inflammation following SCI. We observed that treatment with the selective TRPV4 inhibitor HC-067047 led to a significant reduction in both microglial and astrocytic activation at the lesion site compared to the vehicle-treated controls. In addition, HC-067047-treatment significantly attenuated the loss in splenic mass that is indicative of the activation and recruitment of the peripheral immune system observed following CNS trauma. Our results suggest that trpV4 inhibition may reduce spinal vascular leakage and attenuate both spinal and systemic immune activation/inflammation following SCI. Ongoing studies are exploring the role of TRPV4 activation or inhibition in the evolution of both spinal and systemic inflammation as well as the functional ramifications of acute, systemic, TRPV4 suppression.

Title: $cPLA_2$ activation-mediated mitochondrial dysfunction and neuronal death after spinal cord injury

Authors: ***N.-K. LIU**[1], L.-X. DENG[1], Q.-B. LU[1], J.-L. LI[2], S.-W. YOU[3], X.-M. XU[1]; [1]Indiana Univ., Indianapolis, IN; [2]Dept. of Human Anat. and Histoembryology, [3]Inst. of Neurosci., Fourth Military Med. Univ., Xi'an, China

Abstract: Traumatic spinal cord injury (SCI) is prevalent in the United States, with more than 12,000 cases every year. To date, there is no effective pharmacological treatment for SCI. A deep understanding of the molecular mechanisms underlying functional deficits in patients with SCI is crucial for developing novel strategies for treating it. Mitochondrial dysfunction has been shown to contribute to the secondary neuronal injury following SCI. However, limited information is available concerning mechanisms underlying mitochondrial dysfunction in SCI. Previously, we showed that the expression of cytosolic phospholipase A_2 ($cPLA_2$) was increased in rodent models of SCI and that such an increase induced cell death and functional impairment (Liu et al. Ann Neurol 75:644-658, 2014). Here we explored whether $cPLA_2$ activation plays a role in mediating SCI-induced mitochondrial dysfunction and cell death. Our results show that mitochondrial $cPLA_2$ expression and activation were markedly increased at day 1, peaked at day 7, and maintained at high levels up to day 14 post-SCI. *In vitro* experiments show that ceramide-1-phosphate (C-1-P), a $cPLA_2$ activator, induced $cPLA_2$ translocation to mitochondria, leading to mitochondrial dysfunction and neuronal death; such effects were substantially reversed by AACOCF3, a $cPLA_2$ inhibitor. Electron microscopic images showed that activated $cPLA_2$ was translocated to both outer and inner mitochondrial membranes after SCI. Remarkably, blocking $cPLA_2$ pharmacologically with AACOCF3 reduced mitochondrial dysfunction, cytochrome C release, and neural apoptosis after SCI. Genetic deletion of $cPLA_2$ in $cPLA_2$ knockout mice also inhibited mitochondrial dysfunction, resulting in neuroprotection after SCI. These findings collectively suggest that SCI-induced $cPLA_2$ activation and translocation to mitochondria may play a crucial role in mitochondrial dysfunction and neuronal death following SCI, and that mitochondrial $cPLA_2$ could be an attractive therapeutic target for ameliorating secondary SCI.

Abstract: We previously developed a novel compound, Denosomin, exhibited axonal growth activity in cultured neurons. Denosomin administration to contusive spinal cord-injured (SCI) mice, p.o., showed significant improvement of motor dysfunction. At the injured area, Denosomin increased the number of vimentin-expressing astrocytes inside glial scars of SCI mice and 5-HT-positive axonal growth occurred in a vimentin-dependent manner. Moreover, extracellular addition of vimentin to cortical cultured neurons resulted in axonal growth that was even sustained on inhibitory chondroitin sulfate proteoglycan (CSPG)-coated slides. Vimentin, an intermediate filament protein, is an intracellular protein that is known to be involved in a various cellular processes. Several groups have recently reported that vimentin also appears in the extracellular space and shows novel protein activity. Our discovery that extracellular vimentin induced axonal growth in cultured neurons suggests that extracellular vimentin may act as a novel nerve growth factor. Here, we aimed to clarify whether increased extracellular vimentin can promote axonal extension related to motor improvement after spinal cord injury in vivo. To investigate the effect of extracellular vimentin on motor improvement in SCI mice, recombinant vimentin or vehicle solution (artificial cerebrospinal fluid) was administered for 21 days into the lateral ventricle using osmotic mini-pump following spinal cord injury. As a result, extracellular vimentin treatment significantly ameliorated motor dysfunction compared with vehicle-treated group. In vimentin-treated mice, 5-HT-positive axons (raphespinal tracts) increased significantly at the rostral and central areas of the lesion, and total axonal densities increased in the central and caudal parts of the lesioned area. At that time, the sizes of glial scar were not changed between groups. Our results suggest that extracellular vimentin may be a novel therapeutic factor that enhances axonal growth activity and motor function in SCI.

Title: LPA pathway modulates intrinsic axon growth of intact CNS neurons after spinal cord injury

Authors: *K. FINK, S. STRITTMATTER, W. CAFFERTY;
Yale Univ., New Haven, CT

Abstract: Neurons in the adult central nervous system (CNS) are unable to regenerate after spinal cord injury (SCI) due to an inhibitory environment and a decreased intrinsic growth capacity. Modulating environmental inhibitors and their neuronal receptors such as Nogo Receptor 1 (NgR1) results in increased regeneration and sprouting of intact neurons spared by injury, which correlates with enhanced functional recovery. Cell intrinsic factors also increase regeneration and sprouting, but side effects and limited functional improvements suggest these factors do not activate endogenous sprouting mechanisms. We sought to identify the mechanisms underlying spontaneous sprouting of intact neurons after incomplete SCI. We completed a unilateral corticospinal tract (CST) lesion (pyramidotomy, PyX) in transgenic wild type (n=6) and NgR1 knockout mice (*ngr1-/-*, n=6) expressing GFP under the μ-crystallin (*crym*) promoter (*crym*-GFP) for intrinsic corticospinal tract (CST) labeling. Two weeks post-lesion, mice received infusion of the retrograde tracer fast blue (FB) into the denervated spinal cord to label sprouting CST neurons. Two weeks later, we used laser capture microdissection to isolate CST neurons in a quiescent (GFP+FB-) or active (GFP+FB+) growth state. With enhanced sprouting in *ngr1-/-* mice, an abundance of FB+ sprouting neurons allowed us to complete RNAseq and conduct a transcriptomic analysis. 1174 genes were significantly differentially expressed (SDE) between sprouting and quiescent neurons, with lysophosphatidic acid (LPA) receptor 1 (*lpar1*) the most downregulated gene in sprouting neurons. Lpar1 interactors, including a negative regulator of Lpar1, lipid phosphate phosphatase related protein 1 (*lppr1*), were also SDE in sprouting neurons, suggesting a role for the LPA pathway in regulating intrinsic CNS axon growth. Overexpressing Lppr1 in cortical neurons *in vitro* resulted in an increase in neurite outgrowth and an increase in growth in an *in vitro* injury model. Next we sought to determine if modulating the LPA pathway *in vivo* would enhance functional sprouting. Adult wild type mice received PyX or sham lesion and either cortical infusion of AAV-Lppr1 (n=21), oral treatment with an Lpar1 antagonist AM095 (n=15), or vehicle control (n=19). Lppr1-expressing and AM095-treated mice had significantly enhanced sprouting of CST neurons into the denervated

ventral horn and AM095-treated mice recovered greater fore and hind limb function in a grid walking task. With these data, we have demonstrated that bidirectional modulation of the LPA pathway is beneficial for axon growth with therapeutic potential for restoring function after SCI.

Hosp., Heidelberg, Germany

Abstract: The dynamic regulation of chromatin structure is central to the orchestration of neuronal regeneration. Genes are flanked by cis-elements, which are occupied by trans-acting factors such as transcription factors (TFs), silencers or epigenetic regulators that modulate their expression. We have previously shown that the epigenetic histone acetyltransferase p300/CBP associated factor (PCAF) is an essential player in the transcriptional regulation of key regeneration-associated genes (RAGs). Here, we investigate the transcriptome (RNAseq) of wildtype and PCAF null mouse dorsal root ganglia (DRG) following a peripheral nervous system (PNS) conditioning lesion, a known inducer of axonal regeneration in the non-permissive central nervous system (CNS). Previously, we have shown that viral overexpression of the PCAF in vivo mimics the conditioning regenerative effect and when it is knocked out the regenerative conditioning effect is abolished. Therefore, we have isolated PCAF-dependent RAGs which lend further insight to key mechanistic pathways in axonal regeneration. Moreover, we used this

dataset to find essential PCAF co-transcriptional regulators, which we have confirmed via DRG neurite length analysis following siRNA knockdown. Furthermore, we have combined transcription factor enrichment, GO and pathways analysis to understand which upstream pathways are involved in the regulation of these transcriptional switches and PCAF-dependent RAGs. By defining key PCAF-dependent transcriptional regulators of essential RAGs in the regenerative process we are able to find a common upstream pathway that may be activated therapeutically to induce long-distance regeneration of the central nervous system following traumatic spinal cord injury.

Title: Activation of NLRP3 inflammasomes in a rat spinal cord injury model.

Authors: *S. YANAGISAWA, H. KATOH, M. KUROIWA, T. IMAI, M. WATANABE; Tokai Univ., Kanagawa, Japan

Abstract: After spinal cord injury (SCI), oligodendrocyte progenitor cells (OPCs) within the injured spinal cord proliferate, but are mostly lost to apoptosis without differentiating into functional oligodendrocytes. We previously reported that the vulnerability of OPCs to endoplasmic reticulum (ER) stress leads to their apoptosis, and that increasing the ER stress response with amiloride inhibited OPC apoptosis and increased differentiation into oligodendrocytes, improved remyelination, and improved hind limb function. In recent years, cell death mediated by inflammasomes has been attracting attention, and inflammasome activation by ER stress has been reported in other areas. To investigate the association of inflammasomes in SCI, we investigated the expression of inflammasome component proteins in the injured spinal cord by immunohistochemistry.
A contusive SCI was induced in female Sprague-Dawley rats using an IH-impactor (LI group: 100 kdyne, HI group: 200 kdyne). At 1, 3, 7, and 14 days after SCI, animals were killed and the

spinal cords were resected and processed for immunohistochemistry (n=5 per group). Double immunostaining for markers of inflammasome component proteins (NLRP3, ASC, and Caspase-2) and cell markers (NG2: OPCs, GFAP: astrocytes, and NeuN: neurons) were performed, and the expression of inflammasome component proteins in each cell type was examined.
The ratio of cells expressing NLRP3, ASC, and Caspase-2 were significantly higher in OPCs of both the HI and LI groups compared with the sham group at days 1,3, and 7 ($P < 0.01$). The expression ratio of NLRP3, ASC, and Caspase-2 were significantly higher in OPCs compared to astrocytes at day 1 ($P < 0.01$). The ratio of OPCs expressing ASC was significantly higher in the HI group compared to the LI group at day 1 ($P < 0.05$).
The expression of inflammasome component proteins after SCI were significantly higher in OPCs, suggesting that inflammasome-mediated cell death may also play a role in the high rates of apoptosis observed in OPCs after SCI.

Title: Astrocyte scar formation aids CNS axon regeneration

Authors: M. A. ANDERSON[1], J. E. BURDA[1], Y. REN[1], Y. AO[1], T. M. O'SHEA[1], R. KAWAGUCHI[1], G. COPPOLA[1], B. S. KHAKH[1], T. J. DEMING[2], *M. V. SOFRONIEW[1]; [1]UCLA Schl Med., Los Angeles, CA; [2]UCLA Engin, Los Angeles, CA

Abstract: Transected axons fail to regrow in the mature central nervous system (CNS). Astrocyte scars are widely held to be causal in this failure. Here, using three genetically targeted loss-of-function manipulations in adult mice, we show that preventing astrocyte scar formation, attenuating scar-forming astrocytes, or deleting chronic astrocyte scars all failed to result in spontaneous regrowth of transected corticospinal, sensory or serotonergic axons through severe spinal cord injury (SCI) lesions. In striking contrast, sustained local delivery via hydrogel depots of required axon-specific growth factors not present in SCI lesions, plus growth-activating priming injuries, stimulated robust, laminin-dependent sensory axon regrowth past scar-forming astrocytes and inhibitory molecules in SCI lesions. Preventing astrocyte scar formation worsened this stimulated axon regrowth. RNA sequencing revealed that both astrocytes and non-astrocyte cells in SCI lesions express multiple axon-growth supporting molecules. Our findings show that contrary to prevailing dogma, astrocyte scar formation aids rather than prevents CNS axon regeneration.

Title: E2F4 promotes recovery after spinal cord injury in zebrafish

Authors: *S. SASAGAWA[1], Y. NISHIMURA[2], Y. HAYAKAWA[2], S. MURAKAMI[2], Y. ASHIKAWA[2], M. YUGE[2], S. OKABE[2], K. KAWAGUCHI[2], R. KAWASE[2], Y. SHIMADA[2], T. TANAKA[2];
[1]Mie Univ. Sch. of Med., Tsu/Mie, Japan; [2]Dept. of Pharmacol., Mie Univ. Grad. Sch. of Med., Tsu/Mie, Japan

Abstract: It is well known that mammals exhibit poor recovery after spinal cord injury (SCI), whereas non-mammalian vertebrates, such as amphibians and fish, exhibit significant spontaneous recovery after SCI. However, the mechanisms underlying this difference have not been fully elucidated. In this study, we focused on differences between zebrafish and mouse/rat in the genes that are differentially expressed after SCI. Using a systems biology approach, we were able to demonstrate that a transcriptional repressor, e2f4, and a transcriptional activator, foxm1, were activated and inhibited, respectively, in zebrafish SCI but not in mouse/rat SCI, resulting in the down-regulation of many genes related to mitosis. We also developed a novel SCI model using larval zebrafish suitable for quantitative assessment of locomotive behavior and in vivo imaging of the spinal cord. Using the SCI model, we were able to demonstrate that the recovery of locomotive function and neuronal regeneration after SCI were significantly inhibited in zebrafish treated with an E2F4 inhibitor. These results suggest that activation of e2f4 after SCI in zebrafish may be responsible, at least in part, for their significant recovery. These results provide novel insights into the mechanism underlying poor recovery after SCI in mammals and indicate potential therapeutic strategies.

Title: Deep sequencing transcriptome of axoplasm from regenerating axon tips in the lamprey spinal cord

Authors: *L.-Q. JIN[1], C. R. PENNISE[1], M. E. SELZER[1,2];
[1]Shriners Hosp. Pediatric Res. Ctr., [2]Dept. of Neurol., Lewis Katz Sch. of Med. at Temple Univ., Philadelphia, PA

Abstract: Intra-axonal protein synthesis plays an important role in axon growth during development, in peripheral nerve regeneration and *in vitro*. Previous studies showed axons contain hundreds to thousands of mRNAs in their growth cones by microarray or next-generation technologies. To confirm that the local protein synthesis is involved in axon regeneration in the

injured mature CNS, we micro-aspirated axoplasm from growing tips of lamprey reticulospinal neurons and performed one end (3') RNA sequencing using next-generation technologies after PCR-amplification. A total of 467 genes (FRKM: 1-338563) were identified by RNAseq, among them 185 genes (FRKM > 10) were manually analyzed. They can be categorized into 10 groups: 1. Protein synthesis and translation (n=54, 29% of total identified genes, e.g. *rpl11*, *rps21*, *RPL37A*); 2. Metabolic (n=27, 15%, e.g. *MT-ATP6*, *MT-ND2*, *MT-CO2*); 3. Cytoskeletal proteins and molecular motors (n=10, 5%, e.g. *nefl*, *cenpe*, *tpt1*); 3. Signaling (n=6, 3%, e.g. *tmem64*, *lamtor5*, *ran*); 4. Protein degradation and apoptosis (n=5, 3%, e.g. *faf1*, *cflara*, *psmb4*); 5. Membrane trafficking (n=5, 3%); 6. Transmembrane and cell surface receptors (n=7, 4%, e.g. ssr3, *slc5a11*, *atp2b1b*); 8. Secreted molecules and extracellular matrix (n=8, 4%, e.g. *hyal3*, *CTRL*, *cadpsa*); 9.Cell cycle and nuclear proteins (n=7, 4%, e.g. *rbx1*, *CCNB1IP1*, *ncapg2*) and 10. Others undefined (n=17, 9%, e.g. *C20orf24*, *tmem260*, *tmem126a*). Genes involved in protein synthesis include 21 ribosomal proteins for large subunit (L7,L9,L10,L10a,L11,L13,L13a,L15,L19,L22-24,L26-27, L31-32,L34-35,L37,L37a,L-P2) and 15 small subunit ribosomal proteins (S2-3,S6-7,S9-12,S15a,S17,S21,S23-24,S26,S27-like), proteins for transcription (*chd5*), mRNA splicing (*sf3b5*), poly(A)RNA binding (*PABP*), translation factors (*eef1da*, *eif3hb*), and nascent protein processing (*acot13*, *stt3b*). The results suggest that proteins used as translational machinery and a variety of proteins related to axon elongation may be synthesized within the axonal tips. **Acknowledgements**: We thank Caroline Austell for her work in developing single cell PCR.

Title: The effect of transplanted olfactory ensheathing cells on endogenous stem/progenitor cells after spinal cord injury

Authors: *X. LI[1], A. HONORE[2], N. GUÉROUT[2];
[1]Dept. of Neurosci., Karolinska Institutet, Stockholm, Sweden; [2]Inst. for Res. and Innovation in Biomedicine, Univ. of Rouen, Rouen, France

Abstract: Cell therapies have raised great hope for regenerative medicine. It has been shown that endogenous spinal cord stem cells, together with astrocytes and pericytes significantly contribute to the recovery of spinal cord injury (SCI). More recently, clinical data showed olfactory ensheathing cells (OECs) obtained from a patient's nasal cavity enhanced functional recovery and could be a very attractive therapeutic approach. However, the cellular mechanisms behind the effect of transplanted OECs on spinal cord stem/progenitor cells after SCI is still poorly understood, which leads to the failure of repetition of the clinical treatments. Thus, we further study the effects of transplanted OECs on spinal cord stem/progenitor cells after SCI. Using FoxJ1-CreER^{T2}::YFP transgenic mice, our primary neurosphere assay showed that upon SCI, ependymal cells have higher self-renewal potential after OECs transplantation, and their capability of differentiation to oligodendrocytes is also highly up-regulated. Similarly, our *in vivo* fate-mapping data showed that upon SCI with OEC transplantation, there is higher proliferation and migration to the lesion site of ependymal cells. More interestingly, we used FoxJ1-Rasless mice to specifically block the cell cycle of ependymal cells, we found that after transplantation, the self-repair capacity of astrocytes and pericytes is highly recruited compared to vehicle, and the lesion site after transplantation was significantly sealed.Altogether, we here describe the transplanted OEC can better activate stem cell potential of ependymal cell after SCI and trigger their potential to differentiate into oligodendrocytes. Moreover, OECs transplantation promotes the self-repair capacity of endogenous glial cells, which suggests transplantation of OECs to injured spinal cord would be a beneficial therapeutic possibility for the recovery after SCI.

Title: Acute hyperglycemia is a treatable risk factor for spinal cord injury - translational research from animals to humans -

Authors: *K. KOBAYAKAWA[1,2], K. SHIBA[3], K. HARIMAYA[1], Y. MATSUMOTO[1], K. KAWAGUCHI[1], M. HAYASHIDA[1], R. IDETA[3], Y. OHKAWA[1], H. TOZAKI-SAITOH[1], K. INOUE[1], Y. OHKAWA[1], Y. MAEHARA[1], Y. IWAMOTO[4], S. OKADA[1];
[2]Dept. of Orthopaedic Surgery, Emergency & Critical Care Ctr., [1]Kyushu Univ., Fukuoka, Japan; [3]Spinal Injuries Ctr., Izuka, Japan; [4]Kyushu Rosai Hosp., Kitakyushu, Japan

Abstract: Spinal cord injury (SCI) is a devastating disorder for which the identification of exacerbating factors is urgently needed to provide effective treatment. We herein demonstrate that transient hyperglycemia in acute SCI is a detrimental factor for the functional outcome in both animal experiments with two acute hyperglycemic models and a multivariable cohort analysis of 528 SCI patients. Under hyperglycemic conditions, both *in vivo* and *in vitro*, inflammatory reactivity was exponentially enhanced with the promotion of NF-κB nuclear translocation in microglial cells. ChIP-PCR analysis identified NF-κB-dependent downstream gene expressions. After SCI, the hyperglycemic mice exhibited the progressive expansion of neural damage, with more severe motor deficits than that noted in the normoglycemic mice. Especially, microglia isolated from injured spinal cords of hyperglycemic mice after SCI exhibited markedly upregulated gene expressions of inflammatory cytokines. Consistent with the animal study findings, a Pearson chi-square analysis of the data from 528 SCI patients indicated that hyperglycemia on admission (glucose level ≥ 126 mg/dl) was a significant risk predictor of a poor functional outcome (Odds ratio, 2.66; 95% CI, 1.52 to 4.72; P <0.001). Moreover, a multiple linear regression analysis showed admission hyperglycemia to be a powerful independent risk factor for a poor motor outcome, even excluding diabetes mellitus cases associated with chronic hyperglycemia (regression coefficient: -1.37, 95% CI: -2.65 to -0.10, $P < 0.05$). Manipulating the blood glucose level in acute SCI rescued the exacerbation of the pathophysiology and the motor functional outcomes of the hyperglycemic mice. Our findings reveal that hyperglycemia in acute SCI is a novel prognostic factor with a negative impact on the motor function, highlighting the importance of achieving tight glycemic control after central nervous system injury.

Title: Locomotor-respiratory coupling after spinal cord injury and the effects of locomotor rehabilitation

Authors: *T. SUTOR[1,2], N. J. TESTER[1,3], D. FULLER[1], K.-A. STREETER[1], K. A. BUTERA[1,2,3], E. J. FOX[1,2,3];
[1]Univ. of Florida, Gainesville, FL; [2]Brooks Rehabil., Jacksonville, FL; [3]Malcom Randall V.A. Med. Ctr., Gainesville, FL

Abstract: *Background* Temporal coupling of respiratory and locomotor patterns may provide a neuromechanical advantage to breathing. Following incomplete spinal cord injury (ISCI), supraspinal input to spinal motoneurons is disrupted. Propriospinal pathways, however, often remain intact after ISCI and respiration and locomotion may remain neurologically coupled. Coupling of these motor behaviors in human ISCI has not been extensively examined. Additionally, limited information exists about the effect of rehabilitation on locomotor-respiratory coupling (LRC). The purpose of this pilot study was to examine LRC during walking after ISCI. The extent of LRC was quantified using a stride-by-stride method to assess coordination between walking and breathing rhythms. Additionally, the effects of three weeks of locomotor training on LRC were examined.
Methods Two adults with chronic ISCI were assessed during over ground and treadmill walking. Subjects were evaluated before and after 15 sessions of locomotor training with manual assistance and partial body-weight support. Stride cycles during walking were measured based on the onset of left quadriceps activation. Respiratory timing was determined with a flow thermistor, with inspirations defined as peaks of the flow thermistor trace. The coupling interval, the percent time of each stride cycle at which the first inspiration of that cycle occurred, was calculated. Adapting a previously published method (Hill et. al., 1988), breaths were considered coordinated if the coupling interval was the same +/- 9% for at least 4 inspirations in a row.

Percent coordination (%COORD) was determined as the percentage of total first inspirations in each stride cycle which were coordinated.
Results One subject (C6, AIS D) demonstrated no coordination, before or after locomotor training, in either the over ground or treadmill conditions. The other subject (L2, AIS C) demonstrated a decrease in %COORD over ground after training (pre-training, 73%; post-training, 43%), while demonstrating an increase in %COORD during treadmill walking after training (pre-training, 0%; post-training, 35%).
Conclusion These data are consistent with previous evidence that LRC can occur after ISCI in humans, and suggest that LRC may be altered by rehabilitation. Future research must consider the speed and amount of time subjects walk during evaluations, as coupling may not occur during short walking bouts or at low speeds as was seen in one subject. Injury level and severity may also affect LRC, and warrants further investigation. Determining functional implications of the effects of rehabilitation on LRC requires additional examination.

Title: Spinal cord injury in rats disrupts bowel function and daily activity rhythms

Authors: *A. D. GAUDET, M. AYALA, L. K. FONKEN, S. F. MAIER, L. R. WATKINS; Psychology & Neurosci., Univ. of Colorado Boulder, Boulder, CO

Abstract: In addition to conspicuous effects on sensorimotor function, spinal cord injury (SCI) disturbs more subtle systems of the body. Many individuals with chronic SCI are afflicted with bowel dysfunction (incontinence and/or constipation). Further, SCI could perturb circadian rhythms causing homeostatic disruption that hinders recovery. Improving post-SCI bowel

regularity and normalizing circadian rhythms could enhance recovery and quality-of-life. Here, we hypothesize that SCI in rats causes bowel dysfunction and disrupts circadian rhythms. Female and male rats were subjected to moderate-to-severe T9 contusion SCI (or sham surgery). Fecal production was then assessed at acute-to-chronic post-SCI times. Our novel data show that female and male rats have disrupted fecal production at acute times after SCI. Rats with acute SCI had reduced whole-gut transit time, suggesting potentially deficient nutrient absorption. SCI rats also produced more fecal pellets than shams during the inactive phase, implying that they may have disrupted circadian rhythms. Ongoing experiments will establish whether SCI alters circadian activity in rats. These studies reveal a novel strategy for assessing post-SCI fecal production and circadian rhythms in rats, and suggest that SCI disrupts bowel and circadian function.

Title: Time course of axon initial segment plasticity caudal to a complete spinal cord transection in rats

Authors: *K. P. DIMINTIYANOVA, J. WIENECKE, D. B. JENSEN, C. F. MEEHAN; Univ. of Copenhagen, Kobenhavn N, Denmark

Abstract: Recent work in vitro has demonstrated activity dependent plasticity of axonal initial segments (AISs). In vivo we have shown that following a complete spinal cord injury (where motoneurones are deprived of their descending inputs) the axon initial segments of the spinal motoneurones below the injury become longer, wider and closer to the soma (Azam et al, Proceedings of the Phys. Soc. 2014). This could explain the hyperreflexia observed in this model which has been implicated in the development of spasticity. Recent work by Evans et al (Cell Rep, 2015) suggests that AIS plasticity can occur within 3 hours in dentate granule cells in vitro. The hyperreflexia in the spinal cord injury model we are using, however, occurs at approximately 3-4 weeks post transection. Furthermore, acutely following spinal cord injury there is a suppression of L-type calcium channel activity (Hounsgaard et al, 1988 J Physiol),

which returns by about 3 weeks post-injury (Eken, Hultborn and Kiehn, Prog. Brain Res. 1989). This is important as L-type calcium activity has been shown to be necessary for AIS plasticity in vitro (Grubb and Burrone, Nature, 2010). We therefore explored possible AIS plasticity in more acute time points following transection. We performed a complete transection of the spinal cord at the sacral (S2) level, under isoflurane anaesthesia, in 7 adult male Wistar rats. At 24 hours post-transection the tails showed a flaccid paralysis with no sign of spasticity as normally observed at later time points. Immunohistochemistry was used to label Ankyrin G as a marker of AISs and Choline Acetyltransferase as a marker of motoneurones on the spinal segments immediately below the injury. Three-dimensional images were captured using confocal microscopy (Zeiss LSM 700) and AISs were measured in 3-dimensions and compared to controls (8 rats). Mann-Whitney tests revealed no significant differences between AISs of motoneurones in control and spinalized rats with respect to length, distance from cell body and proximal AIS width. This was the case for both alpha and gamma motoneurones. Distal AISs widths were, however, significantly wider for both alpha and gamma motoneurones (26 % wider, $P<0.0001$ and 30% wider, $P<0.05$ respectively). Conclusions and implications: The AIS plasticity that we have observed at more chronic time points post-transection (when a hyperreflexia of tail muscles is present) was not observed at more acute time points before the onset of hyperreflexia. This fits with the initial loss of L-type calcium channel activity in this model, suggesting that this is also necessary for AIS plasticity in vivo.

Title: Transcranial magnetic stimulation (TMS) evoked responses from hind limb muscles are diminished in spinal cord injured animals and partially recovered following improved plasticity induced by repetitive electromagnetic stimulation at spinal levels

Authors: *V. ALESSI[1,2], H. PETROSYAN[1], J. SNIFFEN[3], S. A. SISTO[4], M. A. KAUFMAN[1], V. L. ARVANIAN[1];
[1]Northport VAMC, Northport, NY; [2]Neurobio. & Behavior, [3]Physical Therapy, [4]Hlth. and Rehabil. Sci., Stony Brook Univ., Stony Brook, NY

Abstract: Electro-magnetic stimulation is a non-invasive approach to activate human central and peripheral nervous systems. TMS has been used in numerous studies as a neurophysiologic technique: a marker of cortical excitability and conduction in central motor pathways in humans and rats. Electromagnetic stimulation applied over spinal level (SEMS) was shown to activate spinal nerves and is gaining large acceptance as an alternative to electric stimulation. We have previously demonstrated that SEMS is able to activate synaptic inputs at spinal neurons and when given repetitively, SEMS induced an LTP-like facilitation, i.e. strengthened synaptic transmission in rat damaged spinal cord by increasing the function of NMDA receptors and recruiting additional AMPA receptors to the synaptic site. In these terminal experiments we measured signals from spinal cord neurons and legs muscles in response to electric stimulation of specific spinal pathways. Objective of the current study was to examine whether effects of repetitive SEMS in SCI animals could be evaluated by non-invasive TMS technique. In intact non-injured animals TMS consistently evoked MEP in hindlimb muscles (amplitude 0.29 ± 0.13 mV, latency 14.1 ± 1.9 ms; n = 7). In most animals with chronic T10 contusion SCI, however, MEP responses recorded from hindlimb muscles and evoked by TMS were almost abolished. TMS was not able to evoke MEP in hindlimb muscles in five out of seven contused rats and in remaining two contused animals TMS evoked MEP of very small amplitude, barely distinguishable from background noise (0.04 ± 0.03 mV; n = 7). MEPs evoked by SEMS at the thoracic level were, however, obtained reliably in all these contused animals, although amplitude of these MEPs evoked by SEMS was significantly diminished in contused animals (0.25 ± 0.02 mV; n=7) compared to non-injured animals (0.78 ± 0.06 mV; n = 7). After measurement of MEP evoked by single SEMS, a train of repetitive SEMS was applied. After LTP-like facilitation of SEMS-evoked MEP was observed, the coil was moved back to same position at cranial level and TMS-evoked MEP were measured again. Interestingly, after induction of LTP-like facilitation evoked by SEMS at spinal levels, TMS evoked reliable MEPs in the same SCI animals that had not displayed TMS-evoked responses prior to application of repetitive SEMS. Mean amplitude of TMS-evoked MEP after application of SEMS at thoracic level was 0.11 ± 0.05 mV vs 0.04 ± 0.03 mV (n=7) in these contused animals. This study confirms that TMS-evoked responses can be used as an adequate measure of transmission in cortico-spinal circuitry and application of SEMS induces facilitation of these TMS-evoked responses in animal SCI model

Title: Assessing motor deficits in a rodent model of spinal cord hemisection that mimics the human Brown-Sequard syndrome

Authors: *X. LIN[1], T.-B. ZHAO[2], M. WALKER[1], W. WU[1], X.-M. XU[1];
[1]Indiana Univ. Sch. of Med., Indianapolis, IN; [2]Gen. Hosp. of Jinan Military Region, Jinan, China

Abstract: Incomplete spinal cord injuries (SCI) often lead to severe and persistent impairments of sensorimotor functions and are clinically the most frequent type of SCI. Brown-Séquard syndrome in humans is caused by damage to one half of the spinal cord, resulting in paralysis and loss of proprioception on the same (or ipsilateral) side of the injury, and loss of pain and temperature sensation on the opposite (or contralateral) side. Hemisection models of the spinal cord in rodents mimic the Brown-Séquard syndrome in humans. To date, standardized protocols for evaluating sensorimotor function in the hemisection or unilateral lesion model are lacking. In the present study, we used a TreadScan System (Clever Sys Inc., Reston, VA) to analyze the differential spontaneous recovery of the ipsilesional and contralesional hindlimb locomotor recoveries by detailed kinematic analysis in adult rodents after a T9-10 unilateral thoracic hemisection, a rodent model of the human Brown-Séquard syndrome. We found that the contralateral hindlimb locomotion showed substantial recovery, whereas the ipsilateral hindlimb remained in a very poor functional state. On the basis of this observation, we developed a protocol to assess limb coupling after the hemisection. The coupling data derived from this protocol appear to be useful and sensitive measures of functional deficits in this model. Although we only demonstrated the use of limb-coupling in a hemisection model of thoracic SCI, this methodology may also be applied to other levels of incomplete spinal cord injuries as well as to both acute and chronic injuries.

Wings for Life

Title: Comparative transcriptomic analysis of sprouting and regenerating corticospinal neurons.

Authors: *G. H. POPLAWSKI[1], K. KHOO[1], N. MEHTA[1], R. KAWAGUCHI[2], E. ROSENZWEIG[1], K. KADOYA[1], P. LU[1], G. COPPOLA[2], M. TUSZYNSKI[1];

Abstract: The corticospinal tract (CST) is a critical motor system in humans for voluntary movement. The inability of adult corticospinal axons to spontaneously regenerate after spinal cord injury (SCI) may be attributable in part to incomplete activation of neuronal growth programs after injury. Recently we reported that robust corticospinal regeneration can be elicited in neural stem cell (NSC) grafts implanted into sites of injury (Kadoya et al., Nat Med 2016). To gain insight into intrinsic corticospinal neuronal mechanisms associated with successful regeneration, we performed transcriptomic analysis of regenerating corticospinal neurons. In a second study, we performed complimentary transcriptomic analysis on CST neurons in which compensatory regenerative sprouting was triggered by a unilateral pyramidotomy. Bioinformatic data mining and gene regulatory network analysis of both datasets revealed several master regulatory hub genes that are converging in both models. We are now testing several of these potential master regulators of regeneration in in vitro and in vivo models of spinal cord injury.

Title: Effect of iron oxide nanocarriers on the morphology of rat cortical neuron

Authors: *S. SEBASTIAN[1], R. A VEETTIL[1], T. MCALLISTER[2], S. GHOSH[2], D. HYNDS[1]; [1]Texas Woman's Univ., Denton, TX; [2]Dept. of Physics and Engin. Physics, Southeast Missouri State Univ., Cape Girardeau, MO

Abstract: Development of novel nanocarriers to encourage axon regeneration and guidance is promising for functional recovery from spinal cord injury and damage. Biocompatible nanocarriers that are capable of crossing the blood-spinal cord barrier can be used to target therapeutics to damaged corticospinal neurons. In our work, biocompatible, thermoresponsive iron oxide nanocarriers were used to study the time and dose dependant effect on neurons and neuron like cells. Our previous studies showed that upto 3 µl of iron oxide nanocarriers did not affect the morphology of B35 neuroblastoma cells and PC12 pheochromocytoma cells. In the present study, P0 rat cortical neurons were treated with different concentrations of iron oxide nanocarriers for different time intervals to see if there is any effect on neurite morphology. Effects of iron oxide nanocarrier treatment on neurite outgrowth were analyzed using Nikon A1 confocal microscope system by measuring the number of neurites per cell, number of branches per cell, longest neurite per cell, percent neurite bearing cells and the total neurite outgrowth. We expect to see no effect on rat cortical neuron morphology following the treatment with iron oxide nanocarriers. In future, drug loaded nanospheres will be used to asses uptake, drug transport and axonal guidance in rat corticospinal neurons.

Title: Uptake efficiency of surface functionalized nanospheres by different cells in rat mixed cortical culture

Authors: *R. AMMASSAM VEETTIL[1], S. SEBASTIAN[1], T. MCALLISTER[2], S. GHOSH[2], D. HYNDS[1];
[1]Biol., Texas Woman's Univ., Denton, TX; [2]Dept. of Physics and Engin. Physics, Southeast Missouri State Univ., Cape Girardeau, MO

Abstract: Degenerative or traumatic damage to the central nervous system causes acute neuronal death and the inability of damaged neurons to regenerate their axons leads to persistent loss of function. Nanomaterial-based drug delivery systems can be targeted to specific neurons to encourage axon regeneration. In the present study, we used -COOH and -NH2 surface functionalized nanospheres (SFNPs) to study the uptake efficiency by different cells in a rat mixed cortical culture. Mixed cortical cells are extracted and cultured from neonatal rat brain (P1- P4) and treated with SFNPs and fixed. To assess SFNP uptake by different cell types, mixed cortical cultures were immunolabeled for specific cell types: neurons, astroglia, oligodendrocyte and microglia. Image analysis from micrograph captured using a 40X objective and DAPI, FITC and TRITC filters on a Nikon Ti eclipse A1 confocal system. Different cell types were analyzed for SFNP abundance by comparing mean fluorescence intensity from SFNPs. Our results showed a consistent but not statistically significant increase in SFNP uptake by neurons compared to glial cells. This suggests that these SFNPs can be used as nanocarriers to target therapeutics to neurons and glial cells.

Title: Endothelin B receptor agonist, IRL-1620, enhances neurogenesis in an *Ex vivo* model of adult mouse spinal cord injury

Authors: *M. FORNARO[1], A. ZURNEY[1], B. PAUS[1], A. CHANG[2], D. LAWLOR[1], H. SHARTHIYA[1], S. BRIYAL[3], A. GULATI[3];
[1]Dept of Anat., [2]Dept. of Biomed. Sci., [3]Dept. of Pharmaceut. Sci., Midwestern Univ., Downers Grove, IL

Abstract: Spinal cord injury (SCI) causes substantial damage to the tissue due to increased vascular permeability, infiltration of inflammatory cells, focal edema and apoptosis. Clinical treatment is currently inadequate. However, adult SCI is mentioned among the first conditions for which stem cells might provide a therapeutic strategy and recent discovery of endogenous multi-potent neural stem/progenitor cells (NSPCs) within the adult spinal cord has shed light on stem cell therapies for SCI.
Our group previously demonstrated that stimulation of Endothelin-B (ET_B) receptors reduces apoptosis and increases VEGF and NGF expression. Stimulation of ET_B receptors with IRL-1620, an agonist of ET_B receptor, in adult rats with focal cerebral ischemia reduces the infarct volume by 83% and leads to recovery of neurological and motor functions. Administration of IRL-1620 was also found to reduce memory impairment in a rat model of Alzheimer`s disease (AD).
The hypothesis for this study is that a stimulation of the endogenous NSPCs and their differentiation into mature neurons could be key to contrast the apoptosis observed in SCI and promote re-networking of the neuronal circuitry and functional recovery.
IRL-1620 was tested in an *ex vivo* explant model for SCI. 250-300um thick transverse cryostat sections were obtained from spinal cords of adult NIH-Swiss mice and maintained for up to 4 days in culturing conditions (37C, 5% CO2, Minimum Essential Media, MEM). Four treatment groups were created: MEM-CTRL (1), MEM + NGF (2), MEM + IRL-1620 1mM (3) and 10mM (4). Samples were processed for immunofluorescence, western blot and microarray analysis. Preliminary results showed the presence of cells immuno-positive for Musashi, Nestin and Sox-2 within the ependymal and sub-pial layers thus confirming the presence of endogenous NSPCs in the adult spinal cord. Western Blot analysis showed 50% increase of Sox-2 and Musashi expression and 66% increase of Nestin in the IRL-1620 groups at 1 day in vitro (DIV) compared

to control thus suggesting a role for IRL-1620 in enhancing neurogenesis. GAP-43 expression in the IRL-1620-treated group compared to control decreased 50% at 1DIV but increased over 60% at 4DIV. A more dramatic increase (75%) was seen for GFAP expression at 4DIV. Because of the increase of GAP-43 and GFAP we speculate a role for IRL-1620 in promoting axonogenesis. Finally, microarray analysis showed a two-fold increase in the expression of 364 genes in the samples treated with IRL-1620 compared to control. The up-regulation of these genes will be further analyzed to investigate the mechanism by which IRL-1620 enhances neurogenesis and axonogenesis.

Title: Virtual adiposity: relationship with glucose metabolism in persons with and without spinal cord injury

Authors: *A. L. KIMBALL, R. K. SHIELDS;
Physical Therapy and Rehabil. Sci., Univ. of Iowa Carver Col. of Med., Iowa City, IA

Abstract: Metabolic syndrome is disproportionally distributed among certain populations in the United States. People with spinal cord injury (SCI) are one such group that carries increased risk. Physical inactivity, overnutrition, skeletal muscle adaptations, and autonomic dysfunction are key contributing factors. Active healthy individuals with SCI also have greater visceral adipose tissue than matched able bodied counterparts. Outwardly, they may not appear obese but this state of “virtual adiposity” may be a significant contributor to increased metabolic instability in phenotypically lean SCI individuals. In this study, we investigate glucose metabolism in a cohort of individuals across a spectrum including mobility status and body composition. **Purpose:** Determine how increased adiposity, mobility status and presence of SCI impact glucose metabolism. We also examined variables that may predict homeostatic glucose response. **Methods:** Thirty-five subjects were divided into four groups; able bodied lean (n=10, 6 female),

able-bodied non-lean (n=10, 4 female), paraplegia (n=6, 1 female) and tetraplegia (n=9, 1 female). Able-bodied individuals were matched for age and height but divided into lean and non-lean groups according to standard obesity criteria. **Results:** Able-bodied non-lean and tetraplegics had higher visceral adipose tissue thickness compared to lean ($p < 0.01$) and paraplegics ($p = 0.05$), respectively. Tetraplegics exhibited impaired glucose disposal ($p < 0.05$) compared to all able bodied individuals. Tetraplegics exhibited 40-62% higher glycemic responses than paraplegics at 30 and 120 minutes, respectively ($p = 0.057$). Visceral adiposity was higher in power chair ($p < 0.05$) users. Glucose AUC was increased in both power ($p < 0.05$) and manual ($p < 0.01$) chair users. Visceral adipose tissue thickness is a moderate predictor ($r = 0.45$, $p = 0.006$) of the glucose response of subjects in this study. **Conclusions:** The presence of higher lesion level leads to less flexibility during glucose metabolism. Visceral adiposity and mobility status (power chair vs. self-propel) influenced glucose mobilization despite lesion level. Visceral adipose tissue may be a relevant clinical measure to predict abnormalities in glucose disposal, particularly in those who are phenotypically lean.

Title: *In vivo* observation of acute vascular dysfunction following spinal cord injury

Authors: *C. CHEN[1,2], Y. ZHANG[3], Y. SUN[1,2], C. SHIELDS[3], W. XIONG[2], X. JIN[2], X.-M. XU[1,2];
[1]Indiana Univ. Dept. of Neurolog. Surg, Indianapolis, IN; [2]Spinal Cord and Brain Injury Res. Group, Stark Neurosciences Res. Institute, Goodman and Campbell Brain and Spine, Indiana

Univ. Sch. of Med., Indianapolis, IN; [3]Norton Neurosci. Institute, Norton Healthcare, Louisville, KY

Abstract: The vascular network is an integrated part of the spinal cord. During development, angiogenesis accompanies neurogenesis. After maturation, the vascular network provides blood circulation and regulates the exchange of gasses and nutrients with the spinal cord through the blood-spinal cord barrier (BSCB), forming a pair of closely connected systems. Disruption of the vascular system, initiated by the primary mechanical impact of spinal cord injury (SCI), could break the supply-and-demand balance and exacerbate the progression of neuronal and glial cell damage originating from the injury epicenter. Compared to neurons and glial cells, the acute vascular changes following SCI have been understudied. Previous studies have attempted to address these issues but, due to technical limitations, most analyses were performed on post-mortem samples and were unable to capture the dynamic changes of the vascular network under traumatic conditions. In this study we have developed a two-dye in vivo imaging method, using two-photon laser scanning microscopy (TPLSM), which can overcome the technical barricades and monitor acute vascular dynamic changes following contusive SCI. This approach allows to detect blood flow and vessel diameter at various sites of the same rat pre- and post-injury, as well as other vascular pathology. With this powerful tool, we found that blood flow was initially increased and gradually decreased over time at the epicenter and in adjacent areas. We also discovered that vessels started to dilate 30 minutes post-injury at the injury epicenter and in adjacent areas, and were consistently enlarged in diameter up to 4 hours post-injury. Not only were vessels disrupted in the injury epicenter, but also blood extravasation was seen in the penumbra area at 2 hours post-injury while leaving the remote area intact. The leakage indicates the permeability of vasculature changes in the so-called “transitional zone” at an early stage post trauma, whereas our histological data shows spared neurons and other cells in this zone. This observation suggests that vascular dysfunction at the transitional zone occurs before tissue damage and potentially plays a role in the secondary progression of neural degeneration. Overall, this method provides an excellent venue for investigating vascular dynamics. Meanwhile, these findings suggest a new perspective for preventing progressive tissue damage after SCI.

Title: Developing models of spinal cord injury using optogenetic cellular ablation

Authors: *K. MRUK, J. K. CHEN;
Chem. and Systems Biol. and Developmental Biol., Stanford Univ., Stanford, CA

Abstract: Spinal cord injury (SCI) is a complex problem because a cascade of pathophysiological events results in greater injury than was initially sustained leading to varying degrees of severity and impairment. Animal models that are capable of regeneration are perhaps our best resource for discovering ways to promote recovery from SCIs. In particular, the zebrafish central nervous system (CNS) shares many organizational, cellular and molecular pathways with humans, yet it is capable of functional regeneration even after complete spinal cord transection. Zebrafish models of SCI are unique, valuable tools for studying this regenerative process, particularly since the optical transparency of larvae enables direct visualization of the CNS in real time and optogenetic manipulations. To better understand how the CNS responds to SCI, we are developing optogenetic approaches to selectively ablate cells in the zebrafish spinal cord and monitor regeneration of these neural populations in real time. Combining the ability to control light in both space and time with tissue-specific promoters allows us to create reproducible, neural specific ablation, thus sparing the surrounding tissue and allowing us to decouple these complex events.

Title: Spinal cord injury in mice - functional performance by kinematic motion analysis and tissue pathology by mri

Authors: *E. LATONUMMI, J. KHABBAL, K. LEHTIMÄKI, L. TOLPPANEN, A. NURMI;
Charles River Discovery, Kuopio, Finland

Abstract: Spinal cord injury may lead to life time disability and currently there are no effective therapies to promote functional recovery and rehabilitation. One critical element in rodent models of spinal cord injury is the remarkable spontaneous recovery after the injury which limits the translational properties of rodent models to understand therapeutic efficacy and mechanisms

that enhance recovery after injury. Many current behavioral methods also lack the sensitivity to detect minor, possibly clinically relevant improvements in functionality. Furthermore, tissue pathology is typically evaluated by histological and immunohistocemical analysis in animal models, which is often time consuming and not possible in clinical settings. In this work we evaluated mouse spinal cord contusion injury, classical scoring systems by using BMS scoring and rotarod but also by using kinematic analysis to understand how functionality changes in detail from initial complete hindlimb paralysis to partial recovery after several weeks. In this study we also evaluate the usefulness of small animal MRI in the assessment of spinal cord injury. Female C57Bl/6J mice were subjected to T9-T10 level of spinal cord contusion injury using electromechanical impactor (PinPoint). Before and following contusion injury, functional performance was evaluated by BMS scoring and rotarod test. High resolution kinematic monitoring was done in wading mode on day 10 and 44, where mice were partially submerged in water to assist and support detection of any partial movements of the hind limbs after the spinal cord injury. MRI evaluations of the spinal cord injury were coincided with early and later behavioral analysis during the study. Taken together, this study describes kinematic analysis data in relation to classical functional measures used in SCI model in mice. Functional changes were as expected with partial to complete hindlimb paralysis in response to SCI but also showed marked recovery with traditional functional assays during the follow-up period. Kinematic analysis, however, revealed persistent deficits in the model throughout the follow-up period without robust recovery. Usefulness of in vivo MRI findings from acute and chronic phase are also discussed in relation to typical histopathological findings from the model.

Title: Spinal cord stimulation in sheep models of chronic neuropathic pain and spinal cord injury-induced spasticity

Authors: *J. W. MILLER[1], C. G. REDDY[1], S. WILSON[1], K. O. ABODE-IYAMAH[1], N. A. DEVRIES-WATSON[2], D. C. FREDERICKS[2], G. T. GILLIES[4], T. J. BRENNAN[3], M. A. HOWARD, III[1];

Abstract: Chronic pain and spinal cord injury are debilitating health problems that combined affect tens of millions of people worldwide. In order to further our understanding of these conditions - and eventually improve clinical care - large animal models are necessary to fill the translational research gap that currently exists between small animal models (e.g. rat and mouse) and clinical trials. Our laboratory is developing separate models of these two conditions in sheep with the intent of investigating the therapeutic effects and mechanisms of spinal cord stimulation. The sheep's similar anatomic scale to humans and its ability to perform various behavioral tasks make it the best available large animal model for investigating the clinical relevance of spinal cord stimulation. Spinal cord stimulation (SCS) was performed via implantable Medtronic pulse generators and paddle-type epidural electrodes. The neuropathic pain model was established through chronic constriction of the common peroneal nerve. The behavioral and neurophysiological manifestations of pain were measured through von Frey filament testing, gait analysis, and terminal dorsal horn recordings. The von Frey withdrawal thresholds were measured daily after nerve injury both with and without constant 40 Hz SCS. A weight drop contusion was used to induce spinal cord injury (SCI). Data collected from gait analysis, chronically implanted electromyography (EMG) electrodes, stretch reflex, and h-reflex tests were collected pre and post-SCI in order to characterize the onset and severity of spasticity. Constriction of the peroneal nerve resulted in a neuropathic pain condition that persisted longer than 100 days post injury and could be modulated via spinal cord stimulation. In particular, we observed that epidural stimulations from 0.1 to 0.5 V resulted in an apparent increase in von Frey filament withdrawal thresholds as well as a decrease in spontaneous activity recorded from neurons in the dorsal horn. With regard to the SCI spasticity model, in the animal with one of the most severe injuries, spinal cord stimulation during treadmill ambulation modulated gait metrics towards their pre-injury values. EMG recordings revealed the expected out-of-phase firing of antagonistic muscle groups during pre-injury gait recordings. For both the pain and SCI models, the animals' injuries resulted in chronic conditions that were studied with a range of behavioral and neurophysiological techniques. The establishment of these large animal models is necessary for improving the field of spinal cord stimulation research and its clinical relevance.

Title: Sympathetic control enhances heart rate variation in humans with spinal cord injury

Authors: *C. L. MCHENRY, R. K. SHIELDS;
Physical Therapy and Rehabil. Sci., Univ. of Iowa, Iowa City, IA

Abstract: The autonomic nervous system is compromised after spinal cord injury with a greater loss of sympathetic drive with lesions above T-1. Frequency analysis of the 24 hour recorded electrocardiographic response (R-R interval) offers a novel technique to assess sympathetic drive. Heart rate variability requires precise sympathetic nervous system control. Currently, we have incomplete evidence on the extent to which this recording technique is sensitive to the variation in heart rate across various injury levels and as compared to healthy controls. **Purpose:** We assessed heart rate variability in people with and without SCI at various levels of physical activity over a 24 hour period. We hypothesized that tetraplegics would have a greater reduction in heart rate variability and sympathetic drive as compared to paraplegics and that SCI would have reduced variability as compared to healthy controls. **Methods:** Ten individuals with spinal cord injury (5 tetraplegia, 5 paraplegia) and 10 healthy, age-matched controls participated in this study. Heart rate and accelerometer data from the wrist and ankle were monitored for 24 hours. The heart rate was then separated into three, 1 hour time bins of low, moderate, and high heart rate. Low frequency (LF) power, a measure of heart rate variability and sympathetic drive, was calculated within each time bin. Physical activity was quantified over the entire collection period using the wrist and ankle acceleration. **Results:** The heart rate bins for the tetraplegic, paraplegic, and non-SCI groups were comparable (low=60-65 BPM, moderate=75-80 BPM, high=90-95 BPM). Tetraplegics had a reduced capacity to modulate low frequency power (sympathetic drive) compared to paraplegics ($p<0.05$) and non-SCI individuals ($p<0.05$) in response to increased cardiac load. The difference in LF power between the low to moderate and low to high was only 2% in the tetraplegic group. The paraplegic group and the non-SCI groups shifted their LF power by 11% and 22%, respectively. Individuals with tetraplegia had 75% and 45% less physical activity compared to paraplegics and non-SCI groups, respectively ($p<0.05$); while the paraplegic group had 54% less physical activity than the non-SCI group ($p<0.05$). **Conclusions:** These results support that the heart rate variability is seriously compromised, especially in people with higher levels of injury (tetraplegia); a finding supported by more

extensive loss of sympathetic drive. Future studies that evoke a reflex modulation of sympathetic activity through electrical stimulation may lead to training adaptations that increase heart rate variability at rest and with activity.

Title: The in-cage automation of the single pellet reaching task. A test for dexterity in rats.

Authors: *D. GADIAGELLAN, T. NANAYAKKARA, L. D. F. MOON;
Neurorestoration, Kings Col. London, London, United Kingdom

Abstract: Nervous system diseases and injuries affect millions of individuals. Rats are often used to assess therapies that might improve reaching and dexterity using Ian Whishaw's Single Pellet Reaching Task. Typically daily, a researcher takes the rat from its cage to the apparatus, and trains it to retrieve sugar pellets from one of two pedestals. After neurological injury, rats may be assessed weekly for one or two months. The researcher may be occupied with training, rehabilitations and testing for several months. Globally, researchers spend thousands of hours each year training and testing rats. We and others have been developing methods for automating this task (Fenrich et al., 2014, 2015; Wong et al 2015).
Methods: We have developed a miniature robotic system that is capable of the in-cage training, rehabilitation and assessment of rats using the Single Pellet Reaching test. Prototypes were designed using computer aided design software, manufactured using 3D printing technologies and controlled using miniature computing hardware, custom designed electronics and an array of sensors.
Results: (1) RatBots enable many animals to be trained, assessed and/or rehabilitated simultaneously. (2) The user can specify schedules for training, assessment and rehabilitation for each rat independently. (3) Devices can work 24 hours a day, 7 days a week (i.e., including the rat's active night phase). (4) We show that the devices can detect deficits in dexterity induced by cortical (photothrombotic) stroke in elderly rats.

Discussion: (1) In-cage automation allows multiple studies to be run in parallel by a single user. (2) Studies can be larger and better powered. (3) RatBots are cost-effective because they enable each researcher to gather much more data.
In summary, in-cage automation of the single pellet reaching task should accelerate discovery of new therapies for nervous system disease and injury.

Title: Selective activation of TRPV1-lineage neurons and analyses of nocifensive behavior and synaptic transmission in acute spinal cord slices reveal synaptic plasticity of inhibitory, but not excitatory circuits

Authors: *D. M. DUBREUIL[1], D.-S. KIM[2], E. J. LOPEZ SOTO[1], S. DENOME[1], J. A. KAUER[1], D. LIPSCOMBE[1];
[1]Brown Univ., Providence, RI; [2]Dept. of Anat., Soonchunhyang Univ., Soonchunhyang, Korea, Republic of

Abstract: Optogenetic methods make it possible to target populations of neurons that share genetic signatures and mediate specific behavioral responses and enable us to monitor synaptic function both *in vivo* and *in vitro* using similar stimulation paradigms. In the somatosensory system, the activity of primary nociceptors mediates nocifensive paw withdrawal behavior primarily via spinal cord circuitry, but conventional methods used to activate nociceptors *in vivo* and *in vitro* differ. Behavioral analyses rely on naturalistic thermal or mechanical stimuli to trigger paw withdrawal, whereas *in vitro* studies use electrical stimulation to drive synaptic activation. We crossed TRPV1-Cre driver and Cre-dependent ChR2-EYFP reporter mouse strains to generate a TRPV1/ChR2-EYFP mouse strain to monitor optically-evoked behavioral responses *in vivo* as well as synaptic events *in vitro* in acute spinal cord slices. We observed robust nocifensive responses in TRPV1/ChR2-EYFP mice in response to blue LED light applied remotely to the plantar hindpaw. Responses consisted of immediate paw withdrawal, paw shaking, and prolonged licking, and response probability was light-intensity dependent. Using both ChR2-EYFP and TdTomato to report Cre expression, we found that approximately 65% of TRPV1-lineage neurons co-express nociceptor markers and that 75% of all nociceptors are labeled in TRPV1/ChR2-EYFP mice. In acute spinal cord slices, activation of the same population of afferent fibers drives monosynaptic, DNQX-sensitive post-synaptic responses as well as polysynaptic inhibitory responses that are picrotoxin sensitive. To examine if TRPV1-lineage neurons can support synaptic plasticity, we stimulated acute spinal cord slices with blue light at 2 Hz for 2 min. Averaging over all cells (n=16), post-synaptic current peak amplitude increased to 150% ± 25% of baseline levels. In total, 50% of cells (8/16) showed an increase in peak amplitude greater than 120% of baseline. Interestingly, potentiation was absent in the presence of picrotoxin. We next stimulated one hindpaw of anesthetized TRPV1/ChR2 at 2 Hz for 30 min using 465 nm blue LED light. A similar protocol was used for $Na_V1.8$-lineage neurons expressing ChR2 *in vivo* and shown to induce mechanical and thermal hyperalgesia lasting at least 5 hrs. By contrast, we found no evidence of hyperalgesia following light exposure in our TRPV1/ChR2-EYFP mouse strain. Our findings indicate that, prolonged low-frequency stimulation of TRPV1-lineage neurons does not induce hyperalgesia, but similar stimulation of these neurons in vitro potentiates inhibitory circuits in spinal cord dorsal horn.

Title: A transcription factor essential for organ differentiation is expressed in sensory neurons and regulated by nerve injury

Authors: *J. L. SALOMAN, B. M. DAVIS;
Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Background: PDX1, pancreatic duodenal homeobox 1, is an essential transcription factor (TF) for proper differentiation of the pancreas. We recently discovered that this TF is also expressed in a subset of sensory neurons. This study was designed to assess expression and function of PDX1 in the peripheral nervous system. **Methods**: Utilizing cre-lox technology and tdTomato fluorescent protein, various peripheral nerves and ganglia were examined for PDX1-cre driven tdTomato expression. Quantitative PCR was used to assess sensory neurons for expression of PDX1 mRNA as well as several genes known to be upstream or downstream of PDX1 in the pancreas (e.g. ATF3, PKCα/ε, SERCA, ERK1/2). These genes were examined to determine whether PDX1 signaling pathways contribute to sensory neuron changes observed in a model of neuropathic pain. Calcium imaging was used to assess functional changes associated with gene changes. **Results**: The tdTomato expressing somata were observed in both trigeminal and dorsal root ganglia, with tdTomato-positive fibers in a variety of nerves, but particularly prominent in the infraorbital nerve (ION). TdTomato expression was observed as early as P1 in the trigeminal ganglia (TG) and ION. As predicted, ATF3, a common marker of nerve injury, was significantly upregulated in TG following ION injury. Similar to pancreas, upregulation of ATF3 expression was correlated with suppression of PDX1 mRNA in the TG. Furthermore, following ION injury, PDX1 downregulation was associated with a reduction in SERCA, a regulator of cytosolic calcium, particularly the duration of high K^+-evoked Ca^{2+} transients. Previous studies (Scheff et. al. 2013) demonstrated that persistent inflammation (CFA model) is accompanied by increases in the magnitude and duration of high K^+-evoked Ca^{2+} transients. In these experiments, we observed changes in high K^+-evoked Ca^{2+} transients following ION injury, specifically the duration. Finally, in neuro2A cells overexpression of PDX1 was associated with an increase in SERCA. **Conclusions**: These preliminary studies suggest that a transcriptional pathway involving the 'pancreas-specific' transcription factor, PDX1, may modulate changes in calcium signaling observed following infraorbital nerve injury and could contribute to changes associated with chronic pain.

Title: A trpv1-/nav1.8+ subset of neurons mediates lymphatic antigen restriction

Authors: *G. H. IMPERATO[1], M. GUNASEKARAN[1], T. TSAAVA[1], W. HANES[2], S. S. CHAVAN[1], K. J. TRACEY[1];

Abstract: The lymphatic system is a conduit for the transit of pathogens which may gain access to the systemic circulation. Immunization status affects whether an antigen is restricted to draining lymph nodes, or flows freely to the systemic circulation and the viscera. The mechanism by which immunization status restricts antigen trafficking is unknown. Lymph nodes are innervated by both adrenergic and peptidergic neurons, and neural signaling has been implicated in modulating lymphocyte trafficking. Here, we developed a model system to characterize the trafficking of Keyhole Limpet Hemocyanin (KLH) through the lymphatic system under conditions of neural stimulation and nerve blockade. We observed that electrical stimulation of the lower extremity nerves in adult BALB/c mice restricts KLH to the popliteal lymph nodes after innoculation subcutaneously in the hindpaw. NaV1.8-Cre/DTA and littermate control animals were immunized with KLH. Following secondary immunization with KLH in the dorsum of the hindpaw, increased amounts of antigen were observed in the sciatic lymph nodes of NaV1.8-depleted animals as compared with control animals. Some NaV1.8-expressing nociceptive neurons also express the transient receptor potential channel vanilloid 1 (TRPV1) nociceptor, capsaicin-sensitive neurons that have been implicated in neuronal responses to pathogens. The increase in antigen retained in lymph nodes observed in NaV1.8-DTA animals was not recapitulated in TRPV1-DTA animals. These data suggest that a TRPV1-/NaV1.8+ cell population is required for neuronal input leading to antigen restriction in lymph nodes following immunization.

Title: *In vivo* optogenetic activation of nociceptors expressing voltage-gated sodium channel Nav1.8 and their response properties to natural stimuli.

Authors: *M. L. UHELSKI[1], D. BRUCE[1], P. SÉGUÉLA[2], G. WILCOX[1], D. SIMONE[1];
[1]Univ. of Minnesota Twin Cities, Minneapolis, MN; [2]McGill Univ., Montreal, QC, Canada

Abstract: The advent of neuronal stimulation through optogenetics has enabled selective activation of neurons which express light-sensitive channelrhodopsin2 (ChR2). Use of optogenetic methods to induce expression of ChR2 in the brain has enabled rapid, selective activation of specific subtypes of neurons or groups of neurons to determine their specific functions. However, the characteristics of light-sensitive peripheral neurons have not been fully explored. Using a transgenic mouse model in which neurons co-express $Na_v1.8$, a tetrodotoxin-resistant voltage-gated sodium channel, and ChR2, we have been able to selectively activate nociceptors in the plantar skin of the hind paw and characterize their response properties to mechanical, heat and cold stimulation. The majority of C-fiber nociceptors (41 of 50) and slightly less than half of Aδ-fiber nociceptors (4 of 9) were found to be responsive to light. Response characteristics, including conduction velocity and responses to mechanical stimuli were comparable between light-responsive and non-light-responsive fibers. However, whereas none of the non-light-responsive C-fibers were sensitive to heat or cold, nearly all (80%) light-sensitive fibers were excited by heat and/or cold stimuli, suggesting that $Na_v1.8$ is predominantly expressed by polymodal C-fiber nociceptors. Similarly, 3 of the 4 light responsive Aδ-fiber nociceptors were also sensitive to heat and/or cold, while only one of the non-light responsive fibers responded to cold. Overall, nociceptor responses did not differ from those found in control mice that do not express ChR2. Ongoing studies aim to explore how responses to light are altered during acute and chronic pain states and how these changes compare to alterations in responses evoked by mechanical, heat and cold stimuli. $Na_v1.8$ has previously been shown to be involved in the development of neuropathic pain conditions. The ability to activate peripheral nociceptors with light provides a novel method of stimulation that is non-invasive, does not require mechanical interruption of the skin, and adequately stimulates fibers whose receptive fields would be difficult or impossible to stimulate with standard stimuli. Also, use of a light stimulus is advantageous for repeated testing as the light stimulus is delivered without manipulation of or trauma to the skin. Optogenetic approaches are useful to study the functions of primary afferent fibers that possess certain receptors, ion channels, and other signaling molecules.

Title: A subset of vagal sensory neurons mediating bronchoconstriction

Authors: *L. HAN[1], N. LIMJUNYAWONG[2], Z. LI[2], O. HALL[2], W. MITZNER[2], B. UNDEM[2], B. CANNING[2], X. DONG[2];
[1]Sch. of Biol., Georgia Inst. of Technol., Atlanta, GA; [2]Johns Hopkins Univ., Baltimore, MD

Abstract: Asthma, accompanied by lung inflammation, bronchoconstriction and airway hyperresponsiveness, is a significant public health burden. Infection with respiratory viruses, such as influenza virus, exacerbates asthma and cause morbidity and mortality. Although primary sensory neurons have been shown to contribute to the pathogenesis of asthma, the underlying mechanism is largely unknown. Here we report that MrgprC11, a previously identified itch receptor, is expressed in a small subset of vagal sensory neurons innervating the lung. Activation of MrgprC11 evokes changes in the respiratory patterns in mice similar to the effects induced by a bronchoconstrictor. We further demonstrated that MrgprC11 mediate cholinergic bronchoconstriction. Mice lacking Mrgpr genes showed reduced anaphylactic bronchoconstriction. Moreover, the loss of Mrgpr genes significantly reduced influenza virus-induced airway hyperresponsiveness. Conversely, stimulation of MrgprC11+ vagal sensory neurons enhances airway responsiveness in the absence of lung inflammation. These findings highlight the neural mechanisms of asthma and provide a potential therapeutic target for the management of airway obstruction.

Med., Gainesville, FL; [6]Lab. de Neurosciences Intégratives et Adaptatives, Aix-Marseille Univ., Marseille, France

Abstract: Human C-tactile afferents (CTs) respond vigorously to gentle stroking of the skin, and have been a focus of recent research due to their important role in signaling positive affective touch. We recorded from individual CTs and C-mechanoreceptive nociceptors (CMs) in human participants, stimulating the afferents electrically at their receptive fields, and compared spike latency changes during repetitive stimulation of different frequencies. We show that, in addition to previously defined differences in mechanical thresholds, CTs and CMs show non-overlapping modulations of their electrically-elicited spike latencies, during both natural mechanical stimulation and 2 Hz electrical stimulation. We propose that either method of stimulation can be used to classify the afferents unequivocally. Latency changes during higher frequency stimulation (10-50 Hz) were lower in CTs than CMs, suggesting that there is less adaptation in CTs at physiological discharge frequencies. We conclude that CTs and CMs have substantially different mechanisms governing excitability changes following repetitive activity, consisting fundamentally separate populations. Targeting distinct axonal mechanisms governing excitability changes may facilitate selective modulation of CT or CM firing, which has implications for affective touch processing, especially in pathological situations involving tactile dysfunction such as allodynia.

Title: Reduction of axonal transport and chemosensitive receptor accumulation following cfa or vinblastine treatment

Authors: *R. M. GOVEA, G. BOVE;
Dept. of Biomed. Sci., Univ. of New England, Biddeford, ME

Abstract: We have previously shown that nerve inflammation (neuritis) leads to ectopic axonal mechanical sensitivity (AMS) and ongoing activity in nociceptors innervating deep structures. This phenomenon likely contributes to mechanically induced and ongoing radiating pain. Ongoing activity generated from the affected axon segment suggests ectopic sensitivity to noxious chemicals found in the inflammatory milieu. We recently reported that both neuritis and transient vinblastine (VIN) application reduce axoplasmic flow, and proposed that mechanically sensitive channels accumulated and became functional at the affected part of the axons. In the present study, we proposed that both agents would cause sensitivities to noxious chemicals, and that the specific channels for these chemicals would be increased at the affected site. In adult female rats, we treated nerves with either CFA (for neuritis) or VIN, and after 4-7 days performed single unit recordings from mechanically sensitive Group IV nociceptors of the L4 or L5 dorsal roots. The sciatic nerve was exposed and tested for mechanical sensitivity, followed by topical and then sub-perineurial chemical sensitivity using a mixture of bradykinin, serotonin, histamine, and PGE2 (IS; all at 10^{-5}M), pH 5.2 buffer, and 5 μM ATP. Lastly, the receptive field was tested for response to IS. We obtained recordings from 21 neurons (6 control, 7 CFA, 8 VIN) with CVs ranging from 0.31 to 1.23 m/s. Results demonstrate that no axons in the control group had AMS, compared to 29% and 50% in the CFA and VIN groups, respectively. No axons within intact sciatic nerves were sensitive to any topical chemical; however, sub-perineurial injection of InSoup into the sciatic nerve evoked a response from 0%, 86%, and 38% axons in the control, neuritis, and VIN groups, respectively. To investigate reduction in axonal transport and the subsequent accumulation of receptors, the sciatic nerve was partially ligated and treated with CFA, VIN, or SIF (synthetic interstitial fluid). 6-7 days following partial ligation surgery the nerves were harvested and immunolabeled for bradykinin 2 and histamine 3 channels. We observed a greater accumulation of the histamine 3 receptor proximal to the ligation site in control+ligation axons compared to CFA+ligation axons. These findings support our hypothesis that nociceptor axons are capable of developing ectopic chemical sensitivity, and that this sensitivity is associated with specific channel accumulation. This observation is consistent with development of ongoing radiating pain due to nerve inflammation.

Title: AAV-mediated transduction of primary afferent neurons following intracolonic viral vector administration

Authors: *M. S. RIEDL, R. GORE, H. HEYDER, C. N. HONDA, L. VULCHANOVA; Dept Neurosci., Univ. Minnesota, Minneapolis, MN

Abstract: AAV vectors have emerged as a preferred tool for gene transfer to neurons in basic research applications (McCown, 2011) and as promising candidates for therapeutic gene delivery vectors(Kotterman and Schaffer, 2014). While AAV vectors have been widely used for gene transfer in the central nervous system, peripehral nervous system applications have been more limited. AAV-mediated transduction of primary afferent neurons via intrathecal, intraneural, or intraganglionic routes of administration has been described in a number of studies, demonstrating the utility of AAV vectors for manipulation of afferent functions (Schuster et al., 2013; Storek et al., 2008; Towne et al., 2009; Vulchanova et al., 2010). In this study, we addressed the hypothesis that selective gene transfer to primary afferent neurons innervating visceral organs can be achieved through peripheral administration and retrograde transport of AAV vectors. AAV9 carrying the reporter gene tdTomato was injected in the colon wall of mice as previously described for neuronal tracers (Christianson et al., 2006). tdTomato expression in lumbosacral and thoracolumbar dorsal root ganglia (DRG) was analyzed by imagining whole-mount preparations with a multiphoton imaging system.Consistent with the distribution of neuronal tracers injected in the colon wall, transduced sensory neurons were adundant at the lumbosacral level when the vector was injected in the distal colon, while labeling in thoracolumbar DRG was more sparse. Injections in proximal colon resulted in sparse labeling in both lumbosacral and thoracolumbar DRG. These results demonstrate that AAV9 is able to transduce primary afferent neurons following uptake into peripheral terminals within the colon wall and provide proof-of concept for organ-selective AAV-mediated gene transfer to the afferent innervation of viscera.

Title: Localization of the sixteen currently recognized glutamate receptors in the rat cornea: a western blotting and immunofluorescent study

Authors: *B. K. CARR, K. E. MILLER;
Oklahoma State Univ. Ctr. For Hlth. Sci., Tulsa, OK

Abstract: Background: Upon high threshold stimulation, nociceptive sensory afferents release glutamate from peripheral nerve terminals to cause autocrine and/or paracrine activation and sensitization via glutamate receptors (Miller et al, 2011a). In previous immunohistochemical studies from our lab, glutamate receptor subunits for NMDA, AMPA, and Kainate (KA) have been observed to be present in the cornea. 6,7-dinitroquinoxaline-2,3-dione (DNQX), an antagonist of the AMPA and KA receptors, also was effective in antagonizing glutamate-induced nocifensive behavior from the rat cornea. In the current study, we aim to identify all remaining glutamate receptor subunits presence or absence in the rat cornea. **Aim:** To determine the presence or absence of the sixteen currently recognized Glutamate receptor subunits in the rat cornea. **Method:** Twelve naïve rats were euthanized for cornea retrieval and analyzed to determine the presence or absence of the sixteen currently recognized glutamate receptor subunits using Western Blotting techniques. Twelve rats were also used for immunofluorescence along with a confocal microscope to verify the presence of the subunits along with location of the subunits within the rat cornea. **Results**: A variety of Glutamate receptor subunits were found to be present in the rat cornea in nerve fibers and epithelial cells. Further investigation should be to immunohistochemically co-localize the Glutamate receptor subunits. **Conclusion:** Knowledge of which glutamate receptor subunits are present in the rat cornea will lead to a better understanding of corneal function. As observed in this study, specific glutamate subunits are on the primary sensory afferents as well as the corneal epithelial cells. Further studies need to be conducted to identify the purpose of each of glutamate receptor on either the primary sensory afferent and the corneal epithelial cells.

Title: DWN10899, a novel Nav1.7 blocker inhibits human DRG neuroexcitability and neuropathic pain

Authors: *S. PARK, I.-H. KIM, S.-Y. KIM, M. JUNG, H.-G. LEE, C. LEE, B. LEE; Daewoong Pharmaceut. Co. Ltd., Yongin-Si, Gyeonggido, Korea, Republic of

Abstract: The voltage gated sodium channel, Nav 1.7 is highly expressed in the nociceptive and sympathetic neurons. Gain-of-function of *SCN9A*, which encoding Nav1.7, leads to severe burning pain (ex, Erythromelalgia), whereas loss-of-function of *SCN9A* results in congenital insensitivity to pain (CIP) in human. Here we characterized DWN10899 as potent and selective Nav1.7 blocker in vitro and in vivo pain models. DWN10899 selectively stabilizes the slow-inactivated state of Nav1.7 and does not block the resting state. Concentration-dependent response studies revealed that DWN10899 inhibited human Nav1.7 channel with an IC_{50} value of 50nM, and human Nav1.5 channel with an IC_{50} value of 6.3 μM in slow inactivation state. Also, the compound has selectivity against other subtypes. DWN10899 inhibits Nav1.7 current in use-dependent (frequency-dependent) manner. In human DRG neurons studies, DWN10899 has an IC_{50} value of 313 nM in TTX-sensitive Na^+ current and not inhibits TTX-resistant Na^+ current. DWN10899 increases action potential rheobase and inhibits excitability in use-dependent manner. In addition, in vivo experiments showed that single administration of DWN10899 (30 mg/kg, p.o.) blocked chronic-constriction-injury (CCI)-induced neuropathic pain induced by various stimuli including mechanical allodynia, heat hyperalgesia, and cold allodynia in mice. These data suggest that DWN10899 is a potential candidate for the treatment of peripheral painful neuropathies.

Title: Activateion of Adelta and Abeta fibers by one electrode at the same site

Authors: *M. NISHIHARA;
Aichi Med. Univ., Aichi, Japan

Abstract: Intra-epidermal electrical stimulation (IES) can be used for selective activation of Adelta-fibers. The functional difference between Adelta and Abeta-fibers is important for clinical evaluation. The aim of this study is to investigate whether the electrode for intra-epidermal stimulation can also be used for Abeta-fibers. For nociceptive Adelta-fibers stimulation, we used three concentric bipolar needle electrodes and for tactile Abeta-fibers stimulation, we used the same electrodes for IES without needle part by standard monopolar stimulation (transcutaneous electrical stimulation: TES) at the same site. Cortical response to IES and TES to the hand and foot were measured in twelve healthy subjects and a patient with Wallenberg syndrome. TES elicited evoked potentials (N2 and P2 components) in all subjects, and IES elicited evoked potentials in all healthy subjects, however could not elicit any response in a patient with Wallenberg syndrome. Thus, this convenient method may have potential for a useful clinical tool to investigate the differences between nociceptive and tactile pathways.

Title: Anethole inhibit neuronal excitability of dorsal root ganglia neurons via voltage-dependent sodium channel blockade

Authors: L. MOREIRA-JÚNIOR[1], F. W. FERREIRA-DA-SILVA[1], K. S. SILVA-ALVES[2], V. B. CAVALCANTE[2], T. SANTOS-NASCIMENTO[2], N. M. SILVA-DOS-SANTOS[2], *J. H. CARDOSO[3];
[1]Superior Inst. of Biomed. Sci., State Univ. of Ceará, FORTALEZA, Brazil; [2]Superior Inst. of Biomed. Sci., State Univ. of Ceará, Fortaleza, Brazil; [3]Univ. Estadual do Ceara, FORTALEZA, Brazil

Abstract: Anethole is a molecule widely found in essential oils of many plants used in popular medicine. This molecule has many biological and pharmacological effects, such as anti-inflammatory, antispasmodic, skeletal muscle relaxant and blocks the compound action potential (AP) of sciatic nerve. Due to its properties, this study aims to investigate the anethole effect on the excitability of dorsal root ganglia (DRG) neurons. Wistar rats of both sexes (200-250 g) were used. For intracellular recording, we used intact DRG and passive and active properties were measured. For patch clamp experiments, DRG's were exposed to enzymatic treatment for isolation of individual neurons and electrophysiological recordings were made between 6 and 24 h after dissociation. The whole-cell voltage-clamp configuration was employed and voltage protocols (test pulse, I-V plots and steady-state Na+ current inactivation curves) were used to investigate the effect of anethole on the blockade of Na+ channels. In intact DRG, anethole inhibited action potentials within 5 min and the effect was reversible after washout. These effects were concentration-dependent and at 0.3, 0.6 and 4.0 mM anethole the percentual of neurons with full AP blocked were 0.0, 20.0 ± 6.5 and 100.0 ± 0.0 % (n = 9, for each concentration). Although anethole blocked AP's, in all neurons (with or without full AP blockade) it did not significantly changed ($p < 0.05$, ANOVA) resting potential or input resistance. Regarding dissociated DRG neurons, anethole also exhibited a concentration-dependent curve in the range of 0.1 to 20 mM and washout partially reversed anethole effects. Since 6 mM anethole promoted a blockade of 51.5 ± 5.9 % (n = 7) of control Na+ current, we performed kinetics experiments with this concentration and I-V plots were constructed in presence of control and anethole-containing solutions. The normalized conductance curves show that the V1/2 of Na+ channel activation voltage-dependence was not changed in the presence of anethole and V1/2 values in control and anethole conditions were -22.11 ± 0.2 and -18.44 ± 0.4 mV (n = 6), respectively. However, exposure to 6mM anethole significantly shifted inactivation voltage-dependence and V1/2 values were -30.4 ± 0.7 mV (n = 6) in control and -48.5 ± 0.6 mV in the presence of anethole ($p < 0.001$, n = 6). Our results demonstrate that anethole is efficient in inhibits the neuronal excitability of DRG and confirms a hypothesis that anethole possess anesthetic activity. The action mechanism is probably by a direct blockade of Na+ current with great changes in Na+ channel inactivation kinetics.

Title: Position dependent burning mouth syndrome

Authors: *P. SALARIA[1], A. R. HIRSCH[2];
[1]Aureus Univ. Sch. of Med., Fair Lawn, NJ; [2]Smell and Taste Treatment and Res. Fndn., Chicago, IL

Abstract: Introduction:
A number of sensory systems are sensitive to body position. However, no description of posture dependent Burning Mouth Syndrome (BMS) has been described. A case is reported.
Methods
Case Study: A 60-year-old right-handed female, eight years prior to presentation, noted the onset of constant burning of her mouth and tongue that worsened as the day progressed. Over a three month time period this gradually resolved. Six months prior to presentation she noted recurrence of her burning mouth. Her burning pain continued and worsened with exposure to odors including soap, perfume, the aroma of laundry, coffee, and raw onions. Her pain was made worse when she would touch her tongue to her teeth. The pain was in the center of her tongue and palate, and in the right front of the tongue. The burning worsened as the day progressed. The burning pain is constant and is a 9/10 in severity when sitting or standing. When in a supine position the BMS pain drops to a 5/10 in severity. No other change in position affects the intensity of the pain.
Results:
Chemosensory Testing: Olfaction: Brief Smell Identification Test: 9 (normosmia). Alcohol Sniff Test: 23 (normosmia). Pocket Smell Test: 3 (normosmia). Quick Smell Identification Test: 3 (normosmia). Retronasal Smell Testing: 7 (normal). Gustation: Propylthiouracil Disc Taste Test: 6 (normoguesia). Taste threshold: normogeusia to sodium chloride, hydrochloric acid, urea, and phenylthiocarbamide. Ageusia to sucrose.
Discussion:
The mechanism by which posture impacts upon burning mouth is unclear. Since lying down impairs olfactory ability (Lundstrom, 2007) and odors may exacerbate BMS (Hirsch,2005), lying down may improve BMS by functionally inhibiting olfaction and thus reducing the effect of any exacerbating odors. Alternatively, the supine position may induce a pavlovian reduction in muscle tone and associated anxiolysis. Since anxiety worsens pain, reduction of anxiety through position change may thus secondarily reduce the pain. Possibly the act of lying down is a distractor, causing the patient to focus on the position rather that the pain. Moreover, lying down

may have acted to reduce level of alertness , and if the pain was state dependent, it may act to reduce associated burning. Possibly parotid flow rate could change in the supine position, and thus cause drying of the mouth and improvement of the pain (Schneyer, 1956). Laying supine may change the firing, rate of proprioceptive nerve fibers and therefore, through Melzack and Walls Gate Control Theory of Pain, inhibit c fiber firing, resulting in a reduction in burning pain (Melzack, 1965).
Given the above, a trial of supine repose in those with BMS is warranted.

Title: Mechanisms of fractional calcium currents through trpv1 channels in primary sensory neurons.

Authors: *Z. ZHOU[1], M. HU[2], L. ZHENG[1], L. SUN[1], Y. LI[1], Q. WU[1], S. SHANG[1], T. LIU[1], Y. WANG[1], L. JIANG[3], X. ZHU[4], C. WANG[1];

Abstract: TRPV1 and TRPV2 channels are important molecular sensors on the plasma membrane in mammalian physiology (temperature) and diseases (pain) in sensory neurons. These nonselective cation channels permit Ca2+, Na+ and K+ influxes simultaneously through its pores to regulate intracellular Ca2+ homeostasis and Ca2+-dependent neural transmitter release. The Ca2+ influx can be determined by the fractional Ca2+ current (Pf) through a cation channel (Burnashev et al., 1995; Schneggenburger et al., 1993; Yu et al., 2004; Zhou and Neher, 1993). Here, we report (1) Opposite Ca2+ permeability was found as determined by the classic "Goldman-Hodgkin-Katz equation" of PCa/Na (TRPV1 = 7.6 > TRPV2 = 2.8) under non-physiological intra- and extracellular solutions(Caterina et al., 1999; Caterina et al., 1997), or by the "fractional Ca2+-current" of TRPV1 vs. TRPV2 (Pf = 5.5% vs. 22%) under physiological

solutions; (2) The selective filter "GMGX" is similar in TRPV1 and TRPV2, except "X" (X = D for TRPV1 and E for V2). In TRPV1, switching native D to E of TRPV2, Pf(V1, D646E) was greatly increased toward Pf(V2) (from 5.5% to 13%), and vice versa (from 22% to 5.0%); (3) Mutations of two sites outside of the "GMGX", reduced Pf by half; (4) In native neurons replacing TRPV1-WT (Pf = 5.5%) with TRPV1-D646E (Pf = 13%), the release mode of Ca2+-dependent single vesicle events was dramatically altered from partial (kiss-and-run) to full release as determined by TIRF-imaging, implicating a physiological relevance of Pf(TRP) studies. Taken together, TRPV1-D646 (or TRPV2-E604) is the dominant site determining fractional Ca2+-influx through thermal sensitive TRP channels—a novel mechanism of TRPV channels in presynaptic neural transmitter release for temperature and pain sensation. *Supported by grants from NSFC, MOST and DOE 2011-program*

Title: Repeated low-level blast exposure increases transient receptor potential vanilloid 1 (TRPV1) and endothelin-A (ET-A) co-expression

Authors: *E. D. POR, J.-H. CHOI, M. L. SANDOVAL, C. THOMAS-BENSON, B. J. LUND; Ocular Trauma, United States Army Inst. of Surgical Res., San Antonio, TX

Abstract: Background: Blast injuries are generally categorized as primary to quaternary and can evoke a myriad of effects on multiple body systems. Importantly, ocular injuries are the fourth most common battlefield injury, constituting approximately 13% of all combat injuries. Despite extensive research focused on the effects of blast on neurosensory function, limited data is available on the effects on pain and inflammatory processes. Recent studies conducted in our laboratory have revealed increased expression of transient receptor potential vanilloid 1 (TRPV1) and endothelin-1 (ET-1), critical mediators involved in pain transmission, in rat

corneas following single and repeated low-level blast exposure. These data indicate that TRPV1 and ET-1 may contribute to the complex pathophysiology of blast-related injuries. The overall purpose of this study was to characterize the expression of both ET-1 receptor subtypes, endothelin-A (ET-A) and endothelin-B (ET-B), in blast-exposed ocular tissues. Methods: A compressed air shock tube (Applied Research Associates, ARA) was used to deliver a single or repeated low-level blast (68.0 ± 2.7 kPa) to anesthetized rats once or daily for five consecutive days, respectively. Immunohistochemistry analysis was performed on ocular tissues collected at the conclusion of the experiments to determine co-expression of TRPV1, ET-A or ET-B following single and repeated blast exposure. Results: Increased expression of TRPV1 was observed in the rat cornea epithelial and stromal layers following exposure to both single and repeated low-level blast. Increased expression of ET-A was also detected in rat corneas as compared to control animals. Importantly, substantial co-expression of TRPV1 and ET-A was observed in rat corneas exposed to repeated low-level blast. Although modest increases in ET-B expression were observed following low-level blast exposure, these increases were unremarkable compared to ET-A. Conclusions: Single and repeated low-level blast exposure resulted in increased co-expression of TRPV1 and ET-A in the rat cornea as compared to control. These findings provide additional insight into pain signaling pathways activated following blast exposure. Further studies are required to determine if blast-related ocular injuries leads to crosstalk of these receptor systems and the potentiation of pain and inflammatory processes.

Title: Eukaryotic elongation factor 2-mediated activity-dependent inhibition of translation in mouse sensory neurons: Impact of metformin and pterostilbene

Authors: D. C. MOLLIVER[1], C. ESANCY[1], B. K. DRAGOO[1], M. A. SHAH[2], *K. E. HANLON[3], R. GEGUCHADZE[1];
[1]Biomed. Sci., Univ. of New England, Biddeford, ME; [2]Neurobio., Univ. of Pittsburgh, Pittsburgh, PA; [3]Biomed. Sci., Univ. of New England Col. of Osteo. M, Biddeford, ME

Abstract: Eukaryotic elongation factor 2 (eEF2) is a ubiquitous and essential component of the translation machinery that catalyzes translocation of the ribosome relative to the mRNA. Phosphorylation of eEF2 is inhibitory and causes a transient blockade of translation. eEF2 kinase, the only enzyme known to phosphorylate eEF2, is activated by calcium/calmodulin and modulated by several different mechanisms, including phosphorylation by AMP-activated kinase (AMP kinase), a key sensor of ATP availability. Using an antibody selective for phosphorylated eEF2 (peEF2), we examined eEF2 regulation in sensory neurons of the mouse dorsal root ganglion (DRG), with an emphasis on nociceptors. Immunohistochemistry on DRG sections revealed tonically high levels of peEF2 in a subset of primarily small-diameter neurons, including putative nociceptors positive for either TRPV1 or IB4. By comparing peEF2 with staining for eEF2 kinase we found that virtually all neurons with high levels of peEF2 staining showed robust staining for eEF2 kinase. This differential pattern of staining was maintained in DRG neurons in vitro. We then performed a series of in vitro manipulations to examine the regulation of neuronal eEF2 phosphorylation assayed by immunofluorescence densitometry. Application of 50 mM K+ for 1 or 10 minutes induced intense peEF2 staining in virtually all neurons; this staining remained elevated well above baseline 60 minutes after stimulation and was completely prevented by pre-application of a selective eEF2 kinase inhibitor, A484954 (30 micromolar). Increased staining in a subset of neurons was obtained with agonists for Gq-coupled purinergic receptors P2Y1 and P2Y2, suggesting that both depolarization-evoked calcium influx and release of calcium from intracellular stores were sufficient to activate eEF2 kinase. Next we examined the impact of AMP kinase activation on eEF2. Metformin, a widely-used medication for type 2 diabetes that has been suggested as a treatment for neuropathy, acts in part through activation of AMP kinase. Pterostilbene, a structurally unrelated compound found in almonds and blueberries that is chemically related to resveratrol, has also been reported to activate AMP kinase. Pterostilbene is of particular clinical interest because it is widely available and commonly mentioned on patient peer support websites as an alternative to metformin for patients whose doctors choose not to prescribe metformin. Both drugs increased basal peEF2 levels but blunted peak levels induced by high potassium. Our results suggest that ingestion of these drugs alters baseline translation levels and ATP expenditure in DRG neurons.

Title: Modulation of TRPA1 activation by AMP activated protein kinase

Authors: *S. WANG[1,2], K. KOBAYASHI[3], H. YAMANAKA[3], S. YAMAMOTO[1], Y. KOGURE[1], K. NOGUCHI[3], Y. DAI[1,2,3];
[1]Dept. of Pharm., Hyogo Univ. of Hlth. Sci., Kobe,Hyogo, Japan; [2]Traditional Med. Res. Ctr., Chinese Med. Confucius Inst. at Hyogo Col. of Med., Kobe, Hyogo, Japan; [3]Dept. of Anat. and Neurosci., Hyogo Col. of Med., Kobe, Hyogo, Japan

Abstract: Transient receptor potential ankyrin 1 (TRPA1) is an important molecule for pain modulation and transduction. TRPA1 is expressed in sensory neuron and activated by multi-stimuli, including pungent irritants, cold temperature and some inflammatory mediators. AMP activated protein kinase (AMPK), is a widely distributed highly conserved sensor which response to metabolic stress in various tissues. In addition, AMPK has been considered to be involved in the regulation of inflammatory or neuropathic pain. It has been reported that phosphorylation of AMPK suppressed inflammatory and neuropathic pain both in acute and chronic phase. In this study, we investigated the possible interaction of TRPA1 and AMPK. Modulation and interaction of TRPA1 and AMPK were examined by western blot, whole cell patch clamp electrophysiology and behavioral analysis. We conformed that short-term treatment of AMPK activator, metformin, induced the phosphorylation of AMPK by western blot. The treatment of metformin and another well-known AMPK activator 5-aminoimidazole-4-carboxamide-1-beta-d-ribofuranoside (AICAR) inhibited allyl isothiocyanate (AITC)-induced TRPA1 currents in DRG neurons. In behavioral study, pretreatment of metformin suppressed AITC-evoked paw lifting in rats. Therefore, AMPK activation may alleviate pain through inhibiting TRPA1 activity. Our observations indicate that AMPK play a crucial roles not only in energetic metabolism sensor but also in a modulator for sensory functions.

Title: Evaluation of sensory function and thermal pain withdrawal reflexes in MEIS1 knockout mice, a possible animal model for Restless Legs Syndrome (RLS)

Authors: S. MENEELY[1], M.-L. DINKINS[1], Y. LI[3], *S. CLEMENS[2];
[2]Physiol., [1]East Carolina Univ., Greenville, NC; [3]Neurol., Univ. of Florida, Gainesville, FL

Abstract: Restless Legs Syndrome (RLS) is a chronic sensorimotor disorder characterized by uncomfortable sensation and a strong urge to move the legs. Symptoms occur most often in the evening or at night and can severely disrupt sleep. Genome-Wide Association studies (GWAS) point to a role of genetic factors surrounding the MEIS1 (MEIS homeobox 1) gene, which plays a role during neural development. RLS patients show a reduced mRNA and protein expression of MEIS1. Currently, the first line of drug therapy for RLS uses dopaminergic agents, but no behavioral data are available that have assessed thermal pain withdrawal latencies in the MEIS1 knockout (MEIS1 KO) animal model, or their modulation by dopaminergics. Here, we compared pain responses (tail-flick and Hargreaves) in MEIS1 KO mice and their appropriate wild type controls (WT). Animals were i.p. injected with either sham (control), levodopa (L-dopa, 10 mg/kg), pramipexole (a D3R agonist, 0.5 mg/kg), SKF 38393 (D1R agonist, 1 mg/kg), SCH 39166 (D1R antagonist, 0.1 mg/kg), or morphine (2 mg/kg). Following the behavioral experiments, spinal cords were harvested and processed for detection of D1R expression (abcam 78021). Under baseline conditions, thermal withdrawal latencies were similar between WT and MEIS1 KO animals in both Hargreaves and tail-flick conditions. L-dopa, pramipexole and morphine significantly increased withdrawal reflexes in both WT and MEIS1 KO, while block of the D1R pathway increased thermal reflexes significantly in MEIS1 KO only. Further, preliminary WB analyses suggest an up-regulation of spinal D1R expression levels over that of WT animals.
Together, the data from this behavioral study indicate that sensory responsiveness in MEIS1 KO animals is largely unaltered over WT controls, with the possible exception of D1R-mediated responses. As D1R pathways in the spinal cord are predominantly associated with motor functions, our data suggest that the MEIS1 gene may only play a minor functional role in the sensory dysfunctions observed in RLS patients, but rather be associated with the associated motor symptoms and Periodic Leg Movements (PLMs).

Title: Characterization of behavioral and histopathological changes in a mia model of osteoarthritis of the rat ankle joint

Authors: *V. BOURASSA[1], A. RIBEIRO-DA-SILVA[2];
[1]Dept. of Pharmacol. and Therapeut., [2]McGill Univ., Montreal, QC, Canada

Abstract: Osteoarthritis (OA) is a complex disease of the whole joint, resulting in pain and disability, and in humans is more frequent in the knee, ankle, hip and shoulder joints. To this day, there is no satisfying method of relieving osteoarthritic pain, which affects over 27 million American adults. Mechanisms of OA pain have been studied in the rat knee joint by intra-articular injections of the chondrocyte glycolytic inhibitor Mono-Iodoacetate (MIA). MIA-induced pain indicates that this method is clinically relevant and will continue to be useful for the development of better therapeutic strategies. However, most measures that confirm the pain behavior in the osteoarthritic knee joint do so by applying mechanical and thermal stimulus to the paw, an area remote from the knee joint. We suspect that this practice detects secondary hyperalgesia, which is due to sensitization of neurons in the central nervous system (CNS) rather than the local release of inflammatory mediators. The present study characterizes the behavioral changes and histopathological changes of cartilage necrosis and degeneration that occur in a new model of MIA-induced OA in the rat ankle joint, which we believe will more closely replicate the clinical symptoms of the human disease. In this characterization experiment, we determined that a dose of 2.4 mg of MIA in 40 µl of saline administered via intra-articular injection in the right ankle joint generated significant mechanical hypersensitivity starting at 4 weeks post-injection as detected by Von Frey filaments. Mechanical hypersensitivity was accompanied by cold allodynia starting at 5 weeks post-injection as tested by the Acetone Test. Cold allodynia had not been previously reported in the rat osteoarthritic knee joint. Safranin histological staining showed significant cartilage loss matching the pathologic features of the clinical disease, best shown at a dose of 2.4 mg of MIA in 40 µl saline. X-ray microtomography scans (micro CT) of the ankle joint were performed to confirm that bone fragmentation and remodeling associated with the clinical disease are replicated in our osteoarthritis ankle joint model. The present study showed sensitization of the joint, as measured by Von Frey filaments and acetone direct application to the affected osteoarthritic ankle joint. We are confident that these measures are detecting primary hyperalgesia, and predict that the proposed model will more closely replicate

the clinical symptoms than the existing knee joint model, as cold pain is often reported in human patients.

Title: Increased susceptibility to cortical spreading depression and epilepsy in a mouse model for familial hemiplegic migraine type 2

Authors: *L. KROS[1], K. LYKKE-HARTMANN[2], K. KHODAKHAH[1];
[1]Neurosci., Albert Einstein Col. of Med., Bronx, NY; [2]Aarhus Univ., Aarhus, Denmark

Abstract: Migraine is a highly prevalent, debilitating, episodic headache disorder affecting roughly 15% of the population. A rare subtype of this disorder is familial hemiplegic migraine (FHM), a hereditary form of migraine characterized by the occurrence of an aura with hemiplegia prior to attack onset. FHM2 is one of three forms of FHM, in most cases caused by a mutation in the *ATP1A2* gene encoding the α_2-isoform of the Na^+/K^+-ATPase, predominantly found in astrocytes. Comorbidity of this rare type of migraine with aura has been shown with epilepsy and psychiatric disorders like depression and OCD in patients. The neurobiological process underlying the aura is thought to be cortical spreading depression (CSD); a wave of initial excitation followed by prolonged inhibition that slowly propagates over the cerebral cortex. Here we aim to unravel whether a mouse model of FHM2 harboring the G301R mutation ($\alpha_2^{+/G301R}$ mice), a mutation found in two families and causing a particularly severe phenotype, shows an increased susceptibility for cortical spreading depression and a decreased threshold for epileptic seizures. In order to answer these questions, we performed experiments in awake head restrained mice using both $\alpha_2^{+/G301R}$ mice and wild type littermates. We used both electrical stimulation and cortical application of a KCl solution to determine differences in CSD threshold and CSD frequency respectively. Our preliminary results show that the mutants indeed show a decreased threshold for CSDs induced by electrical stimulation and a greatly increased CSD frequency following KCl application. Interestingly, the KCl concentration used (300 mM) consistently resulted in severe tonic-clonic epileptic activity in mutant mice whereas this never occurred in wild type littermates. In combination with previous showing depression and OCD-like behavior in the $\alpha_2^{+/G301R}$ mice, these findings suggest that this mouse model closely

resembles the phenotype found in patients with this mutation and can be utilized to study the neuropathology underlying migraine disorders.

Title: Subcortical volume across development in male migraineurs

Authors: *A. LUDWICK[1], S. L. WILCOX[1], A. LEBEL[1], R. BURSTEIN[2], L. BECERRA[1], D. BORSOOK[1];
[1]Dept. of Anesthesia, Perioperative and Pain Med., Boston Children's Hosp., Waltham, MA;
[2]Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract: Background: Migraine is the second commonest cause of headache in children, affecting approximately 3.2-14.5% of children, often resulting in an alteration of daily activities and school absences. In young children with migraine, the ratio of males to females is approximately equal. However, in adolescence the incidence increases in females while that of males is unaltered, suggesting a female–specific pubertal effect on migraine development. We previously reported unique structural brain differences in pediatric female migraineurs, compared to male migraineurs and healthy controls. Furthermore these differences varied depending on development status (i.e. early vs. mid puberty) (Faria et al, 2015). Here we sought to compare structural brain changes in male migraineurs during development, from childhood to young adult, compared to healthy male controls.
Methods: *Participants*: 21 migraine patients and 21 controls (ages 7 – 26) were enrolled in the study at Boston Children's Hospital. Participants were scanned while headache-free (migraineurs were scanned interictally with no headache ± 48 hours). *Image Acquisition*: 3D T1 anatomical images were acquired from all participants on the same 3T Trio MRI scanner [TR: 2520ms, TE: 1.74ms, FOV: 220x220, slice thickness: 1mm]. *Image Processing*: Subcortical volumes were estimated using FSL's *Integrated Registration and Segmentation Tool (FIRST)*. Group-wise differences were calculated using a two-sample t-test, while differences across ages were examined using a univariate ANOVA.
Results: The normalized volume of the left and right caudate, putamen, pallidum, and

accumbens were calculated for both groups. No significant differences were seen between migraineurs and controls in any regions examined. Additionally, there were no significant differences within the migraine cohort across age brackets (pre/early puberty [8-11] vs. mid/late puberty [12-17] vs. young adult [18-26]).
Discussion: Faria et al. previously showed greater volume in a number of subcortical regions in females migraineurs compared to males and healthy controls, as well as age-related differences within female migraineurs (2015). In stark contrast to changes previously noted in female migraineurs, the present study shows no significant differences in subcortical volume in both male migraineurs vs. controls and across the developmental stages. These results suggest that the relationship between pubertal status, subcortical volume and migraine may be unique to females.

Title: Whisker stimulation can induce cortical spreading depression in pharmacologically primed mouse brain

Authors: *S. HANALIOGLU[1,2], A. TASKIRAN-SAG[2], H. KARATAS[2], E. EREN-KOCAK[2], M. YEMISCI[2], Y. GURSOY-OZDEMIR[3], T. DALKARA[2];
[1]Dept. of Neurosurg., [2]Inst. of Neurolog. Sci. and Psychiatry, Hacettepe Univ., Ankara, Turkey; [3]Dept. of Neurol., Koc Univ., Ankara, Turkey

Abstract: Aims: Cortical spreading depression (CSD) is regarded as the neurophysiological phenomenon underlying migraine aura and a potential triggering event leading to migraine headache. However, it is still unclear how CSD is triggered in a healthy brain given that almost all experimental animal models require injurious stimuli to the brain to generate CSD. In this study, we have tested whether CSD could be triggered by intense whisker stimulation in the mouse barrel cortex following pharmacological sensitization with partial blockage of Na^+-K^+-ATPase. **Methods:** Thirteen Swiss albino mice were anesthetized with urethane and underwent

2x2 mm craniectomy over the somatosensory barrel cortex. A low dose of Na^+-K^+-ATPase blocker ouabain was topically applied to dura over the barrel cortex to make it susceptible to CSD. Thirty minutes after the CSD (or after the last CSD if multiple CSDs observed; i.e. silent phase) contralateral whiskers were deflected continuously with a custom-made stimulator (6-12 Hz; up to 5 minutes). If no CSD occurred, whisker stimulation cycles were repeated at 10 minutes intervals for a total of 90 minutes. CSD incidences in stimulated and non-stimulated control animals were compared using a probabilistic approach. **Results:** Topical epidural application of 0.1 mM ouabain (3-5 uL) was found to induce a single CSD an average of 46,3±4,4 min after the topical application in 38% of the experiments. The average spontaneous CSD incidence was 2.4% within any 5 min period following 30-min silent phase (after the last CSD) in non-stimulated mice. However, whisker stimulation triggered a CSD 14% of the time ($p=0.026$), and this incidence was increased up to 26% if miniature CSDs were also taken into account ($p<0.001$). In total, 7 CSDs were encountered in 38.5% (n=5) of the stimulated mice, whereas 6 mini-CSDs were observed in 30.8% (n=4) of them. Average time lag between stimulation initiation and CSD occurrence was found 2,8±0.6 min. **Conclusion:** These findings show that CSD can be triggered in the susceptible mouse barrel cortex with whisker stimulation. This study, together with recent literature showing that sensory cortices are intrinsically more susceptible to CSD induction, lends further support to the CSD-migraine hypothesis and suggest that sensory stimuli or other triggering factors may be sufficient to initiate a CSD in susceptible migraineur brain.

Title: Nicotinamide riboside: a novel approach to treating peripheral neuropathy induced by paclitaxel

Authors: *M. V. HAMITY[1], S. R. WHITE[2], R. Y. WALDER[2], M. S. SCHMIDT[3], C. M. BRENNER[3], D. L. HAMMOND[2];
[1]Anesthesia, Univ. of Iowa Dept. of Anesthesia, Iowa City, IA; [2]Anesthesia, [3]Biochem., Univ. of Iowa, Iowa City, IA

Abstract: Nicotinamide riboside (NR) is a naturally occurring precursor of NAD^+. Agents that increase levels of NAD^+ can prevent or ameliorate degeneration following axonal transection. As axonal injury is thought to underlie the peripheral neuropathy that develops with several classes of chemotherapeutic drugs, we hypothesized that administration of NR would prevent or ameliorate chemotherapy-induced peripheral neuropathy (CIPN) induced by paclitaxel. To test this idea, adult female Sprague-Dawley rats were injected intravenously with paclitaxel (19.8 mg/kg) or an equivalent volume of its vehicle. This dose of paclitaxel and route of administration more closely mirrors clinical use. NR (200 mg/kg) or vehicle was administered orally once daily in either a prophylactic (7 days prior to the start of paclitaxel or vehicle and continuing for another 21 days) or a therapeutic paradigm (beginning day 14 after paclitaxel and continuing for 3 weeks). Tactile sensitivity and escape-avoidance behaviors were assessed before and at several time-points after the start of paclitaxel treatment. The effect of prophylactic treatment with 100 mg/kg acetyl-L-carnitine (ALC), for which there is substantial preclinical data of efficacy, was also assessed. In our hands, prophylactic administration of ALC failed to prevent or alleviate tactile hypersensitivity and escape-avoidance behaviors in paclitaxel-treated rats. Our findings align with the negative findings of a recent large clinical trial with ALC. In contrast, daily treatment with 200 mg/kg NR, which increased blood levels of NAD^+ by 50%, prevented the development of tactile hypersensitivity and significantly blunted escape-avoidance behaviors in paclitaxel-treated rats. The beneficial effect of NR was sustained for at least 2 weeks after treatment with NR had ceased. In the therapeutic paradigm, daily administration of NR starting14 days after the first dose of paclitaxel, a time at which CIPN was clearly established, ameliorated tactile hypersensitivity in at least in 50% of the animals and significantly blunted escape-avoidance behaviors in nearly all paclitaxel-treated rats. These results establish that NR can effectively prevent the development and ameliorate the severity of peripheral neuropathy in a rat model of CIPN, and that further mechanistic studies are warranted. Furthermore, to the best of our knowledge, this study is the first to demonstrate the ability of an agent to alleviate the aversive components of CIPN in a rodent model. Because NR is already available for human use, clinical application of our results can be greatly accelerated.

Title: Relating spinal cord stimulation to the recruitment and modulation of sensory signaling in the isolated *In vitro* adult mouse spinal cord.

Authors: *S. IDLETT[1,3], M. HALDER[2], M. SAWCHUK[2], J. QUEVEDO[4], W. GU[5], M. MOFFITT[5], S. HOCHMAN[2,3];
[2]Physiol., [1]Emory Univ., Atlanta, GA; [3]Biomed. Engin., Georgia Inst. of Technol., Atlanta, GA; [4]Fisiologıa, Biofisica y Neurociencias, Ctr. de Investigacion y de Estudios Avanzados del Inst. Politecnico Nacional, Mexico, D.F., Mexico; [5]Boston Scientific, Valencia, CA

Abstract: Epidural electrodes are used for spinal cord stimulation (SCS)-based management of neuropathic pain, with over 50,000 spinal cord stimulators implanted yearly. Pain is always a subjective experience, and the sensory qualia surrounding neuropathic pain is particularly complex. This is consistent with reported variability in patient-preferred SCS stimulus delivery patterns, therapeutic efficacy and induced dysesthesias. Currently our understanding of mechanisms producing SCS-analgesia is limited, but multiple pain processing and control systems are theoretically amenable to modulation by SCS.
In vivo electrophysiological studies in animal models support invasive mechanistic inquiry into SCS-analgesia, but the use of anesthetics may fundamentally alter the intrinsic properties of nociceptive circuits and their supraspinal control. We used an adult *in vitro* mouse spinal cord preparation to study the effects of SCS on the isolated spinal cord. This approach affords complete access to the spinal neuraxis involved in somatosensory processing, and has demonstrated viability for up to 8 hours following cord isolation. Glass suction electrodes were placed on various dorsal roots (DRs), on Lissauer's tract, and at multiple locations on or above the dorsal column (DC). A microelectrode recorded population synaptic responses in the superficial dorsal horn (laminae I-III).
We compared evoked responses to different stimulus durations, magnitudes, polarities, and frequencies. Observations include the following: (1) DC stimulation - (a) antidromically recruits afferent fibers in multiple segmental dorsal roots, (b) and can generate synaptically-evoked slower dorsal root potentials (DRPs; a measure of primary afferent depolarization-induced presynaptic inhibition), (c) directly recruits and modulates activity in Lissauer's tract and, (d) evokes convergent population synaptic responses in dorsal horn neurons that depress or facilitate synaptic responses to DR stimulation. (2) DR afferent-evoked responses in Lissauer's tract were

preferentially blocked with SCS at 50Hz—a frequency commonly used in clinical settings. (3) Stimuli applied at various distances above the DC were sensitive to stimulus polarity and directly recruited axons in DC, DR and Lissauer's tract.
In sum, findings implicate largely ignored mechanisms of afferent presynaptic inhibition and modulation of activity in Lissauer's tract as possible contributors to SCS-analgesia.

Title: Activation and conduction block of dorsal column axons by kilohertz-frequency spinal cord stimulation

Authors: *N. D. CROSBY[1], J. J. JANIK[2], W. M. GRILL[1];
[1]Biomed. Engin., Duke Univ., Durham, NC; [2]Stryker Corp., Kalamazoo, MI

Abstract: Spinal cord stimulation (SCS) with high frequency pulse trains (~10 kHz) has emerged as a potential treatment for chronic pain. However, the effects of kilohertz-frequency SCS (KHF-SCS) on spinal dorsal column (DC) axons and its mechanisms of action remain unknown. The objectives of this work were to quantify activation and possible conduction block of DC axons by KHF-SCS across a range of kHz frequencies and waveforms. Male Sprague-Dawley rats were anesthetized with urethane (1.2 g/kg) and the spinal cord was exposed at T10-T12. A custom platinum electrode was inserted epidurally at T10 to deliver bipolar constant-current SCS at different kHz frequencies (1, 5, 10, or 20 kHz) and waveforms (train of biphasic 24 μs per phase pulses or sinusoid). A second electrode at the cervical spinal cord evoked antidromic action potentials to identify projecting DC axons. Single unit activity was recorded with a microelectrode at T12 during 30-second trials of SCS over a range of amplitudes (0.2 mA to 6 mA). KHF-SCS evoked a range of responses in DC axons including brief onset firing, slowly accommodating persistent firing, and conduction block. A majority of activation and block responses occurred well above motor thresholds, but isolated units were activated and/or

blocked within the range of SCS amplitudes documented previously to reduce behavioral sensitivity in the rat. The patterns of SCS-evoked axonal firing were similar across kHz frequencies, although 1 kHz SCS more frequently evoked axonal firing than 5-20 kHz SCS, especially at amplitudes above motor threshold. Sinusoidal SCS delivered 1.32-times more charge per phase than the biphasic pulse train of the same amplitude. Activation and block thresholds were 1.51±0.64 (p=0.19) and 1.42±0.46 (p=0.47) times higher for the biphasic pulse train, suggesting that sinusoidal and biphasic SCS patterns similarly affected DC axons when charge delivery was equalized. The similarities between DC axonal responses to SCS across kHz frequencies are consistent with previous reports that 1 kHz and 10 kHz SCS attenuated behavioral sensitivity equally well in rat models of neuropathic pain. By demonstrating the similar effects of biphasic pulse trains and sinusoidal SCS, this work also provides a link to other bodies of literature (i.e., peripheral nerve stimulation) that have extensively reported on sinusoidal kHz stimulation, to aid in our understanding of the mechanisms of KHF-SCS. Ultimately, by establishing thresholds for fiber activation and block in the rat dorsal columns, this work lays the foundation for further in vivo investigation of the comprehensive mechanisms underlying the pain-relieving effects of KHF-SCS.

Title: The nNOS-NOS1AP protein-protein interface is an analgesic target

Authors: ***W.-H. LEE**[1], Y. LAI[2], M. COURTNEY[3], A. HOHMANN[2];
[1]Interdisciplinary Biochem. Grad. Program, [2]Indiana Univ. Bloomington Dept. of Psychological

and Brain Sci., Bloomington, IN; [3]Turku Ctr. for Biotech., Univ. of Turku and Åbo Akademy Univ., Turku, Finland

Abstract: Elevated NMDAR activity is linked to central sensitization and chronic pain. However, NMDAR antagonists have limited therapeutic potential due to adverse side effects associated with the widespread role of NMDARs in physiological functions. Disruption of protein-protein interactions downstream of NMDAR shows therapeutic potential in several disease states. Specifically, interactions between the scaffolding protein postsynaptic density 95 kDA (PSD95), and both upstream (eg. NR2B-PSD95) and downstream (e.g. PSD95-nNOS interactions) protein partners produces antinociception. However, nNOS not only interacts with PSD95 but also interacts with its adaptor protein, NOS1AP. This interaction is believed to recruit MKK3, an activator of p38MAPK, a MAP kinase known to be activated in pathological pain states. However, whether nNOS-NOS1AP protein-protein interactions are involved in pronociceptive signaling remains unknown and whether disrupting this interaction produces antinociception has not previously been evaluated. We used an AlphaScreen assay to quantify potency and efficacy of TAT-GESV, a putative peptide inhibitor of the nNOS-NOS1AP complex, in disrupting binding between purified nNOS and NOS1AP proteins *in vitro*. We also characterized the specificity of nNOS-NOS1AP disruption by examining ability of TAT-GESV to disrupt binding of PSD95-nNOS protein pairs. TAT-GESV inhibited nNOS-NOS1AP binding without altering binding of PSD95 to nNOS. These observations suggest that TAT-GESV specifically disrupts nNOS-NOS1AP interactions but not other classes of PDZ-PDZ interactions. We also verified that NMDAR-dependent p38MAPK activation could be blocked by TAT-GESV and the efficacy is comparable to the NMDAR antagonist MK-801 using primary cortical neuronal cultures. Finally, we used models of traumatic nerve injury and chemotherapy-induced peripheral neuropathy to evaluate whether nNOS-NOS1AP disruption suppressed neuropathic pain. Intrathecal administration of TAT-GESV suppressed mechanical and cold allodynia induced by either partial sciatic nerve ligation or the chemotherapeutic agent paclitaxel in mice. By contrast, the control peptide, TAT-GES, failed to alter mechanical or cold allodynia in either model. Finally, motor ataxic effects were not observed in TAT-GESV-injected animals. Our results demonstrate for the first time that nNOS-NOS1AP protein-protein interactions are involved in pain signaling and also suggest that blocking this interaction may be a viable analgesic strategy that circumvents unwanted side effects of NMDAR antagonists.

Title: Dissecting the mechanisms by which dietary polyphenols may modulate lower back pain

Authors: *S. TIANO[1], L. HO[1,2,4], A. LAI[3], J. IATRIDIS[3], G. M. PASINETTI[1,2,4];
[1]Dept. of Neurol., [2]Dietary Supplement Res. Ctr., [3]Leni & Peter W May Dept. of Orthopedics, Icahn Sch. of Med. at Mount Sinai, New York, NY; [4]Geriatric Research, Educ. and Clin. Ctr., James J. Peters Veterans Affairs Med. Ctr., Bronx, NY

Abstract: Lower back pain (LBP) is a common and debilitating musculoskeletal disorder, but unfortunately, chronic LBP is often resistant to treatments. The most common cause of LBP is degeneration of intervertebral disks (IVDs) that serve to separate the vertebrae and allow for spinal motion. Key contributory pathogenic characteristics underlying discogenic LBP are IVD inflammation and structural destabilization, as well as in-growth of sensory nerves that leads to hypernociception. Based on evidence suggesting benefits of dietary polyphenols in modulating diverse medical conditions, we explored the potential of developing dietary polyphenols for treating discogenic LBP. Excitedly, we observed that dietary supplementation with a select Bioactive Polyphenol-rich Dietary Preparation (BDPP) significantly reduced hypernociceptive responses in a rat model of painful disc degeneration. The majority of orally consumed polyphenols is extensively metabolized during gastrointestinal absorption and/or post-absorptive xenobiotic metabolism and is typically accumulated in target tissues as phenolic metabolite forms. We identified 30 phenolic metabolites that are biologically available following oral BDPP administration. To gather a better understanding of how BDPP may mechanistically modulate pain associated with disc degeneration, we investigated individual phenolic metabolites for their efficacy in modulating discogenic pathogenic mechanisms using primary cell cultures generated from either nucleus pulposus (NP) or annulus fibrosus (AF), which are the two major IVD structural-functional units. In initial studies, we tested the effects of phenolic metabolites in modulating TNFα-mediated induction of key genes known to associate with IVD inflammation, extracellular matrix degradation and neuron ingrowth. We identified multiple biologically available phenolic metabolites that protected against the induction of many targeted genes. Moreover, we found two biologically available phenolic metabolites that significantly interfere with mechanisms associated with IVD destabilization, IVD inflammation and IVD abnormal sensory nerve in-growth. Ongoing investigations are exploring bioactivities of individual biologically available phenolic metabolites in primary AF cell cultures. Outcomes from our investigation support further preclinical (and eventually clinical) development of polyphenols, in either dietary or pharmacologic applications, to simultaneously target multiple pathologic mechanisms underlying IVD degeneration and pain, which would improve the likelihood of therapeutic efficacy for treating discogenic LBP.

Title: Non-invasive transcranial focal electrical stimulation induced analgesic effects.

Authors: *W. G. BESIO[1], A. ROSILLO-DE LA TORRE[2], L. L. ROCHA-ARRIETA[2];
[1]Electrical Computer and Biomed. Engin. Dept., Univ. of Rhode Island, Kingston, RI;
[2]CINVESTAV, Mexico City, Mexico

Abstract: Prior studies had shown that deep brain stimulation reduces responsiveness to pain. Previously we demonstrated that the non-invasive transcranial focal electrical stimulation (TFS) applied via tripolar concentric ring electrodes (TCREs) modified the release of GABA and glutamate. We further hypothesized that TFS modified the release of opioid peptides inducing analgesic effects. The main goal of the present study was to evaluate the analgesic effect of the non-invasive TFS applied via TCREs. We shaved the head of male Swiss-Webster mice weighting 25-30 g and daily habituated them to the manipulation during 5 days. One day after the last habituation, the TCREs of 6.0 mm diameter were positioned on the shaved scalp centered on the top of the head. Ten-20 electrode paste was used for skin-to-electrode impedance matching. TFS was applied through the outer ring (external diameter of 6.0 mm) to the central disc that consisted of 200 μs symmetrical biphasic square charge-balanced constant current pulses at 10 Hz and 50 mA for 2 min. Thereafter, animals were submitted to Haffner's tail clip test 5 (TFS-5 group, n=7), 15 (TFS-15 group, n=12), 30 (TFS-30 group, n=7) or 45 min (TFS-45 group, n=7) after the TFS. For each period of time, a control group (with the same number of animals of their respective TFS group) was manipulated as described above, except that TFS was not applied. The latency to the first attempt to remove the noxious stimulus for the tail was recorded. The control groups showed the following latencies: 3.14 ± 0.40, 3.25 ± 0.35, 2.85 ± 0.50 and 3.28 ± 0.47 sec, respectively. TFS produced an increase in latencies (5 min 50%, $p<0.05$; 15 min 78%, $p<0.0005$; 30 min 75 %, $p<0.02$; 45 min, 0 %, $p>0.05$). In order to determine if opioid peptides caused the analgesic effect induced by TFS, we carried out an additional experimental group pretreated with naloxone (10 mg/kg, i.p., n=9) 15 min before TFS. Our results revealed that naloxone prevented the TFS-induced analgesic effect in this experimental group (0%, $p>0.05$). The results of the present study demonstrate that the non-invasive TFS induces analgesic effects are mediated by opiate peptides. Further experiments are necessary to investigate the mechanisms by which TFS is able to activate endogenous opioid peptides.

Title: The stress regulator FKBP51 drives chronic pain by modulating spinal glucocorticoids signalling

Authors: ***M. MAIARU**[1], K. K. TOCHIKI[1], M. B. COX[2], X. FENG[3], F. HAUSCH[3], S. M. GERANTON[1];
[1]Cell and Developmental Biol., Univ. Col. London, London, United Kingdom; [2]Dept. of Biol. Sci., Border Biomed. Res. Ctr., University of Texas, TX; [3]Max Planck Inst. of Psychiatry, Munich, Germany

Abstract: Evidence suggests that dynamic pattern of gene expression are important for the development of chronic pain states. We have previously shown that increase in expression of the gene *FKBP5*, an important regulator of the glucocorticoids receptor sensitivity, happened in the spinal cord in the early stages of ankle joint inflammation. While polymorphisms in *FKBP5* are consistently associated with stress-related mood disorders, variants in *FKBP5* influence the severity of pain symptoms experienced after trauma suggesting that FKBP51 could play a role in the development of chronic pain states. The aim of this project was to investigate the role of FKBP51 on pain processing.
We used a behavioural and molecular approach. We compared nociceptive behaviour in FKBP5 knock out (KO) and wild type (WT) mice and in mice that received (1) FKBP51 siRNA intrathecally or vehicle and (2) the FKBP51 antagonist SAFit2 (gift from Felix Hausch, MPI) or vehicle. Behaviour was measured in both acute and long-term pain states, including models of inflammatory and neuropathic pain. To assess mechanical sensitivity, Von Frey's filaments were used. To explore the molecular effects of FKBP51 deletion, we used RTqPCR, measured blood corticosterone levels and measured the behavioural effects of the GR antagonist mifepristone (Sigma) administered intrathecally in and KO mice.
Global deletion of FKBP51 did not affect acute nociception. However, FKBP51 KO mice, as well as mice that received FKBP51 siRNA intrathecally, showed reduced hypersensitivity in a number of chronic pain models. Crucially, the intrathecal injection of the specific FKBP51

inhibitor, SAFit2, also reduced the severity of established pain states. Furthermore, motor functions were improved after SNI both in KO and in mice that received SAFit2 compared with WT and vehicle treated mice, respectively. Finally, KO mice had lower corticosterone levels than WT mice, in naïve and in persistent pain states, and showed impaired glucocorticoid signalling.
In conclusion, our study showed that FKBP51 regulates chronic pain by modulating glucocorticoid signalling and is a suitable target for the treatment of long-term pain states, opening the way for the development of new therapeutic strategies.

Title: Electroacupuncture at st36 acupoint ameliorates reserpine-induced depression and pain in mice

Authors: D.-W. KANG, J.-G. CHOI, J.-W. CHOI, J. PARK, *H.-W. KIM;
Dept. of Physiol. and Med. Science, Brain Res. Inst., Col. of Medicine, Chungnam Natl. Univ., Daejeon, Korea, Republic of

Abstract: We designed this study to investigate curative effect and related neuronal mechanism of electroacupuncture (EA) on the reserpine-induced depression and pain in mice. Reserpine (1 mg/kg) was administered subcutaneously once a day for 3 consecutive days to induce depression-like behavior and pain. EA stimulation (2 mA, 2 Hz, 30 min) was applied into the bilateral ST36 acupoints once daily for 5 days and von-Frey filament test, forced swimming test and open field test were performed. In order to determine the neuronal mechanism of EA, changes of hippocampal brain derived neurotrophic factor (BDNF) and vesicular monoamine transporter (VMAT) were examined by western blot analysis. Repeated EA stimulation significantly attenuated reserpine-induced mechanical allodynia. Additionally, increased

immobility time of forced swimming test and reduced moving distance in open field test were recovered to the normal control level. In conclusion, results of this study suggested that the EA may be a good candidate to treat patients who have both depression and pain.

Title: Neurobiological mechanisms of electroacupuncture inhibiting chronification of acute pain by endocannabinoid system

Authors: *X. YUAN[1], C. WU[2], H. LI[2], F. GAO[2], M. LI[2];
[1]Dept. of Neurobio., Huazhong Univ. of Sci. and Technol., Hubei, China; [2]Dept. of Neurobio., Huazhong Univ. of Sci. and Technol., Wuhan, China

Abstract: Electroacupuncture(EA) has significant effect on acute pain for a long time, but it hasn't solved the clinical problem of long-term recurrent of pain after chronification of acute pain. Diffuse injury inhibitory controls (DNIC) refers to when noxious stimuli apply on a particular region of the body, the analgesic effect can be observed in any other region. It is now recognized as a reliable indicator to predict chronic pain events risk. In the present study, we determined whether EA can reverse impaired DNIC function of KOA during the process of chronification of acute pain and screen for the best EA frequency and intensity. Then we introduce of a variety of cannabinoid receptor knockout mice, to determine whether endocannabinoids CB1 or CB2R are involved in the mechanism underlying EA repairing DNIC function and inhibiting chronification of acute pain. In this study, we found that EA at 2Hz +1 mA has the best effect on improving thermal hyperalgesia and mechanical allodynia and DNIC function of KOA mice, so we chose 2Hz +1 mA EA as the best EA frequency and intensity. We also found that knock out CB2R has no effect on DNIC function, but knockout of CB1R reversed both ananlgesic effect of EA on thermal hyperalgesia and mechanical allodylia and the improving effect of EA on DNIC function of KOA. Our data suggest that EA can enhance the function of endogenous cannabinoid system, and endocannabinoids CB1R rather than CB2R is involved in the mechanism underlying EA repairing DNIC function and inhibiting chronification

of acute pain. Our study also provided a new theoretical basis and therapeutic strategies for clinical applications of EA treating chronification of acute pain.

Title: Improving blood-brain barrier penetration to convert neurotensin bioactive peptides into painkillers

Authors: ***J. COTE**[1], É. BESSERER-OFFROY[1], A. MURZA[1], K. BELLEVILLE[1], É. EISELT[1], A. LAROCQUE[2], A. REGINA[2], J.-M. LONGPRÉ[1], M. DEMEULE[2], P. SARRET[1]; [1]Pharmacol. - Physiol., Univ. de Sherbrooke (FMSS), Sherbrooke, QC, Canada; [2]Angiochem Inc., Montreal, QC, Canada

Abstract: Today, the most important impediment to translating bioactive peptides into effective neurotherapies relies on their inability to bypass the blood-brain barrier (BBB), which shields the central nervous system from potential harmful substances. Among these viable peptide pharmaceuticals, the neurotensin (NT) peptide, which exerts its biological effects by interacting with two distinct G protein-coupled receptors termed as NTS1 and NTS2, has emerged as a promising non-opioid pain target. However, because NT and its minimal biologically active C-terminal hexapeptide fragment (NT[8-13]) have a very short *in vivo* half-life and penetrate only poorly through the BBB, their use as therapeutics remains limited to central injections, thus with weak clinical outcomes. As a result, strategies improving NT peptide brain uptake following systemic administration represent promising avenues for effective management of pain. To this end, we used the Angiopep-2 (An2) ligand acting at LRP1 receptors, highly expressed at the BBB interface, as a Trojan horse approach to enhance NT[8-13] brain penetration. We first reported LRP1-dependent transport of ^{64}Cu-radiolabeled An2-NT[8-13] conjugate across the BBB using PET-CT imaging following systemic injection. We also found that An2-NT[8-13] exhibited an improved metabolic stability compared to unconjugated NT[8-13], without interfering with binding and pharmacological activity of NT peptide. Importantly, intravenous (i.v.) or subcutaneous (s.c.) injection of An2-NT[8-13] was effective in reversing pain behaviors induced either by intraplantar injection of formalin into the right hind paw (formalin tonic pain

model) or chronic constriction injury of the sciatic nerve (neuropathic pain). In parallel, we also monitored some physiological variables associated with NT action, including body temperature and blood pressure, and determined if An2-NT[8-13] induce adverse effects attributed to opioids. At the effective analgesic dose, systemic delivery of An2-NT[8-13] did not cause significant drop in blood pressure or change in body temperature. Furthermore, even at high doses, i.v. and s.c. An2-NT[8-13] did not produce constipation. Altogether, these results demonstrate that the brain-penetrant An2-NT[8-13] conjugate mediates relief of chronic pain after systemic administration and exhibits improved analgesia to side-effect ratios. This study opens the way to the creation of new chemical entities with highly modified versions of NT[8-13] that will favour increase plasma stability and selectivity towards NTS1/NTS2 to deliver safe and effective analgesics for patients suffering from chronic pain.

Title: Use of a non-invasive Trojan horse strategy to improve the delivery of opioid pain relief medications to the brain

Authors: *E. EISELT[1], V. OTIS[1], K. BELLEVILLE[1], A. LAROCQUE[2], A. RÉGINA[2], J.-M. LONGPRÉ[1], M. DEMEULE[2], P. SARRET[1], L. GENDRON[1];

Abstract: The blood brain barrier (BBB) is the primary interface between the bloodstream and the brain parenchyma and represents a restrictive diffusion barrier for a large number of pharmaceutical drugs, including morphine and its active metabolite morphine-6-glucuronide (M6G). Indeed, despite its recognized analgesic action, only a small fraction of subcutaneous (s.c.) administered morphine reaches the brain. There is also compelling evidences suggesting that the antinociceptive potency of M6G and morphine are almost equally potent after systemic administration, whereas the analgesic potency of M6G has been shown to be 100-fold higher than morphine after intracerebral injection. However, the brain penetration of M6G is significantly lower than morphine, thus limiting its usefulness in pain management. Here, we

created new chemical entities by the conjugation of the Angiopep-2 peptide (An2), a 19-amino acid peptide that crosses the BBB by LRP1 receptor-mediated transcytosis, with either morphine or M6G. The resulting new drug conjugates were then evaluated for their ability to penetrate the BBB, to exert superior analgesic activity compared to unconjugated molecules and to limit advert events, such as constipation. Using an *in vivo* brain perfusion paradigm, we first demonstrated improved brain uptake of these new chemical entities compared with that of unconjugated M6G and morphine. This increased BBB permeability was accompanied by an improvement in their analgesic efficacy in rat tail-flick assays. Indeed, intravenous (i.v.) administration of the An2-M6G conjugate exerted greater and more sustained analgesic activity than equivalent doses of either morphine or M6G. Likewise, i.v. or s.c. An2-morphine induced a time- and dose-dependent antinociceptive effect that was more prolonged when compared with unconjugated morphine. We finally assessed the effects of these new chemical entities on the gastrointestinal tract motility using the charcoal meal test in rats. While s.c. An2-morphine significantly reduced the intestinal transit time, s.c. An2-M6G exhibited a reduced constipation profile, as compared to morphine. In summary, we have developed new brain-penetrant opioid conjugates exhibiting improved analgesia to side-effect ratios. These results thus strongly support the use of An2 carrier peptides as an innovative BBB targeting technology to deliver effective drugs such as M6G for the management of pain.

Title: Distribution and efficacy of centrally and systemically administered antisense oligonucleotides in the pain system

Authors: *B. FITZSIMMONS, A. MOHAN, H. ZHAO, Y. JIANG, S. CHUN, F. RIGO, H. KORDASIEWICZ, E. SWAYZE;

Abstract: Chronic pain remains a large unmet clinical need due to limited efficacy of available therapies. Antisense oligonucleotides (ASOs) are stable single strands of DNA that bind to their complementary target RNA and direct its catalytic degradation through the action of RNase H, an endogenous enzyme present in most mammalian cells. Thirty years of ASO optimization has

led to second generation ASOs with characteristics amenable to the treatment of neurodegenerative diseases and are currently being tested clinically. We aim to determine if inflammatory and neuropathic pain are amenable to treatment with ASOs. First, we set out to examine the distribution, suppression of target RNA, and duration of effect of ASO delivered via repeat subcutaneous injections or a single intrathecal (IT) bolus injection in areas involved in pain processing, namely the dorsal root ganglia (DRG), trigeminal ganglia and spinal cord. We have previously reported with systemic administration, robust reductions in target RNA in peripheral ganglia, but not the spinal cord. ASOs are soluble in cerebrospinal fluid (CSF) and are distributed throughout the CNS when administered intrathecally. We demonstrate here that IT administration of ASOs into the CSF is sufficient to reduce expression of target RNA throughout the rodent CNS, including spinal cord, trigeminal and DRG. Due to the remarkably long half-life of ASOs in the CNS, a single injection of ASO into the CSF led to reductions in target RNA that persisted for more than 2 months. Thus, by multiple routes of administration, ASOs are able to target the tissues involved in pain processing and ASO-mediated gene suppression may be a feasible treatment for various forms of pain.

Title: Hydrocodone is more effective than morphine or oxycodone in suppressing burn-induced hyperalgesia at the injury site, but not in the contralateral limb

Authors: ***M. A. EMERY**, M. L. S. BATES, C. HORRAX, P. J. WELLMAN, S. EITAN; Psychology, Texas A&M Univ., College Station, TX

Abstract: Pain is the most frequent complaint of burn-injured patients. Opioids are commonly used in the course of treatment. However, previous findings indicate that various opioids have differential effects despite being considered clinically comparable, and there is a lack of rodent studies that examine these differential effects on burn pain management. Here, we examined the ability of morphine, oxycodone, and hydrocodone to reduce pain in mice with a burn injury, as well as their ability to suppress the development of burn-induced hyperalgesia in both the injured and the non-injured foot. Mice were examined for their baseline pain sensitivity thresholds using the von Frey Filaments test. Then, they were subjected to burn or sham injury, and treated orally with morphine, oxycodone, hydrocodone (20 or 40 mg/kg), or saline twice daily for 28 days. Pain thresholds were re-tested on days 4, 7, 11, 14, 21, and 28 post-injury. Hyperalgesia was observed 4 days post-burn in the injured foot, and intensified with time. Additionally, hyperalgesia emerged in the non-injured foot starting at D21. In the injured foot, 20 mg/kg morphine and oxycodone had only minimal effects to reduce hyperalgesia, and 40 mg/kg did not significantly change pain sensitivity threshold. In contrast, both 20 and 40 mg/kg hydrocodone significantly decreased pain sensitivity in the injured foot starting at D11 and continuing through the end of the study. Surprisingly, none of the opioids, including hydrocodone, significantly reduced the development of hyperalgesia in the non-injured foot of the injured animals at any timepoint. This study demonstrated that hydrocodone is effective in suppressing the development of burn-induced hyperalgesia at the injury site; but that none of the drugs showed efficacy blocking hyperalgesia development on the contralateral side. These findings support the idea that various opioids with similar acute analgesia effects have varied efficacy to block and/or treat long-term aberrant pain development, and underscore the need for additional studies on the differences among various opioids using clinically relevant pain models.

Title: resolvin d1 and resolvin d2 in oral cancer pain

Authors: *Y. YE[1], D. BERNABE[2], J. CURTIN[2], N. SCHEFF[2], P. SARAITHONG[2], B. SCHMIDT[2];
[1]Bluestone Ctr. for Clin. Res., [2]New York Univ., New York, NY

Abstract: Cancer progression and pain result from shared pathways that involve chronic inflammation. Resolvin D-series are endogenous lipid mediators derived from omega-3 fatty-acid that exhibit acute anti-inflammatory actions. Omega-3 fatty-acid has been shown to inhibit cancer proliferation. Resolvin D-series inhibit both inflammatory pain and neuropathic pain in mice models. We therefore hypothesized that resolvin D-series (resolvin D1 and resolvin D2) can inhibit cancer growth and pain in oral cancer. We examined the direct effect of resolvin D1 and resolvin D2 on proliferation of an oral cancer cell line (HSC-3). To study the effect of resolvin D-series *in vivo* we used a cancer supernatant model by injecting HSC-3 supernatant into the mouse tongue, and two tumor models by inoculating HSC-3 cells into the tongue or right hind paw of mice. Supernatant- or cancer-induced inflammation was measured using flow cytometry. Paw mechanical sensitivity was tested with an electronic von Frey device and thermal sensitivity was measured using a Hargreaves' test. Mechanical sensitivity in the tongue was tested using a gnawing device. Facial allodynia was measured using von Frey filaments. Tumor size was measured using a plethysmometer. We found that both resolvin D1 and D2 reduced HSC-3 proliferation in a dose-dependent manner *in vitro*. In the supernatant model resolvin D2 reduced gnawing time in mice, accompanied by reduced inflammation. In the paw cancer model, resolvin D1 treatment significantly increased paw withdrawal latency to thermal stimulation in cancer mice, with no obvious effect on cancer induced mechanical allodynia. Resolvin D2 treatment significantly increased mechanical thresholds in paw cancer mice at week three following HSC-3 inoculation compared to PBS treated cancer mice. However, this inhibitory effect was gone when tumor growth escalated at week four. Paw size was smaller in resolvin D2 treated cancer mice, compared to PBS treated controls. In the tongue cancer model, both resolvin D1 and D2 treatments reduced gnawing time at week three, but not at week four. Resolvin treatment did not reduce facial allodynia in mice with tongue cancer. No difference in inflammation was observed at week four following HSC-3 inoculation between the resolvin D2 and PBS treatment groups. Our finding suggests that resolvin D-series may be analgesic for acute cancer pain.

Title: Intraganglionic gene delivery of the photosensitive chloride channel, iC++, facilitates transdermal light-mediated inhibition of neuropathic pain in rodents

Authors: *C. TOWNE, S. KHAN, C. DISCENZA, A. ARGUELLO, J. AGUADO, T. GALFIN, M. KAPLITT;
Circuit Therapeut. Inc, Menlo Park, CA

Abstract: Optogenetics has been established as a powerful tool to study the central and peripheral nervous systems with its potential for directly treating human disease tantalizingly on the horizon. Optogenetic inhibition of pain in mice has been shown to be effective and provides an attractive initial application. We aim to translate this approach to treat neuropathic pain in humans. The novel blue-light activated chloride ion channel, iC++, was packaged into AAV serotype 6 and tested in the chronic constriction injury (CCI) mouse model of neuropathic pain. The AAV was delivered by nerve injection after the injury and onset of pain to better replicate the clinical time course. Two weeks after injection, we observed that transdermal delivery of blue light could inhibit mechanical allodynia, presumably through hyperpolarization of nerve endings by an intracellular chloride flux. Notably, the observed pain inhibition was more robust for iC++ than observed with the yellow-light activated chloride pump, NpHR. We next tested a novel surgical approach to deliver the iC++. Transforaminal epidural injection is a common clinical procedure used to deliver steroids adjacent to the dorsal root ganglia (DRG) for treating disc herniation pain. The approach has recently been modified to deliver AAV directly to the DRG in large animals and therefore provides an attractive method to restrict gene therapy to the target cells in neuropathic pain. Intraganglionic injections of AAV5 expressing iC++ were made at L4 and L5 spinal levels in rats with preexisting neuropathic pain. Three weeks after vector delivery, we observed transdermal light mediated inhibition of mechanical and thermal allodynia in two different models of neuropathic pain i.e. the tibia fracture/cast immobilization model of Complex Regional Pain Syndrome (CRPS) and the CCI model. Functional pain inhibition was observed up to 12 weeks at which point animals were sacrificed for histology. Interestingly, cell type characterization revealed transduction of multiple sensory neuron types with a trend for higher numbers of iC++ expression in large NF200 positive cells, that have been implicated in mediating mechanical allodynia. Taken together, our results confirm optogenetic therapy for neuropathic pain as a potentially attractive clinical application of this technology.

Title: Monoclonal antibodies that block the binding of artemin to GFRα3 significantly attenuate nociceptive responses in two mouse models of joint pain

Authors: *L. A. CORTES-BURGOS, E. F. THAYER, M. GAO, L. XIE, A. RAFIQUE, J. FAIRHURST, A. BADITHE, R. BABB, F. DELFINO, C. HUNT, W. T. POUEYMIROU, A. J. MURPHY, L. E. MACDONALD, S. D. CROLL;
Regeneron Pharmaceuticals Inc, Tarrytown, NY

Abstract: Artemin is a member of the glial-derived neurotrophic factor (GDNF) family of growth factor ligands (GFLs). It binds with high affinity to the GFL family receptor GFRα3. Upon binding to artemin, GFRα3 forms a complex with the RET tyrosine kinase receptor, leading to activation of intracellular signaling. GFRα3 is preferentially expressed in sensory and sympathetic neurons of the peripheral nervous system, and has been implicated in the initiation, sensitization, and maintenance of nociceptive responses. We generated high affinity mouse and human monoclonal antibodies against GFRα3 that prevent artemin binding, and have used these antibodies in two mouse models of joint pain. In the DMM (Destabilization of the Medial Meniscus) model of osteoarthritic-like pain, knees of adult male C57Bl/6 mice were surgically destabilized. Sixteen weeks after surgery, mice exhibited significant tactile allodynia, measured using Von Frey Hairs, and marked development of knee joint osteophytes, evaluated by μCT scan. Both mouse and human monoclonal antibodies against GFRα3 prevented and reversed tactile allodynia in this model. Administration of anti-GFRα3 did not appear to be disease-modifying, because withdrawal of antibody treatment restored the allodynic response. In addition, knee joint osteophyte burden was similar for animals treated with anti-GFRα3, PBS, or an isotype control antibody. A second model of joint pain, the intra-articular CFA (Complete Freunds' Adjuvant) model, was also used to evaluate the efficacy of anti-GFRα3. In this model, CFA was injected into the knee joint of adult male C57Bl/6 mice and nociceptive responses were evaluated for 5 weeks. Anti GFRα3 significantly prevented both tactile allodynia and thermal hyperalgesia (evaluated with the Hargreaves' Test) in this model. Knee joints were collected at the end of the experiment and inflammation was scored by a blinded evaluator using a subjective rating scale. No differences were observed among the treatment groups in inflammation scores, suggesting that the antibody reduced nociceptive responses without reducing CFA-induced inflammation. Our data suggest that inhibition of artemin binding to GFRα3 may be efficacious against chronic joint pain.

Juárez Autónoma de Tabasco, Villahermosa, Tabasco, Mexico; [5]Neurociencias, Inst. Nacional de Psiquiatría Ramón de la Fuente Muñiz, Mexico City, Mexico

Abstract: It is considered that natural products used in folk medicine can potentiate the effect of drugs. The aim of this study was to evaluate the pharmacological interaction between ethanolic extract of Rosmarinus officinalis, a traditional medicinal plant to treat pain, and the analgesic ketorolac. Individual concentration-response curves of the antinociceptive effect of these compounds were built to calculate the EC50, as well as the pharmacological interaction, by using isobolographic analysis in the formalin test. All treatments decreased significantly and in a concentration-dependent manner the biphasic nociceptive behavior with EC50 values of 11.9 ± 1.5, for Rosmarinus officinalis and ketorolac respectively. An isobolographic analysis allowed the characterization of the pharmacological interaction produced by a fixed ratio combination of $1:1$ of equi-effective doses of these compounds. Theoretical antinociceptive EC50 value of Rosmarinus officinalis+ketorolac was 21.1 ± 1.1 mg/paw, this value was statistically different from those obtained experimentally (5.6 ± 0.5 mg/paw), reporting a synergic interaction. These results provide evidence that this medicinal plant could be useful to treat inflammatory pain.

Title: Novel indole-like Trk receptor inhibitors as potential therapeutics for pain and cancer

Authors: *K. LUBERG[1], R. PARK[1,3], J. TAMMIKU-TAUL[2,4], K. JAANSON[1], D. DOBCHEV[2], D. KANANOVICH[2], A. NOOLE[2], M. MANDEL[5], A. KAASIK[5], M. LOPP[2], M. KARELSON[2,4], T. TIMMUSK[1];

Abstract: The tropomyosin receptor kinase (Trk) family consists of three members - TrkA, TrkB and TrkC, which are tyrosine kinase receptors of neurotrophins. The activation of Trk receptors by their ligand neurotrophins triggers intracellular signal cascades needed for the survival, differentiation and functioning of many neural cells. However, TrkA is responsible for nociceptor sensitization after tissue injury leading to acute or chronic pain. In addition, Trk kinases have been implicated in the development of some tumor types, including the ability of TrkB to suppress anoikis, a type of apoptosis important in prevention of metastasis. For this reason, we conducted a study to find novel inhibitors of Trk receptors and characterize them using biochemical and cellular assays. First, a virtual screening was made for new TrkA receptor antagonists targeting the ATP-binding pocket. Based on these results, a selection of compounds were assessed for their antagonistic activity against Trk receptors using cellular and biochemical assays. Thereafter, based on the structure-activity relationships (SAR), a series of sulfonamide derivates of indoles were designed and synthesized. The best TrkA inhibitor of this selection had a biochemical IC_{50} of 3.7 nM and a cellular IC_{50} of 10.0 nM. Similar results were obtained for TrkB and TrkC, which is expected as the ATP-binding pockets of Trk proteins are highly

similar. No effect on cell viability of these compounds was observed for cortical neurons. 6 potent TrkA inhibtors were also used for *in vitro* kinase profiling. At 100 nM concentration the compounds were relatively TrkA specific, inhibiting up to 3 off-target kinases. In conclusion, we have described a selection of novel potent and selective Trk inhibitors.

Title: Dorsal root ganglionic field stimulation relieves both spontaneous and induced neuropathic pain in rats

Authors: *B. PAN[1], H. YU[1], G. FISCHER[1], J. M. KRAMER[2], Q. H. HOGAN[1];
[1]Anesthesiol., Med. Col. of Wisconsin, Milwaukee, WI; [2]St. Jude Medical, Inc., St. Paul, MN

Abstract: Stimulation of the dorsal root ganglion (DRG) by electrical fields (i.e. ganglionic field stimulation, GFS) has been shown to be effective in relieving clinical pain, including that associated with nerve injury. However, its mechanism has not been explored. We therefore developed and tested a rat model that replicates clinical GFS, in order to identify if quantifiable analgesic effects were present in the context of neuropathic pain. GFS at the lumbar 4 level was applied with a chronically inserted bipolar electrode using parameters replicating clinical use (continuous stimulation at 20Hz, 150μs pulse width, and amplitude just below motor threshold). Neuropathic pain was generated by tibial nerve injury (TNI). Pain behavior was monitored by determining the threshold for withdrawal from punctate mechanical stimulus, by identifying hyperalgesic responses to noxious mechanical stimulus, and by hypersensitivity to cold. The affective dimension of pain was measured by conditioned place preference (CPP). We found that electrode insertion caused no behavioral evidence of pain and produced no histological evidence of DRG damage. Hyperalgesia, allodynia, and hypersensitivity to cold induced by tibial nerve injury were reversed during GFS, and allodynia remained diminished for 15min after GFS. CPP showed that GFS was not rewarding in uninjured control animals but was rewarding in animals subjected to TNI, which reveals analgesic efficacy of GFS for spontaneous pain. We conclude

that GFS relieves neuropathic pain in rats. This model may provide a platform for identifying mechanisms and novel applications of GFS.

Title: Neuromodulation of cranial nerves for migraine and trigeminal neuropathy pain

Authors: *R. M. HARPER[1], D. SNODGRASS[2], F. YAN-GO[3], J. JEN[3], R. K. HARPER[4], M. YAZDIZADEH[5], E. K. SAUERLAND[6];
[1]Neurobio., Univ. of California at Los Angeles, Los Angeles, CA; [2]Audiol. Clin., [3]Dept. of Neurol., [4]Dept. of Neurobio., [5]Sch. of Dent., UCLA, Univ. of California at Los Angeles, Los Angeles, CA; [6]Dept. of Physiol. and Cell Biol., Univ. of Nevada Sch. of Med., Reno, NV

Abstract: Introduction: Neuromodulation of selected cranial nerves with electrical signals has been used for migraine and pain from trigeminal sources, with cutaneous electrical stimulation of cranial nerve V, or invasive cuff stimulation of the vagus (X). These procedures are disadvantageous in that (1) pain often arises from sources other than those served by cranial nerves V and X, (2) long-term electrical stimulation injures the skin, and is often noxious, and (3) invasive vagal stimulation poses multiple risks. We evaluated concurrent activation of cranial nerves 5, 7, 9, 10 and cervical nerves C2, and C3 using only afferent fibers reaching the cutaneous surface, and using mechanical vibration, not electricity, to alleviate pain. **Methods**: Eighteen adults, aged 22-76 years, diagnosed with moderate-to-severe migraine or severe trigeminal neuropathic pain by a UCLA neurologist or pain physician, had silicon impressions taken of the external auditory canals with adjacent portions of the auricle, after which vibration motors were installed within the impressions to activate the auricular branch of the vagus (X), and the IXth, VIIth, and Vth cranial nerves, as well as C2 and C3 sensory nerves. Subjects with a pain attack were exposed to 10 minutes of no vibration, 25 minutes of high-frequency mechanical vibration, and a 10 minute recovery period while instrumented with O_2 saturation, ECG, and respiratory sensors. Pain levels on a 0 to 10 scale were scored before and after

stimulation. **Results:** Of 18 subjects, 17 showed reduction in reported pain, and one showed no change. In some cases, the pain reduction was substantial (e.g., on a pain scale of 0 to 10, where 10 is so severe that the subject is at risk to go unconscious, 10 to 2 on one subject, 9 to 0 on two subjects, 8 to 0, 8 to 1, and 8 to 2 on three additional subjects). The mean before-after levels significantly differed ($p < 0.0001$, paired t-test). The most prominent side effect was a marked tendency to fall into quiet sleep, followed quickly by rapid eye movement sleep. Repeated sessions in a subset of patients resulted in increased time between migraine attacks, and diminished initial pain with subsequent attacks.**Conclusions:** The procedure offers a non-invasive, drug-free, and inexpensive means to address migraine and trigeminal neuropathy pain, with minimal side-effects. The process likely depends on the common projection of the cranial and cervical nerve receptors to the descending nucleus of V, but likely also involves insular and thalamic circuitry, since a progressive improvement in pain perception, i.e., "learning" occurs.

Title: Endocannabinoid enzyme inhibition synergistically potentiates the antiallodynic effects of gabapentin and diclofenac in mice

Authors: ***M. CROWE**[1], R. GUJJAR[2], A. MAHADEVAN[2], M. BANKS[3], S. G. KINSEY[1]; [1]Psychology, West Virginia Univ., Morgantown, WV; [2]Organix Inc., Woburn, MA; [3]Pharmacol. and Toxicology, Virginia Commonwealth Univ., Richmond, VA

Abstract: Neuropathic pain is characterized by altered nerve function that often presents as allodynia, the painful perception of non-noxious stimuli. Neuropathic pain is commonly treated

with steroids, non-steroidal anti-inflammatory drugs (NSAIDs), or GABA analogues. However, in addition to the well-known side effects of steroids, NSAIDs also cause gastrointestinal inflammation and increased risk of cardiac events. GABA analogues, such as gabapentin, are commonly prescribed for nerve pain but also cause dizziness, sedation, and gait disturbance. Similarly, inhibition of the endogenous cannabinoid enzyme monoacylglycerol lipase (MAGL) has analgesic and anti-inflammatory properties, but also induces sedation at high doses. In order to limit these side effects, the present study investigated the analgesic effects of coadministering a MAGL inhibitor with either an NSAID or gabapentin. Mice were subjected to the chronic constriction injury (CCI) model of neuropathic pain and then administered the MAGL inhibitor JZL184 (1-40 mg/kg, i.p.) and the NSAID diclofenac sodium (1-100 mg/kg, i.p.), separately or in combination. A second cohort of CCI-treated mice was administered the MAGL inhibitor or KML29 (1-40 mg/kg, i.p.) and the GABA analogue gabapentin (1-50 mg/kg, i.p.), separately or in combination. Mice were tested for mechanical allodynia and acetone-induced cold allodynia. Dose addition analyses revealed that combined, low dose JZL184 and diclofenac synergistically attenuated mechanical allodynia and had an additive interaction in reducing cold allodynia. Similarly, the combination of low dose KML29 and gabapentin had an additive interaction in attenuating mechanical allodynia and a synergistic interaction in reducing cold allodynia. In order to assess receptor mechanism, the selective cannabinoid receptor 1 (CB_1) antagonist, rimonabant (3 mg/kg, i.p.) or the selective cannabinoid receptor 2 ($CB_{2)}$ antagonist, SR144528 (3 mg/kg, i.p.) was administered prior to the JZL184/diclofenac or KML29/gabapentin combination. Rimonabant, but not SR144528, reversed the analgesic effects of the JZL184/diclofenac combination and partially reversed the analgesic effects of the KML29/gabapentin combination in mechanical allodynia. Neither antagonist blocked analgesia in cold allodynia, indicating that CB_1 activation may be relatively more involved in attenuating sensitivity to mechanical stimuli. These data support the strategy of combining MAGL inhibition with commonly used analgesics as a therapeutic approach for attenuating neuropathic pain.

Title: Behavioral investigation of central and peripheral roles of endothelins in evoked and ongoing pain in a rat model of facial cancer

Authors: *C. KOPRUSZINSKI[1], E. GAMBETA[1], R. C. DOS REIS[1], G. A. RAE[2], A. ACCO[1], T. KING[3], J. G. CHICHORRO[1];

Abstract: Pain represents a frequent symptom of facial cancer and occurs in many ways, such as evoked and ongoing pain, characterized by very poor analgesic management. There is mounting evidence that endothelins participate in different aspects of pain in some types of cancer. Considering their well characterized role in trigeminal nociceptive transmission, the current study aimed to evaluate the participation of endothelins in evoked and non-evoked pain in a model of facial cancer. All experiments were conducted in Male Wistar rats and were previously approved by UFPR's Committee on the Ethical Use of Animals (authorization # 654). Facial cancer was induced by inoculating a suspension of Walker-256 cells into the rat's right vibrissal pad. To assess the influence of endothelins in evoked pain, facial heat hypersensitivity was assessed on day 6 after tumor cell inoculation, before and at 30 min and 1h-intervals after the subcutaneous administration of BQ-123 and BQ-788 (ET_A and ET_B receptor antagonist, respectively, at 30 μg/50 μL, right upper lip), alone or in combination, or Bosentan (mixed endothelin ET_A/ET_B receptor antagonist, at 100 or 300 mg/kg, p.o., and at 10 or 30 μg/50 μL, right upper lip). To assess the influence of endothelins in ongoing pain, spontaneous grooming and the conditioned place preference (CPP) paradigm was performed in tumor-bearing rats after treatment with BQ-123, BQ-788, alone or in combination, or Bosentan. Heat hypersensitivity related to facial tumor was unchanged by BQs, alone or in combination. However, a single administration of Bosentan, at 300 mg/kg and at 30 μg/50 μL, reduced heat hypersensitivity on day 6 after tumor cell inoculation. Additionally, BQs, alone or in combination failed to modify the spontaneous grooming, while Bosentan at 100 mg/kg and 30 μg/50 μL, reduced the spontaneous grooming induced by the inoculation of tumor cells. Systemic, but not local, treatment with Bosentan at 100 mg/kg was also able to induce conditioned place preference on tumor-bearing rats, but not in the control group. This study provides evidence that endothelin may participate on the development of evoked and ongoing pain associated with facial cancer. A systemic lower dose of Bosentan was able to control non-evoked pain compared to evoked pain, suggesting a systemic better efficacy of the drug on ongoing pain management, which increases the relevance of this pharmacological target. Title: The analgesic efficacy of MMG22 in targeting a putative MOR/mGluR5 heteromer in a murine model of bone cancer pain

Authors: S. S. SHUEB[1], M. LUNZER[2], E. AKGÜN[2], G. CATALDO[1], P. S. PORTOGHESE[2], *D. A. SIMONE[1];
[1]Dept.Diagnostic & Biol. Sci., [2]Col. of Pharmacy, Dept. of Medicinal Chem., Univ. Minnesota, Minneapolis, MN

Abstract: Background: Pain has been reported to be among the most common symptoms in patients with cancer. It has been reported that 90% of patients with end-stage cancer experience pain. Management of cancer pain with opiates is a challenge due to their side effects and development of tolerance. Studies have shown that co-administration of mμ opioid receptor (MOR) agonist and a metabotropic glutamate receptor-5 (mGluR-5) antagonist reduced the tolerance and dependence of morphine as well as augmented its analgesic properties. This finding and reported evidence for MOR-mGluR$_5$ heteromers in cultured cells led to the development of MMG22, that contains both mμ agonist and mGluR-5 antagonist joined by a 22-atom spacer. Intrathecal administration of MMG22 potently reduced mechanical hyperalgesia in a mouse model of bone cancer pain and was ~1000x more efficacious than morphine via i.t. administration. In this study, we determined the efficacy of MMG22 given subcutaneously (s.c), and whether analgesic tolerance developed by this route of administration.
Methods: Adult male C3H/He mice were used. Fibrosarcoma cells were injected into and around the calcaneus bone in one hind paw. Mechanical hyperalgesia was defined as an increase in the frequency of paw withdrawal (PWF) evoked by application of a von Frey monofilament (3.9 mN bending force) applied to the plantar surface of the hind paw. PWF was determined before implantation of cancer cells into the calcaneus bone of the hind paw, and before and at 30, 60 and 120 mins post-injection of either MMG22 or morphine on post-cancer cell injection day (PID) 3, 10, 17 and 24. Compounds were administered s.c. to determine peak time effects and $ED_{50/80s}$ were calculated.
Results: MMG22 produced dose-dependent antihyperalgesia. On PID 3, the ED_{50} for MMG22 was 0.36mg/kg) and was 6.23 times more potent than morphine. The ED_{50} dose decreased with tumor growth. ED_{50} doses were 0.15 mg/kg and 0.004 mg/kg on PID 10 and 17; these were 14.9 and 560 times more potent than morphine (ED_{50}: 2.24 mg/kg), respectively. On PID 24 the ED_{50} dose for MMG22 was 0.002 mg/kg, 1120 times more potent than morphine. The peak time of antihyperalgesia following MCC22 was 60 minutes after injection for all doses. Importantly,

unlike morphine MMG22 exhibited no tolerance to its antihyperalgesic effects, and appeared to increase in potency over the time course.
Conclusions: MMG22 potently attenuated hyperalgesia in a murine model of cancer pain when administered s.c. and, unlike morphine, showed potentiation as tumor growth progressed without tolerance. Therefore, MMG22 may be useful for treating cancer pain as well and other pains that are difficult to manage.

Title: Screening for analgesic activity using a panel of behavioral pain models: potential utility in combination studies to assess synergy

Authors: Y. DARBAKY[1], V. MAFFRE[2], *L. DIOP[3];
[1]ANS Biotech, RIOM cedex, France; [2]ANS Biotech, RIOM Cedex, France; [3]ANS Biotech, Riom Cedex, France

Abstract: We have previously shown that our behavioral pain panel, ALGOGram™, can provide a rapid and predictive evaluation of various reference drugs classically used in clinical pain practice. In this sense, ALGOGram™ appears to be a valuable screening tool for a broad range of analgesic activity when used in a signal detection exercise. In order to investigate the level of sensitivity of ALGOGram™, we have utilized it to detect the synergistic effect of combined Morphine and Acteminophen.
Material and methods: ALGOGram™ is a battery of 11 validated animal models/tests spanning a broad range of pain areas (acute and tonic pain, neuropathic pain, inflammatory pain, post-operative pain, and visceral pain). The concept is an assessment of efficacy based on a group size of n=4 rats/model/test, thus providing a general pharmacological profile while reducing costs; assays/tests are run in parallel, thus minimizing timelines. To investigate the level of sensitivity of ALGOGram™, a well-known synergy used in clinical pain practice between Morphine and Acetaminophen was evaluated in the 11 pain models / tests (models: CCI, oxaliplatin, carrageenan, kaolin, post-operative and TNBS; tests: paw pressure, tail flick, writhing and formalin). Behavioral and acute toxicity were also evaluated (modified Irwin grid). Results are expressed for each group as a percentage of activity for each model/test calculated

from the mean value of the vehicle-treated animals from our 9 year-historical database.
Results: Used at sub-threshold doses as determined in earlier fully-powered studies, Morphine (0.3 mg/kg, s.c.) and Acetaminophen (100 mg/kg, p.o.) did not show activity in any of the different somatic pain models. In contrast, animals co-administered both inactive doses of Morphine and Acetaminophen exhibited significant pain relief in post-operative and neuropathic pain (CCI) models. Profiles obtained with n=4 animals in the ALGOGram^{TM} were in line with those generated in various and repeated fully-powered studies as well as those described in the literature.
Conclusion: ALGOGram^{TM} provides a rapid and predictive evaluation of investigational compounds in 11 different pain models/tests, enabling their prioritization for fully-powered studies. Shortened timelines and reduced costs are possible due to small group sizes that are run largely in parallel. ALGOGram^{TM} may prove to be useful in a signal detection exercise for a broad range of potential analgesic activity and appears to be sufficiently sensitive to demonstrate synergistic effects.

Title: Imbalances between Glutamate and GABA within rat insula differentially alter insular levels of amino acid and monoamine neurotransmitters and metabolites

Authors: *I. C. ST CHARLES, C. J. WATSON;
Anesthesiol., The Univ. of Michigan, Ann Arbor, MI

Abstract: Approximately 30% of adults worldwide experience some form of chronic pain (Elzahaf *Curr Med Opin* **2012** 28:1221). Although an excitatory imbalance between glutamate and GABA signaling likely occurs in brain regions that process pain (Phillips *Best Pract Res Clin Rheumatol* **2011** 25:141), little is known about how this imbalance affects other neurochemicals within these regions of interest. Within the brain, glutamate (Glu) is the main excitatory neurotransmitter, and GABA is the main inhibitory neurotransmitter. One brain region

of interest in regards to pain processing is the insula, which plays a role in the sensory/descriptive and affective/motivational components of pain processing (Craig *Nat Rev Neurosci* **2002** 3:655). To test the hypothesis that increased glutamate and increased GABA within the insular cortex differentially alter levels of neurochemicals within the insula, L-*trans*-Pyrrolidine-2,4-dicarboxylic acid (PDC; an excitatory amino acid uptake inhibitor that increases endogenous levels of Glu and Asp) or nipecotic acid (NPA; a GABA uptake inhibitor that increases endogenous levels of GABA) were administered to the insula via reverse dialysis. Administration of PDC or NPA to rat insula has been shown to increase or decrease, respectively, hyperalgesia and allodynia (PW105 2014 Abstract Viewer/Itinerary Planner. IASP, Online). The perfusate from the outlet of the microdialysis probe was collected in 15 μL aliquots for separation and analysis by liquid chromatography with tandem mass spectrometry. Samples were analyzed for concentrations of acetylcholine (ACh), taurine, histamine, serine, glutamine, aspartate (Asp), glycine (Gly), glucose, Glu, GABA, adenosine (Ado), phenylalanine (Phe), tryptophan (Trp), octopamine (Oct), serotonin, L-dopa, norepinephrine (NE), tyramine (TyrA), and dopamine. Compared to Ringer's control, dialysis with 100 μM PDC (n=2) increased levels of Glu, Asp, Gly, NE, Phe, Trp, and Oct by (%±sem) 281±78, 443±192, 157±50, 199±80, 314±59, 210±46, and 254±86, respectively. Dialysis with 100 μM NPA (n=2) increased levels of GABA, ACh, TryA, and DA by 410±159, 160±37, 222±112, and 244±120, respectively. NPA also decreased levels of Ado to 69±16% of control. Ongoing studies involve determining if the observed changes can be replicated in a larger sample population. Future studies will investigate what role, if any, these differential changes in neurochemicals induced by increased Glu or increased GABA play in pain processing. Future studies will also investigate whether decreasing endogenous levels of GABA within the insula has similar effects on insular neurochemicals as increasing Glu within the insula.

Title: Buprenorphine-induced antinociception varies as a function of leptin status in obese mice

Authors: S. MIHALKO[1], Z. GLOVAK[1], K. T. WILES[1], C. ANGEL[1], J. E. JOHNSON[1], H. A. BAGHDOYAN[3], *R. LYDIC[2];
[1]Anesthesiol., [2]Anesthesiol. and Psychology, Univ. of Tennessee, Knoxville, TN; [3]Anesthesiol. and Psychology, Univ. of Tennessee, Knoxville, TN

Abstract: Obesity and leptin are associated with increased reports of pain, and many studies note that leptin alters nociception (Neuroscience 275: 531, 2014). Buprenorphine is a mu opioid receptor agonist and kappa opioid receptor antagonist that produces antinociception. In normal weight subjects, buprenorphine has a ceiling effect for respiratory depression. Recent data suggest that in obese mice leptin modulates buprenorphine-induced respiratory depression (*FASEB J.* 30: 717.1, 2016). The present study is testing the hypothesis that leptin status also influences the antinociceptive effects of buprenorphine. The dependent measure was tail flick latency (TFL) in s for mouse-initiated tail removal from a 49^{o}C water bath. Independent variables were intraperitoneal administration (0.3 mL) of saline (control) or buprenorphine (0.3 mg/kg). Subjects were normal weight C57BL/6J (B6) mice (n=8) and three groups of obese mice including B6 mice with diet-induced obesity (DIO) (n=7); B6.BKS(D)-Lepr^{db}/J (db/db) mice with dysfunctional leptin receptors (n=8); and B6.Cg-Lep^{ob}/J (ob/ob) mice that lack leptin (n=8). All DIO mice were males and each of the three other groups included male (n=4) and female (n=4) mice. Two-way ANOVA ignoring sex and using TFL values averaged for each mouse revealed that TFL varied significantly as a function of drug ($F(1,27)=9.32$; $P=0.0050$) and mouse line ($F(3,27)=9.58$; $P=0.0002$). Bonferroni multiple comparisons test indicate that before buprenorphine administration the only statistically significant difference in mean TFL was between db/db (4.39s) and DIO (2.71s) mice. Buprenorphine increased TFL in all four groups of mice. After buprenorphine administration, Bonferroni multiple comparisons test indicated that TFL of db/db mice (5.59s) was significantly greater than TFL of B6 (3.73s), ob/ob (3.69s), and DIO (3.69s) mice. Small sample sizes of male and female mice precluded statistical evaluation of sex-dependent differences in buprenorphine effects on nociception. The average percent differences in TFL between male and female mice after receiving buprenorphine were B6 (2.95%), db/db (2.82%), and ob/ob (18.1%). Ongoing studies will increase sample sizes enabling statistical evaluation of potential sex-dependent differences in antinociceptive behavior. Considered together, the ANOVA and Bonferroni results support the conclusion that the antinociceptive effect of buprenorphine in these congenic mouse lines varies with obesity and leptin status.

Title: Targeting putative mu opioid/chemokine ccr5 heteromers potently reduces hyperalgesia in a mouse model of sickle cell disease

Authors: *G. CATALDO[1], M. M. LUNZER[2], S. SHUEB[3], E. AKGÜN[2], J. D. BELCHER[4], G. M. VERCELLOTTI[4], P. S. PORTOGHESE[2], D. A. SIMONE[3];
[1]Diagnos. and Biol. Sci., [2]Dept. of Medicinal Chem., [3]Dept. of Diagnos. and Biol. Sci., [4]Dept. of Med., Univ. of Minnesota, Minneapolis, MN

Abstract: *Background*: Pain is a common characteristic of sickle cell disease (SCD), one of the world's most prevalent inherited diseases. Opioids have been the mainstay treatment to manage pain in SCD but pose a serious challenge attributed to the many adverse side effects, including tolerance and dependence. Since analgesics typically used to treat pain in SCD appear to loose efficacy upon chronic use, there is a need for new pharmacological agents to treat chronic pain. MCC22 was designed to specifically target the putative mu opiate receptor (MOR)-CCR5 receptor heteromer as there is evidence for crosstalk between MOR and CCR5 in cultured cells that reduces the efficacy of opioid analgesics employed in SCD. MCC22 contains both mu agonist and chemokine CCR5 antagonist pharmacophores that are linked through a 22-atom-spacer. Since SCD is an inflammatory disorder where activated microglia and chemokines are important for the generation of pain, we investigated whether MCC22 would decrease hyperalgesia in sickle mice. Here we reveal that MCC22 is highly effective as an analgesic in a mouse model of SCD.
Methods: Townes transgenic mice expressing sickle hemoglobin (HbSS/HbAS) and normal hemoglobin (HbAA) controls were used in this study. Hyperalgesia was quantified by determining the frequency of withdrawal responses evoked by a von Frey monofilament with a bending force of 9.3 mN applied to the plantar surface. To evaluate the analgesic effects of MCC22, paw withdrawal frequency (PWF) was determined before and at various times after intraperitoneal (ip) administration of 10 mg/kg.
In correlative electrophysiology studies in vivo, we determined the effects of MCC22 on responses of identified nociceptive dorsal horn neurons. Responses evoked by von Frey

filaments with bending forces of 9.3 and 135.3 mN before and after administration of vehicle and MCC22 (10 mg/kg ip).
Results: HbSS sickle mice exhibited robust mechanical hyperalgesia as shown by an increase in PWF compared to HbAS and HbAA controls ($p<0.001$). PWF in HbAS mice was also greater than in HbAA mice ($p<0.001$), but less than HbSS mice. Administration of MCC22 8.0 mg/kg ip reduced hyperalgesia within 30 minutes as evidenced by a decrease in PWF in both HbSS and HbAS mice ($p<0.001$). Similarly, this same dose of MCC22 potently reduced evoked responses of dorsal horn neurons in HbSS at 15, 30 and 60 minutes after administration.
Conclusions: MCC22 potently decreased mechanical hyperalgesia in sickle mice and reduced evoked activity of nociceptive spinal neurons. The use of bivalent ligands that target heteromers involved in signaling pain may offer a novel and effective approach for treating pain in SCD.

Abstract: Neuropathic pain is a chronic condition caused by damage in the peripheral or central nervous system. This type of pain is characterized by hyperalgesia and allodynia. The therapeutic in this condition is a serious problem because the polytherapy is necessary in most cases. Actually, drugs than use in neuropathic pain treatment in clinical practice are opioids, anticonvulsivant, antidepressant or NSAIDs combination. Unfortunately, the analgesic efficacy of such drugs is often not satisfactory for tolerability problems like gastrointestinal side effects such as nausea, vomiting and constipation. On the other hand, cytidine-5'diphosphocholine (CDP-choline) and magnesium sulfate (MgSO4) have been reported as neuroprotective agents for ischemic conditions, and these can reduce inflammatory cytokines. The purpose of this study was to evaluate the effect of cytidine-5'diphosphocholine (CDP-Choline) and magnesium sulfate (MgSO4) in both spinal nerve ligation and formalin models. We evaluated dose-response curves

for intraperitoneal (i.p.) administration of CDP-Choline (5, 10, 50, 100 mg/kg) and MgSO4 (5, 10, 50, 100 mg/kg). Experiments were performance using male Wistar rats on weight 120-140 g, calibrated nylon Von Frey filaments were used to determine the mechanical sensitivity threshold for nociception, allodynia was evaluated by the up-down method of Dixon and Chaplan. In addition, animals (200-250 g) received an i.p. injection 10 min before formalin injection into the dorsal surface of the right hind paw. Our results suggest that CDP-choline and MgSO4 reduced the nociception and neuropathic pain in rats.

Title: The positive allosteric GABAB receptor modulator rac-BHFF enhances baclofen-mediated analgesia in neuropathic mice

Authors: *K. ZEMOURA[1], D. BENKE, 8051[2], W. RALVENIUS[2];
[1]Inst. of Pharmacol. and Toxicology, Zurich, Switzerland; [2]Inst. of Pharmacol. and Toxicology, zurich, Switzerland

Abstract: Neuropathic pain is associated with impaired inhibitory control of spinal dorsal horn neurons, which are involved in processing pain signals. The metabotropic GABAB receptor is an important component of the inhibitory system and is highly expressed in primary nociceptors and intrinsic dorsal horn neurons to control their excitability. Activation of GABAB receptors with the orthosteric agonist baclofen effectively reliefs neuropathic pain but is associated with severe side effects that prevent its widespread application. The recently developed positive allosteric GABAB receptor modulators lack most of these side effects and are therefore promising drugs for the treatment of pain. Here we tested the high affinity positive allosteric modulator rac-BHFF for its ability to relief neuropathic pain induced by chronic constriction of the sciatic nerve in mice. rac-BHFF significantly increased the paw withdrawal threshold to mechanical stimulation in healthy mice, indicating an endogenous GABABergic tone regulating the sensitivity to mechanical stimuli. Surprisingly, rac-BHFF displayed no analgesic activity in neuropathic mice although GABAB receptor expression was not affected in the dorsal horn as shown by

quantitative receptor autoradiography. However, activation of spinal GABAB receptors by intrathecal injection of baclofen reduced hyperalgesia and its analgesic effect was considerably potentiated by co-application of rac-BHFF. These results indicate that under conditions of neuropathic pain the GABAergic tone is too low to provide a basis for allosteric modulation of GABAB receptors. However, allosteric modulators would be well suited as an add-on to reduce the dose of baclofen required to achieve analgesia.

Title: Development of a clinically-translatable acute heat pain behavioral model in non-human primates.

Authors: P. S. PALL, J. D. VARDIGAN, *H. S. LANGE, J. BALLARD, A. K. HOUGHTON, C. BURGEY, M. E. LAYTON, R. M. KIM, J. M. USLANER;
Pharmacol., Merck Res. Labs., West Point, PA

Abstract: Improved treatment for pain is a significant unmet medical need. Voltage-gated sodium channels are responsible for the generation and conduction of action potentials in the peripheral nociceptive neuronal pathway where the voltage-gated sodium channel 1.7 (NaV1.7) has a critical role. Human loss-of-function mutations in the SCN9A gene, which encodes NaV1.7, result in congenital indifference to pain (Ruitenberg et. al., 2012). Thus, NaV1.7 is a target of interest for the development of analgesic compounds. In order to test the effect of NaV1.7 inhibitors preclinically we have established a clinically translatable acute heat pain behavioral model in rhesus monkeys. *Methods:* An FDA-approved Medoc contact heat-evoked potential stimulator (CHEPS) was used to deliver thermal stimuli to the volar forearm of rhesus monkeys. The heating head of the CHEPS thermode was strapped on to a shaved part of the animal's left volar forearm ~4 cm above the wrist. Brief, 5 second heat stimuli at 4 temperatures (44, 46, 48 and 50°C) were delivered 6 times each per session in pseudo-random order. The heat stimuli evoked a withdrawal response in the test arm that was scored on a three point scale by the experimenter (0=no response, 1= single arm movement and 2= multiple arm or body movements). Eight animals (2 males, 6 females; weight 6-14 Kg) were selected from a larger cohort of 16 animals based on at least two consecutive screening sessions in which measurable responses to the higher temperatures were consistently observed (8 other animals did not meet

these criteria). For analyses, an average response to each test temperature was calculated. All study protocols were reviewed and approved by the Institutional Animal Care and Use Committee (IACUC) at Merck & Co. Inc and were in accordance with IASP guidelines. *Results:* 44°C produced very low levels of withdrawal response, whereas temperatures ≥46°C produced a temperature-dependent increase in the withdrawal response. Subcutaneous injection of morphine (0.3, 1 and 3 mg/kg), fentanyl (0.005 and 0.01 mg/kg), and tramadol (2.5 and 5 mg/kg) produced a significant dose-dependent inhibition of withdrawal responses from 46-50°C. Compound A (1-20 mg/kg), a selective inhibitor of Nav1.7, dose-dependently inhibited the withdrawal responses at 46°C and 48°C. In contrast, the $GABA_A$ receptor agonist diazepam (2 mg/kg, selected as a negative control to test whether reductions in arm withdrawal were related to sedation) had no effect on the response. These results suggest that this novel preclinical pain behavior model is sensitive to clinically active and putative analgesics.

Title: Haloperidol decreases the hyperalgesia in rats with chronic constriction of the sciatic nerve

Authors: *J. ESPINOSA[1], O. A. JARAMILLO-MORALES[2], F. J. LOPEZ-MUÑOZ[2]; [1]Cinvestav-Ipn, Mexico, D.F., Mexico; [2]Cinvestav-sede sur, Mexico, D.F., Mexico

Abstract: BACKGROUND: Haloperidol shows a high affinity for sigma-1 receptors, and these receptors have been considered as a therapeutic target for the treatment of neuropathic pain, in this sense, the objective of this study was to evaluate the anti-hyperalgesic effect of haloperidol

in a model neuropathic pain. METHODS: Wistar male rats were employed and subjected to chronic constriction injury (CCI), 10 days after surgery the anti-hyperalgesic effect (von Frey test) after single-dose of haloperidol (0.018-0.18 mg/kg s.c.), gabapentin (10-100mg/kg s.c.) and BD-1063 (5.6-56.2 mg/kg s.c.) were tested. To establish whether haloperidol decreases hyperalgesia by antagonism of sigma-1 receptors, it was administered in co-administration with PRE-084 (sigma-1 agonist) by intrathecal route. RESULTS: In all cases the anti-hyperalgesic effects increased in a dose-dependent manner. The time-course analysis shows that gabapentin (100 mg/kg) reached its maximum effect at 90 min after the treatment, producing an anti-allodynic effect of 85.0 ± 3.4 %, whereas BD-1063 (56.2 mg/kg) produced their maximum effect at 30 min with 90.8 ± 2.7 % and haloperidol (0.18 mg/kg) at 30 min with 78.3 ± 4.7 %. These anti-allodynic effects remained during 180 min of observation. Analyzing dose-response curves, Haloperidol and BD-1063 exhibited similar efficacy to gabapentin. For its part regarding the analysis of pharmacological potency, we compare the ED50: Haloperidol BD-1063 antagonist showed higher potency than BD-1063 and gabapentin. The hyperalgesic effect of a sigma-1 agonist was blocked by intrathecal administration of haloperidol. CONCLUSION: These results suggest that haloperidol decreased the hyperalgesic effect in CCI and its effects is mediated by the sigma-1 antagonism, in addition, haloperidol reached similar effects in comparison with gabapentin, suggesting may be potentially useful in the treatment of neuropathic pain.

Title: The long-term effects of saccharin-induced analgesia in infancy on learning and memory during adulthood in rats: role of endogenous opioid system

Authors: *K. NUSEIR[1], K. H. ALZOUBI[2], M. AL-AZZANI[2];
[2]Clin. Pharm., [1]Jordan Univ. of Sci. and Technol., Irbid, Jordan

Abstract: Premature infants are exposed to multiple painful procedures in the NICU. These painful procedures are poorly managed due to difficulty in assessment and fear of adverse effects. Several studies have shown that sweet-tasting solutions given orally produce analgesia, which can be blocked by opioid receptor antagonists. Animal models have shown that intake of

saccharin solution for relatively long periods of time causes analgesia. In this study we examined, using rat pups model, the hypothesis that repetitive painful stimuli during infancy will alter pain sensitivity and impair learning and memory during adulthood, and saccharin will prevent this through its analgesic effects. Naltrexone was given orally to evaluate weather saccharin-induced analgesia is mediated via endogenous opioid system. Pain in rat pups was induced via needle pricks of the paws on (P0). Radial Arm Water Maze test (RAWM) was used to assess learning and memory. Pain threshold through foot-withdrawal response to a hot plate was measured. At the end of behavioral tests animals were killed, hippocampus was dissected, and hippocampal levels of β-endorphin, enkephalin, and brain derived neurotropic factor (BDNF) were assessed using ELISA. At 4 weeks, results show that naltrexone before saccharin with/without noxious stimulation significantly decreased pain sensitivity. At 10 weeks, noxious groups had significantly reduced pain thresholds, and other treatment groups normalized these pain thresholds. Noxious stimulation decreased hippocampal enkephalins and pretreatment with saccharin significantly normalized and increased their level. Naltrexone reversed such effects. Also, hippocampal BDNF were lowered, saccharin before noxious insult significantly prevented such decrement, and naltrexone treatment was comparable to noxious stimulation. In conclusion, acute repeated neonatal pain induced long-term memory impairment during adulthood, and pretreatment with saccharin prevented this via mechanisms that appear to involve BDNF. Interestingly, naltrexone did not antagonize the effects of saccharin, and it may have augmented saccharin effects. Finally our study showed that saccharin with noxious stimulation increased pain threshold probably via a mechanism that involve endogenous opioids.

Title: *In vitro* pain responses of dorsal root ganglion neurons using multi-electrode arrays

Authors: *I. SUZUKI[1], T. IIDA[1], N. MATSUDA[1], A. ODAWARA[1,2,3];
[1]Tohoku Inst. of Technol., Sendai, Miyagi, Japan; [2]Tohoku Univ., Sendai Miyagi, Japan; [3]JST, Tokyo, Japan

Abstract: Dorsal root ganglion (DRG) sensory neurons are pain-related neurons and have a variety of sensory receptors that are activated by chemical, thermal, and mechanical stimuli. Establishment of pharmacological assay in pain research and drug screening is important issue.

Here, we used the multi-electrode array (MEA) system to detect the electrophysiological responses by chemical and thermal stimuli in cultured DRG neurons. After 2 days of culture on the MEA, we observed spontaneous activities and chemical responses. Addition of the capsaicin and menthol induced significant changes of the firing rate and concentration-dependent responses. Furthermore, temperature elevation increased the number of firings and it showed the largest increase at 43 degrees. We confirmed that the typical response of DRG neurons can be easily obtained at same day using MEA system. These results suggested that electrophysiological measurements in DRG neurons using a MEA system may be beneficial for clarifying the functions of DRG neurons in pain research and for drug screening applications.

Title: PI3K isoforms change expression patterns in spinal cord and DRG after inflammation and nerve injury

Authors: *L. S. SORKIN, R. A. PRITCHARD;
Univ. of California San Diego, La Jolla, CA

Abstract: Phosphoinositide 3-kinases (PI3K) are membrane associated signaling enzymes involved in many cellular processes. Class I PI3Ks include α-, β- δ- and γ- isoforms. Blockade of individual PI3K isoforms at different loci is effective in separately reducing inflammation and/or pain behavior. Previous findings indicate distinct cellular loci of PI3Ks within spinal cord and DRGs of naïve rats. The present study extends these findings to animals with peripheral inflammation and nerve injury (SNI).
Sprague Dawley rats were divided into 3 groups; naïve, intraplantar carrageenan (Carra) and SNI. Animals were perfused, spinal cord and L4/5 DRGs were harvested, cryoprotected, sectioned (30 μm for spinal cord, 10μm for DRGs) and prepared for immunohistochemistry. All findings were observed in multiple sections from at least 3 rats. Sections were double labeled with rabbit anti PI3Kα, β, γ or mouse anti PI3Kδ and a cell marker, mouse or rabbit anti-NeuN (neurons), mouse or rabbit anti-glial fibrillary acidic protein (GFAP, astrocytes), anti-Iba1 (microglia), rabbit anti-Olig-2 or mouse anti-APC (oligodendrocytes), mouse anti-CGRP

(peptidergic nociceptive marker), IB4-isolectin (nonpeptidergic nociceptive marker) or mouse anti-NF200 (Aβ marker), to confirm cell locations of each isoform. Images were captured with a Leica TCS SP5 confocal system; single optical sections and z-stacks were taken and images processed with LAS AF software.
In naïve spinal cord, PI3Kα was found in primary afferent terminals in superficial dorsal horn, both Carra and SNI increased PI3Kα intensity, but did not change cell type localization. PI3Kβ was the only isoform found in neurons in any condition, PI3Kβ was also in white matter oligodendrocytes and a small number of astrocytes. Following Carra or SNI, this was largely unchanged. PI3Kδ was found in oligodendrocytes and astrocytes primarily towards the lateral edges of the white matter; following Carra, but not SNI, PI3Kδ glial staining increased and encompassed areas closer to the grey matter. Faint PI3Kγ staining was seen in white matter oligodendrocytes in naïve animals, it was more distinct after Carra and SNI. Co-staining was never seen for any isoform with microglial markers.
In DRG, PI3Kα and β were found in most neurons of all types. In naïve tissue, PI3Kγ was seen in 40.7% ±3.6 (SEM) of all neurons, this did not change with Carra (46.1%±4.9) or SNI (40.9%±4.2). It was highly co-localized with IB4, less so with CGRP and not with NF200. PI3Kδ was not seen in DRG.
Cell types expressing PI3K staining were remarkably stable across all 3 conditions. Acute inflammation increased spinal expression of PI3Kδ in stained glia.

Title: Development of PainScan: An automated videotracking system to measure pain behavior in rodents.

Authors: *B. L. ADAMS[1], R. T. GORS[1], F. LI[2], X. BAI[2], R. M. A. SIMMONS[1], B. FORSTER[1], V. KOBLA[2], Y. LIANG[2], K. L. KNOPP[1];
[1]Neurosci. Drug Discovery, Lilly Res. Labs, Indianapolis, IN; [2]CleverSys, Inc., Reston, VA

Abstract: The automated detection and quantification of behavioral endpoints in pre-clinical research provides a means to screen drugs with a marked improvement in throughput. The tradeoff for high throughput has often been fidelity, in that the probability of including false negatives and false positives is greater. This is particularly of concern when screening putative

analgesics where apparent anti-nociception could in fact be sedation or another side effect confounding the endpoint. In this study, we show the development of a novel video tracking system, PainScan. This system allows automated, high throughput quantification of a number of pain-related behaviors in the rat, while simultaneously identifying potentially confounding behaviors typically indicative of side effects. Leveraging the intraplantar formalin assay, we show that this system detects nocifensive behaviors such as caudally-directed biting similar to human observational scoring. We also show that this system can detect behaviors not typically quantified manually, such as guarding behavior and locomotor activity. Pharmacological modulation of these behaviors with tramadol produced a dose-dependent decrease in the formalin response in both male and female rats. Interestingly, it appeared female rats were more sensitive to the effects of tramadol as the ED50 was 2-fold more potent than in male rats. More importantly, the assay was able to demonstrate presumed analgesic efficacy of a compound that also produced hyperactivity, an effect that could potentially 'wash-out' an analgesic signal in a traditional motion-based automated assay. Here we show that a TRPM8 receptor agonist selectively reduced the caudally-directed licking and biting response to formalin in male and female rats, however also increased activity which would mask an analgesic effect when measured with a traditional automated assay. Further advantages of the system allow us to observe drug effects on activity levels prior to and during testing, potentially reducing the need for secondary assays such as rotorod. Importantly, recorded videos allow the option to re-analyze experiments with new models or algorithms, or even confirm findings by manual scoring without having to repeat a study. Taken together, our data suggest the PainScan system has a number of advantages over existing automated systems which can be leveraged in a number of rodent pain models. Further, the potential to quantify a number of behaviors simultaneously allows for the potential reduction of animals needed in analgesic research.

Abstract: Orthosteric agonists and positive allosteric modulators (PAMs) of the alpha7 nicotinic acetylcholine receptor (nAChR) represent novel therapeutic approaches for pain modulation. Moreover, compounds with dual function as allosteric agonists and PAMs, known as ago-PAMs add further regulation of receptor function. Initial studies examined the alpha7 ago-PAM, GAT107, in the complete Freund's adjuvant (CFA) chronic inflammatory pain model. Additional studies examined the locus of action of GAT107, and immunohistochemical markers in the dorsal horn of the spinal cord in the CFA model. To understand the effectiveness of GAT107 in acute models, the tail flick and hot plate acute thermal nociceptive assays were used. Complementary pharmacological approaches confirmed that the dose-dependent antiallodynic and antihyperalgesic effects of GAT107 were mediated through alpha7 nAChR. However, GAT107 was inactive in the tail-flick and hot-plate assays. Furthermore, intrathecal, but not intraplantar, injections of GAT107 reversed nociception in the CFA model, suggesting a spinal component of action. Immunohistochemical evaluation revealed an increase in the expression of astrocyte-specific glial fibrillary acidic protein and phosphorylated p38-mitogen-activated-kinase within the spinal cords of mice treated with CFA, which was attenuated by intrathecal GAT107 treatment. Importantly, GAT107 did not elicit motor impairment. Collectively, these results provide the first proof-of-principle that alpha7 ago-PAMs represent an effective pharmacological strategy for treating chronic inflammatory pain.

Title: Endomorphin analogs provide potent and long-lasting antinociception in multiple pain models relative to morphine

Authors: *A. K. FEEHAN[1], J. MORGENWECK[4], A. AMGOTT-KWAN[1], X. ZHANG[2,5], J. E. ZADINA[1,2,3,5];
[1]Neurosci. Program, [2]Med., [3]Pharmacol., Tulane Univ., New Orleans, LA; [4]Jackson Lab., Bar Harbor, ME; [5]SE Louisiana Veterans HCS, New Orleans, LA

Abstract: Opioids that act at the mu-opioid receptor have been the clinical standard for pain relief even though side effects of these compounds have led to an epidemic of abuse and overdose deaths. We recently characterized mu-opioid receptor selective endomorphin (EM) analogs that provide potent antinociception with reduction or absence of numerous side effects of traditionally prescribed opioids including: abuse liability, respiratory depression, motor impairment, tolerance, and inflammation. The current study explores the effectiveness of these EM analogs relative to morphine in models of neuropathic, inflammatory, and postoperative pain by both intrathecal and intravenous injection in male, Sprague-Dawley rats. Mechanical allodynia was assessed using Von Frey testing after spared nerve injury (SNI), a model of neuropathic pain, and paw incision surgery, a model of postoperative pain. Mechanical hyperalgesia was evaluated by Randall-Selitto testing in the SNI model, and thermal hyperalgesia was determined by Hargreaves testing in the Complete Freund's Adjuvant (CFA) model of inflammatory pain. In all tests, EM analogs, particularly analog 4 (ZH853), were of equal or greater potency and had greater duration of action relative to morphine. The data suggest that this EM analog could provide effective therapy for a broad range of pain conditions with low risk of addiction and other adverse side effects caused by currently used opioids such as morphine.

Title: Characterization of new stable NTS2-selective neurotensin analogs

Authors: ***M. VIVANCOS**[1], R. FANELLI[2], M. ORLIAGUET[1], J. COTÉ[1], É. BESSERER-OFFROY[1], A. MURZA[1], J.-M. LONGPRÉ[1], J. THOMAS[3], J. MARTINEZ[2], F. CAVELIER[2], P. SARRET[1];

Abstract: The tridecapeptide neurotensin (NT) has emerged as an important modulator of nociception transmission exerting its biological activity by interacting with class A G protein-coupled receptors, namely NTS1 and NTS2. Over the past few decades, much research effort has been directed at designing stable and selective NT compounds acting at the NTS1 receptor site. However, binding of NT to NTS1 not only induces analgesia but also results in hypotension and hypothermia, which may represent barriers to adequate pain management. Importantly, as opposed to NTS1, there is now substantial evidence supporting that NTS2-selective agonists may mediate analgesia without exerting changes in blood pressure or body temperature. Here, our goal was thus to design and characterize novel NT analogs with high affinity and selectivity toward NTS2. To this aim, we synthesized a series of NT(8-13) analogs harboring site-specifically modified natural or unnatural amino acids and reduced amide bonds. Binding studies demonstrated that the substitution of the aromatic residue in position 11 by a positively charged amino acid (Lys) as well as incorporation of a reduced amide bond between Lys^8-Lys^9 (called JMV-5964) improved the selectivity by more than 100-fold toward NTS2 (4500 nM and 28.7 nM for NTS1 and NTS2, respectively) and greatly increased the plasma stability, with half-life exceeding 2 hours. Additional modification of this compound by replacement of the Leu^{13} residue with the more hydrophobic (trimethylsilyl)alanine (TMSAla) non-natural amino acid (designed as JMV-5966) resulted in improved affinity for both NTS1 and NTS2 receptors (166

nM and 1.38 nM, respectively). In the acute thermal tail-flick test, we found that intrathecal (i.t.) injection of JMV-5966 at a dose of 30 µg/kg produced a significant and sustained analgesic response for up to 1 hour compared to saline–treated rats while JMV-5964 had no analgesic effect at the equimolar dose tested. Both JMV-5964 and JMV-5966 did not produce hypothermia at the effective analgesic dose and were not effective in inhibiting carbachol-induced ileal smooth muscle relaxation. Finally, the *in vivo* NTS2-selectivity of JMV-5966 was demonstrated with the NTRC-844 compound, acting as a potent NTS2-selective antagonist. Indeed, a significant reversal of the analgesic effects on thermal hypersensitivity was observed when 30 µg/kg of JMV-5966 was injected i.t. in the presence of an excess of NTRC-844. In conclusion, these results reinforce the importance to develop new stable NTS2-selective agonists to improve pain control and reduce the peripheral effects of NT related to NTS1 activation.

Title: Novel RET agonist for the treatment of experimental peripheral diabetic neuropathy

Authors: *H. VIISANEN-KUOPILA[1], Y. A. SIDOROVA[2], U. NUOTIO[2], V. JOKINEN[1], T. LILIUS[1], P. RAUHALA[1], E. KALSO[1,3], M. KARELSON[4], M. SAARMA[2];

Abstract: Background and aims: Treatment of pathological pain such as pain due to peripheral diabetic neuropathy (PDN) is complicated since many pathophysiological processes within the nervous system such as hyperexcitability and loss of sensory neurons are mediated. There is no existing regenerative treatment for PDN. The proteins supporting and regenerating neurons such as the glial cell line-derived neurotrophic factor (GDNF) family ligands (GFLs) artemin and

GDNF alleviate the symptoms of neuropathic pain. We have discovered and characterized a chemical compound, a GFL mimetic MIM4, that activates GFL receptors. Here we studied whether MIM4 attenuates the behavioural pain responses of experimental diabetic neuropathy.
Methods: DM was induced by streptozotocin (60 mg/kg i.p.) in male Wistar rats. The GFL mimetic MIM4 or vehicle was administered subcutaneously (s.c.) every other day for six weeks after one day of the induction of diabetes. Mechanical hypersensitivity was assessed using the paw pressure test and cold allodynia was tested with acetone test.
Results: The GFL mimetic MIM4 (5 mg/kg s.c.) attenuated mechanical hypersensitivity and cold allodynia in diabetic animals.
Conclusions: Results suggest that the GFL mimetic MIM4 is a potential lead for the development of novel pain-relieving agents for the treatment of peripheral diabetic neuropathy.

Title: Validation of a nitroglycerin-induced episodic migraine model in rats

Authors: *H. M. HARRIS[1], J. M. CARPENTER[2], J. R. BLACK[1], T. A. SMITHERMAN[1], K. J. SUFKA[1];
[1]Psychology, [2]Res. Inst. of Pharmaceut. Sci., Univ. of Mississippi, University, MS

Abstract: This research sought to further validate a nitroglycerin (NTG) induced episodic migraine model in rats by 1) tracking endpoints of photophobia, motor activity, and facial pain expressions across each NTG episode and 2) introducing a novel apparatus for quantifying spontaneous allodynia 3) evaluating the effects of NTG vehicle against a sham (saline) control on these behavioral endpoints. Rats received NTG (10 mg/kg/2ml), NTG vehicle, or saline every third day over 14 days. Behavioral endpoints were assessed 110 minutes post NTG

administration and included time spent light/dark chambers for photophobia as well as activity, facial pain expressions, and tactile allodynia. Animals administered NTG experienced photophobia, decreased activity, and increased facial pain expression. The progression of tactile allodynia was apparent in the NTG group alone. Animals treated with the NTG vehicle experienced photophobia, decreased activity, and facial pain expressions similar to that of NTG treated animals. These findings suggest the NTG vehicle alters migraine-related behavioral endpoints to some degree and thus the most appropriate control group should be either a sham (i.e., saline) or a negative control. These findings align with the clinical symptoms of migraine and provide a more translational and clinically- relevant model of episodic migraine.

Title: A novel pain assay using a transgenic mouse expressing hNa_v1.7 with an inherited erythromelalgia mutation: comparison with traditional models for inflammatory and neuropathic pain

Authors: S. HOWARD[1], G. BANKAR[1], K. NELKENBRECHER[1], M. WALDBROOK[1], Z. XIE[1], K. KHAKH[1], E. CHANG[1], C. YOUNG[1], S. LIN[1], J. P. JOHNSON, Jr.[1], L. E. SOJO[1], A. LINDGREN[1], N. [1]Xenon Pharmaceuticals, Burnaby, BC, Canada; [2]Genentech, South San Francisco, CA

Abstract: Na_V1.7 is an attractive target for analgesic drug development because loss-of-function mutations result in congenital indifference to pain with little or no effect on motor or cognitive function. Moreover, gain-of-function mutations result in inherited erythromelalgia (IEM) and other painful conditions. We have developed novel blockers of hNa_V1.7 that are highly selective vs. Na_V1.5 and a humanized transgenic mouse was developed for *in vivo* testing of drug development candidates. Transgenic FVB mice were generated by incorporation of a BAC gene coding for hNa_V1.7 with the IEM mutation I848T. Target engagement was evaluated in these mice with a novel aconitine-induced hindpaw flinching/licking assay that employs manual scoring.

Transgenic mice express high levels of hNa_V1.7 mRNA in DRGs and olfactory bulbs, areas of high expression of the endogenous mouse channel. When challenged with a subcutaneous hindpaw injection of the sodium channel agonist, aconitine, a reproducible and quantifiable flinching/licking response is observed for up to 60 minutes. The aconitine effects are dependent on the presence of the transgene since a comparable injection of aconitine into wild type mice induces minimal nocifensive behaviors. The model provides a well-defined PK-PD relationship and facilitates the rapid evaluation of compounds. The analgesic activity of sodium channel blockers was characterized both in the transgenic IEM assay and in traditional pain assays using littermate wild-type mice. We have utilized two acylsulfonamides that are potent inhibitors of [^{3}H]GX-545 binding to Na_V1.7. This ligand targets a binding site on VSD4 that can have a high degree of molecular selectivity (Ahuja et al., 2015). One compound has limited selectivity against Na_V1.1, Na_V1.2, and NaV1.6, while the second is >10-fold selective against these isoforms. However, with allowance for modest differences in IC_{50} for mouse vs. human Na_V1.7, both compounds are equipotent in the IEM target engagement assay and in assays using littermate wild type mice. The assays include inflammatory pain induced by complete Freund's adjuvant or formalin or neuropathic pain caused by treatment with streptozotocin. These comparative studies with compounds that differ in selectivity among Na_Vs indicate that block of Na_V1.7 alone is sufficient for broad analgesic activity against inflammatory and neuropathic pain.

Polytechnic Inst., México, Mexico; [4]Lab. of Neuropharm. of Natural Products. Neurosci. Div., Natl. Inst. of Psychiatry "Ramón de la Fuente Muñiz, Ciudad de Mexico, Mexico

Abstract: Fibromyalgia (FM) is a musculoskeletal syndrome characterized by chronic widespread pain, tenderness to palpation and various concomitant symptoms, including affective disorders such as depression. FM affects almost a 2% of the population. Drugs with confirmed efficacy for the treatment of FM produce adverse effects promoting treatment discontinuation. Scientific studies have corroborated analgesic and anti-inflammatory properties of flavonoids such as quercetin. In this study, we analyzed the antiallodynic activity of quercetin using the reserpine-induced myalgia model of FM. Three groups (n=6/group) of male Wistar Rats (250-300 g) were trained to Randall-sellito test 3 days before vehicle (acetic acid 0.05%) or reserpine administration (1 mg/kg, s.c. during 3 consecutive days), muscle pressure and cold allodynia

thresholds were determined during thirty days post-inducction. In addition, we evaluated on day 5 after, the last reserpine injection, the effect of vehicle (solution saline), quercetin (562.3 mg/kg i.p.) and fluoxetine (10 mg/kg i.p). The muscle pressure and cold allodynia thresholds were measured before drugs' administration and at 30, 60,120, 150, 180, 210 and 240 min after treatment. Analysis by two-way repeated-measures ANOVA revealed that subcutaneous injection of reserpine produces significant diminution in the muscle pressure threshold in 50% of subjects, whereas, in the cold allodynia test, the injection of reserpine increased in 9-fold the time response in acetone spray test.Quercetin and fluoxetine reverted the effect of reserpine in the muscle pressure threshold in 82.97% and 71.93%, respectively. Latency to the antiallodynic effect of quercetin was delayed at 30 min reaching a maximum effect after one hour remaining during 3 hours more. In conclusion, these results give evidence that systemic quercetin administration produces analgesic effects in an experimental model of FM supporting the potential of quercetin for the FM therapy. Supported by CONACYT 226454 and 80811 grants.

Pharmacol., Soonchunhyang Univ., Cheonan, Korea, Republic of

Abstract: Valeriana genus has been widely used in popular medicine for centuries, to treat sleep disorders, anxiety, epilepsy, and insomnia. Recent studies have focused on the novel

pharmacological effects of Valeriana fauriei Briq. (VF) species. Some of these have attempted to explain the pharmacological aspects in various diseases in humans as being neuroprotective effects of reducing pain and stress. In the present study, we constructed a fibromyalgia (FM) animal model that was induced by intermittent cold stress (ICS) with slight modification. We examined whether VF has antinociceptive effects on the FM-like model after oral administration of VF extracts. The effects of VF extracts on the FM model were investigated by analysis of behavioral activity from pain and analysis of protein expression. In the behavioral analysis, the nociception tests showed that the pain threshold was significantly decreased in the FM group. Subsequently, western blot analysis and immunohistochemical analyses of the medial prefrontal cortex and hippocampus showed downregulation of BDNF and phospho-CREB (pCREB) proteins in the FM group. These results provide evidence that the effects of VF extract in the FM model may be related to its modulating effect on the BDNF signaling pathway in the hippocampus and medial prefrontal cortex, which may be involved in the mechanism by which VF extract is effective as a therapeutic agent for FM.

Title: Mixed sigma-1 / sigma-2 ligands as analgesics: studies with ANAVEX 1066 in animal models of neuropathic pain and visceral pain

Authors: *J. S. SPROUSE[1], N. REBOWE[1], Y. DARBAKY[2], L. DIOP[2], D. KLAMER[1], C. MISSLING[1];
[1]Anavex Life Sci., New York, NY; [2]ANS Biotech, Riom, France

Abstract: BACKGROUND: ANAVEX 1066 (AV1066), a mixed Sigma-1/Sigma-2 receptor ligand, has previously demonstrated antitumor activity as well as analgesic effects in animal models (Riganas et al., J. Med. Chem. 55:1041, 2012). Current therapies for neuropathic and visceral pain are not satisfactory and thus new drugs acting on novel molecular targets are actively being investigated. Earlier work supports the role for Sigma receptors in modulating nociception and, in the present study, AV1066 was further evaluated in models of neuropathic pain and visceral pain.
METHODS / RESULTS: Chronic constriction injury (CCI) was employed as a model of

neuropathic pain (Bennett & Xie, Pain 33:87, 1988). Briefly, a loose ligature around the sciatic nerve was performed in rats, resulting in mechanical hyperalgesia in the ipsalateral hind limb as measured 14 days later. Single administration of AV1066 (10, 30, 100 mg/kg PO, n=10/group) produced a dose-dependent reduction in nociceptive threshold in the affected paw. Efficacy was apparent 30 minutes post dose and remained significant for 2 hours, a time course comparable to the single SC dose of morphine that served as the positive control. In separate experiments, colonic hypersensitivity was induced by injection of TNBS (2,4,6-trinitrobenzenesulfonic acid) directly into the proximal end of the colon; 7 days later inflation of a balloon inserted into the distal end was employed to yield a painful response (Diop et al., JPET 302:1013, 2002). Single PO administration of AV1066 (n=10/group) returned the colorectal distention threshold to control levels within the same dose range as that used in the CCI model. U-50,488H, a kappa agonist, served as the reference standard. No untoward effects of AV1066 were observed in either study.
CONCLUSIONS: AV1066 showed robust, dose-dependent efficacy in 2 different animal models of pain, the CCI model of neuropathic pain and the TNBS model of visceral pain, suggesting therapeutic potential in 2 distinct and poorly served patient populations. Further studies will (1) confirm the safety profile suggested in the current studies, (2) explore synergy in combination with subthreshold doses of marketed analgesics, and (3) expand the product profile with the use of additional animal models of chronic pain.

Title: Endocannabinoid system alterations in chronic pain states

Authors: *Y. MULPURI[1], D. DANG[2], B. L. SCHMIDT[2], H. H. SELTZMAN[3], I. SPIGELMAN[1];
[1]Div. of Oral Biol. & Med., UCLA Sch. of Dent., Los Angeles, CA; [2]Dept. of Oral & Maxillofacial Surgery and Bluestone Ctr. for Clin. Res., New York Univ. Col. of Dent., New York, NY; [3]Ctr. for Drug Discovery, Res. Triangle Inst. Intl., Research Triangle Park, NC

Abstract: We developed synthetic peripherally-restricted cannabinoids (PRCBs) and demonstrated low efficacy of their antinociceptive effects (e.g., changes in latency to tail-flick in response to radiant heat) (Mulpuri et al, SFN Abstr. Vol. 37:173.21, 2012). However, PRCBs are highly effective at alleviating mechanical and thermal allodynia symptoms in rodent models of cancer, burn injury, sciatic nerve entrapment (SNE)-induced neuropathy, and chemotherapy (cisplatin)-induced peripheral neuropathy (CIPN). Here we tested the hypothesis that the higher anti-allodynic versus antinociceptive efficacy of PRCBs is due to disease-induced alterations in the endocannabinoid system. Naïve and sham treatment animals were compared to murine models of oral cancer and rat models of burn injury, SNE- and cisplatin- induced neuropathies for PRCBs' effects on withdrawal thresholds to mechanical or thermal stimuli. Lumbar (L4 and L5) dorsal root ganglia (DRG) from separate cohorts were examined using qPCR for changes in the mRNA expression of cannabinoid receptors CB1R and CB2R, endocannabinoid synthesizing enzymes N-acyl-phosphatidylethanolamine (NAPE), diacylglycerol lipase (DAGL), metabolizing enzymes monoacylglycerol lipase (MAGL), and fatty acid amide hydrolase (FAAH). Changes in CB1R expression were also examined using Western blot in DRG. Paw cancer (inoculated with human oral carcinoma cells) mechanical allodynia was ~75% suppressed by 0.6 mg/kg intraperitoneal PrNMI (4-{2-[-(1E)-1[(4-propylnaphthalen-1-yl)methylidene]-1H-inden-3-yl]ethyl}morpholine). In SNE rats, PrNMI (0.6 mg/kg, i.p.) increased ipsilateral mechanical thresholds by 29 ±2 g, but only by 8±4 g in sham rats. Similarly, in burn injury and CIPN rats PrNMI (0.6 mg/kg, i.p.) increased mechanical withdrawal thresholds by 20±3 and 29±4 g, respectively. CB1R immunofluorescence was previously shown to increase in L5 DRG of paw cancer mice (Guerrero et al, Neurosci. Lett. 12:77-81, 2008). In DRG ipsilateral to burn injury, only CB2R mRNA was significantly (~38%) upregulated. By contrast, neither the receptors nor the endocannabinoid system enzymes were significantly upregulated in DRG of SNE or CIPN rats. DAGL was significantly downregulated in CIPN versus control rat DRG. Our data suggest that in SNE and CIPN neuropathies, increased efficacy of PRCBs is not due to increased CBR expression in sensory neurons.

Abstract: Fibromyalgia (FM) is a musculoskeletal syndrome characterized by chronic widespread pain, tenderness to palpation and various concomitant symptoms, including sleep and affective disorders. In addition, several surveys have reported that approximately 80 to 90 % of FM patients are women and has been reported that hormonal abnormalities due to an early age-of-onset menopause might play an important role in the altered processing of somatosensory information. Drugs with confirmed efficacy for the treatment of FM produce adverse effects that promote treatment discontinuation. Scientific studies have corroborated analgesic and anti-inflammatory effects of flavonoids such as rutin (quercetin-3-O-rutinoside) that is a glycoside of the well known aglycon quercetin. Different animal models of FM mimetic the pain and depression-like behaviors, but have not considered other factors such as sleep disturbance, therefore, we decided analyze if some of the sleep disorders reproduce in the reserpine-induced myalgia model. In addition we analyzed the effect of rutin flavonoid in the pain and sleep disorders. Twelve groups (n=8/group) of female Wistar Rats (200-250 g) were ovariectomized 14 days before reserpine (1 mg/kg, s.c. during 3 consecutive days) injection. An extra healthy control group was added. Rutin was administrated at increasing doses (30-1000 mg/kg, i.p.). Pramipexole (1 mg/kg s.c.) was used as the analgesic reference drug. All drugs were evaluated on day 5 after the last reserpine injection. In the experiments of sleep architecture electrodes were implanted in cerebral cortex, hippocampus and muscle. Rutin was administrated at 562 mg/kg i.p. Analysis by two-way repeated-measures ANOVA revealed that rutin, in a dose-dependent manner, reverted the effects of reserpine on muscle pressure (ED30=288 mg/kg), tactile response (ED30=894 mg/kg) and cold allodynia (ED30=929 mg/kg), reaching its maximum effect after one hour. Respect to sleep architecture we found increases in the total wake time and decreases in the total N-REM y REM time, systemic administration of rutin reverted increases in the total wake time and partially decreases of the total N-REM time. In conclusion, these results give evidence that systemic rutin administration produces analgesic

effects and procudes positive changes in sleep architecture in an experimental model of FM supporting the potential of rutin for the FM therapy.

Title: An objective method to assess the anti-migraine properties of delta-9-tetrahydrocannabinol (THC) in the female rat

Authors: *R. KANDASAMY[1], C. M. MISKELL[2], M. M. MORGAN[2];
[1]Integrative Physiol. and Neurosci., Washington State Univ., Vancouver, WA; [2]Psychology, Washington State Univ. Vancouver, Vancouver, WA

Abstract: Migraine affects 15% of the world's population, yet treatment options are either ineffective or accompanied by adverse effects such as medication overuse headache. Anecdotal and clinical evidence suggest that cannabinoids present in marijuana have anti-migraine properties. Unfortunately, the assessment of new treatments is limited by the difficulty assessing migraine in animal studies. Thus, the two objectives of the present study are to determine whether depression of home cage wheel running can be used to assess migraine pain in female rats, and to assess the anti-migraine properties of delta-9-tetrahydrocannabinol (THC). Most preclinical studies of migraine assess hindpaw and/or periorbital allodynia as a measure of migraine pain; however, allodynia is not present in all patients and may only be a marker for the progression of migraine. Furthermore, these studies only include male rodents, despite the fact that migraine is three times more common in women than men. The present study tested the hypothesis that administration of THC prevents migraine-depressed wheel running in female rats. Migraine pain was induced in female rats by microinjection of the TRPA1 agonist allyl isothiocyanate (AITC, 1-10%) onto the dura via a cannula previously implanted through the skull. Rats were injected with saline, THC (0.32-3.2 mg/kg), or the prototypical anti-migraine agent sumatriptan (1 mg/kg) 1 min later. Microinjection of AITC caused a concentration-

dependent reduction in wheel running that lasted approximately 4 hours. Low doses of THC and sumatriptan prevented migraine pain-depressed wheel running. In contrast, higher doses of THC depressed wheel running, suggesting that these doses are sedative. Taken together, these data indicate that wheel running is an effective approach to assess the functional consequences associated with migraine pain and that THC may be an effective treatment.

Title: Targeting NGF and TrkA to control neuropathic pain: long lasting analgesic effect of anti-NGF and anti-TrkA antibodies in Chronic Constriction Injury mouse model

Authors: *M. D'ONOFRIO[1], E. FIORI[2,1,3], R. BRANDI[1], I. ARISI[1], F. MALERBA[4,1], F. LA REGINA[1], R. CERNA[4,1], S. TURTURRO[1], S. MARINELLI[3,5], V. VACCA[3,5], F. PAVONE[3], A. CATTANEO[4,1];

Abstract: Background and Aims: So far, there are no effective treatments for neuropathic pain (NP) and current treatments suffer from unwanted side effects. The NGF ligand-receptor system has emerged as a promising target for NP. We have previously demonstrated that anti-NGF (mAb alphaD11) and anti-TrkA (mAb MNAC13) monoclonal antibodies induce a long lasting analgesic effect in NP models (Ugolini et al 2007;Covaceuszach et al 2012). To understand the role of the NGF system in NP, we evaluated in a mouse model of NP: i) how long the analgesic effect was maintained following the end of the antibody treatment ii) structural and morphological changes in peripheral and central nervous system iii) the long-term gene expression changes during and after the NGF/TrkA targeting analgesic treatments. Methods: To induce NP, Chronic Constriction Injury (CCI) of the right sciatic nerve was performed in C57BL/6J adult male mice. Mice were intraperitoneally administered with mAb MNAC13 or mAb alphaD11 (70 or 100 microg/mouse/day) from day 3 until day 10 post CCI. Analgesic effects were tested with a Dynamic Plantar Aesthesiometer. Spinal cords and sciatic nerves were

collected for immunohistochemistry while Dorsal Root Ganglia (DRG), spinal cord and cortex for microarray analysis, at days D3, D11, D24, D90 post CCI. Measurement of serum antibody levels was performed by ELISA. The experimental protocol was approved by Italian Ministry of Health (n. 21/2014, according to D.Lgs 26/2014). Results: Treatment with anti-NGF mAb alphaD11 or anti-TrkA mAb MNAC13 induces significant dose- and time-dependent analgesic effects. The higher doses of both antibodies have long-lasting antiallodynic effect, from D10 to D90 post-CCI. Immunohistochemistry shows significant differences in inflammatory and myelination markers, with better nerve regeneration and reduced astrocyte activation. mAb MNAC13 treatment modulates the highest number of Differentially Expressed Genes (DEGs) in DRG, compared to spinal cord and cortex. Analysis of DEGs following anti-NGF treatment is ongoing. The remarkable long lasting analgesia by NGF/TrkA targeting antibodies will be correlated to changes in gene expression and measurement of serum antibody levels. Conclusions: Data prove that i) anti-NGF and anti-TrkA antibodies counteract NP, showing a very long lasting analgesic effect and induction of regenerative processes ii) the DEGs induced by mAb MNAC13 reveal a number of new targets linked to long lasting analgesia. This is the first direct comparison of the analgesic effects of anti-NGF and anti-TrkA antibodies. The results strongly support the importance of targeting NGF and TrkA for the control of NP.

Title: Structural basis of human glycine receptor potentiation by a novel class of analgesic small molecules

Authors: *J. R. SIMARD[1], X. HUANG[2], P. SHAFFER[2], S. AYUBE[2], H. BREGMAN[3], H. CHEN[4], S. LEHTO[5], J. LUTHER[1], D. MATSON[1], S. MCDONOUGH[1], S. SCHNEIDER[1], Y. TEFFERA[6], S. YI[3], M. ZHANG[5], E. DIMAURO[3], J. GINGRAS[1];

Abstract: Current classes of therapies to treat persistent pain and neuropathic pain are limited by poor efficacy, side effects, and risk of addiction. Here, we present a novel class of potent, selective and CNS-penetrant potentiators of glycine receptors (GlyRs), ligand-activated chloride ion channels expressed in the spinal cord. AM-1488 increased inhibitory synaptic transmission in mouse spinal cord and in vivo demonstrated robust reversal of mechanical allodynia induced by nerve injury, a model of neuropathic pain. An X-ray co-crystal structure was obtained of human homopentameric GlyRa3 channels complexed with AM-3607, a potentiator of the same class with increased potency, and the agonist glycine, at 2.6Å resolution. Glycine binds to the orthosteric site at the subunit interface in the extracellular domain with a water molecule that forms part of the binding site. AM-3607 binds to a novel allosteric site between subunits, adjacent to the orthosteric site. Our results provide new insights into the potentiation of Cys-loop receptors by positive allosteric modulators and offer promise of structure-based design of GlyR modulators for the treatment of neuropathic pain.

Title: Development of a high capacity assay for identification of compounds specifically modulating excitability in pain conducting sensory neurons

Authors: C. NODIN, C. LINDWALL-BLOM, Å. JÄGERVALL, J. PIHL, J. SVENSSON DALÉN, S. LARDELL, A. KARLSSON, M. KARLSSON, *P. KARILA;
Cellectricon AB, Molndal, Sweden

Abstract: Patch clamp recordings performed using cultured dorsal root ganglion (DRG) neurons, afford unique insight into the excitability of native tissue but is extremely low-throughput. Alternatively, by utilizing arrayed electric field stimulation (EFS) electrodes to induce membrane depolarization, in combination with a calcium-sensitive fluorescent dye, the action potential can be indirectly monitored in excitable cells cultured in a plate-based format. The EFS technique therefore provides a dramatically higher-throughput means of quantifying the excitability of native tissues such as primary DRG neurons.

However, although the cells that respond to EFS consist exclusively of neurons, they belong to different sensory modalities (nociceptors, mechanoreceptors and proprioceptors). We hypothesized that being able to specifically investigate the pharmacological action on pain-conducting (i.e. nociceptive) neurons would increase the disease relevance of the assay and thus steer away from compounds acting more broadly on all types of sensory neurons. The goal of the current study was therefore to develop a new assay to specifically investigate the pharmacological effects of modulators of cellular excitability in the pain-signalling population of DRG neurons.
To meet the project goal, we developed a combined single cell resolution EFS and high content screening (HCS) assay to specifically analyze pharmacological effects in nociceptive neurons. We transfected adult rat DRG cultures with a genetically encoded calcium sensor, GCaMP6, using electroporation on the Cellaxess® Elektra platform after two days in vitro (DIV). After another two DIV, the DRG neurons were excited by EFS and subsequently stained for RIIβ. This enabled analysis of pharmacological action on excitability in the nociceptive (RIIβ-positive) neurons only.
For the non-selective tool compounds (e.g. tetracaine and mexiletine), we found an excellent correlation between sodium channel blockade measured by EFS in the previously reported Ca5 assay and the newly developed GCamP6/HCS assay. For more subtype selective compounds, the potency was dramatically increased in the newly developed GCamP6 assay which is therefore more suitable for detecting more subtle compound effects.
The results strongly suggest that this EFS platform can be used to screen for modulators of excitability with preferential action on targets in nociceptive neurons such as NaV1.8 and NaV1.9 in a high-throughput manner, enabling identification and prioritization of compounds likely to modulate chronic pain early on in the drug development process.

Title: Voluntary exercise can attenuate many abnormal behaviors and perigenital allodynia resulting from early life stress in male mice

Authors: *I. FUENTES, A. N. PIERCE, O. C. ELLER, R. WANG, J. A. CHRISTIANSON; Univ. of Kansas Med. Ctr., Kansas City, KS

Abstract: Chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) and interstitial cystitis/painful bladder syndrome (IC/PBS) share overlapping symptomology and are commonly co-diagnosed. Nearly half of those diagnosed with CP/CPPS or IC/PBS also suffer from mood disorders, such as depression and/or anxiety. Many of these patients have a history of early life stress, which has been associated with maladjusted stress response in adulthood driven by improper functioning of the hypothalamic-pituitary-adrenal (HPA) axis. Etiology of either syndrome remains to be elucidated; therefore, diagnosis and development of effective treatment strategies are complicated or hindered. However, voluntary exercise has been shown to improve symptom severity and reverse many symptoms attributed to HPA axis dysfunction in clinical and preclinical studies. Here we investigated the therapeutic potential of voluntary wheel running in preventing or reversing perigenital and anhedonic behaviors, as well as associated molecular changes in a male mouse model of neonatal maternal separation (NMS). Mice were born in house and underwent NMS from postnatal day 1 to 21. Mice were given running wheels at 4 (-Eex) or 8 weeks of age (-Lex). Sedentary controls for each group (-Esed and -Lsed, respectively) remained in their home cages. NMS-Esed and NMS-Lsed mice exhibited perigenital mechanical allodynia, and increased micturition rates; which were not observed in NMS-Eex or NMS-Lex mice. Mice displayed variable anhedonic and anxiety behaviors in response to NMS and exercise as measured by sucrose preference and elevated plus maze, respectively; though NMS mice ran shorter distances than naïve mice and could suggest altered reward signaling. Increased mast cell degranulation in the bladder and prostate were prevented and reversed by exercise, though there were varying effects on mast cell associated gene products in those tissues. Central gene changes, in addition to mast cell degranulation, supported a dysregulation of the HPA axis. Early and late exercise had varying effects on hypothalamic and hippocampal mRNA levels. Early exercise increased CRF_2 mRNA in the hypothalamus, though no significantly different changes in other genes were observed in late exercised mice. Late exercise increased mineralocorticoid receptor and brain derived neurotrophic factor (BDNF) mRNA levels in the hippocampus, but this was not observed in early exercised mice. Together, these data suggest NMS in male mice may be a viable pre-clinical model for commonly co-diagnosed urogenital and mood disorders

and voluntary exercise may be a therapeutic intervention for increasing limbic regulation of the HPA axis.

Title: Investigating the impact of early life stress and voluntary exercise on comorbid chronic pain and mood disorders in mice

Authors: *O. ELLER, A. PIERCE, I. FUENTES, J. CHRISTIANSON;
Univ. of Kansas Med. Ctr., Kansas City, KS

Abstract: Millions of Americans suffer from co-morbid chronic pain and mood disorders, which has been linked to altered functioning of the hypothalamic-pituitary-adrenal (HPA) axis, often caused by adverse experiences during development. We have established a mouse model of early life stress, neonatal maternal separation (NMS), that displays urogenital hypersensitivity, as well as altered limbic regulation of the HPA axis. Here we are investigating if NMS mice display evidence of comorbid abnormalities, including facial allodynia and altered reward behaviors, and whether exercise can attenuate changes associated with disrupted HPA axis regulation. Mice were born in-house and underwent NMS from postnatal day (P) 1 through 21 or remained undisturbed in their home cage (naïve) until weaning on P22. At either 4 or 8 weeks of age, NMS and naïve mice were placed in cages equipped with running wheels (exercised, -ex) or remained in their home cage (sedentary, -sed) for 4 additional weeks. Measurements of interest were taken

at 8 and 12 weeks of age. Facial allodynia was measured by recording the time spent grooming the face and head following the application of a fine water mist to the face. Female NMS-sed mice spent a significantly longer time grooming than naïve-sed mice and exercise beginning at 4 weeks reduced facial grooming time in both groups. No difference in grooming time was observed between male NMS-sed and naïve-sed mice. Sex differences were also observed in mast cell (MC) degranulation and distribution patterns in female and male dura mater, a tissue involved in migraine. Female NMS-sed mice displayed a significantly higher percentage of degranulated MC, whereas male NMS-sed mice exhibited significantly greater MC infiltration compared to their naïve counterparts. Exercise normalized both MC activation and infiltration. Female NMS mice displayed evidence of altered reward behaviors, including running fewer km/day than female naïve mice. Female NMS-sed mice also had a significantly higher preference for 1% sucrose in a two-choice liquid preference test, compared to naïve-sed mice. No differences in sucrose preference were observed between naïve-ex and NMS-ex mice. Evidence of altered facial sensitivity and reward behaviors, in addition to our previously documented urogenital hypersensitivity, suggest that NMS mice may provide a useful model for elucidating many of the consequences of early life stress exposure. Furthermore, our observed sex differences and beneficial response to voluntary exercise are indicative of clinical findings.

Title: Optogenetic investigation of epithelial-neuronal communication in the colon

Authors: *S. NAJJAR, P. PATEL, K. ALBERS, B. DAVIS;
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Functional gastrointestinal disorders such as irritable bowel syndrome (IBS) affect over 11% of the global population and their pathophysiology is largely unknown. These painful disorders are characterized by visceral hypersensitivity, which originates in the primary afferent neurons innervating the colon. In addition to intrinsic changes in these afferents, epithelial cells

in the colon may also contribute to this hypersensitivity. It is known that these epithelial cells can release neurotransmitters such as ATP, acetylcholine, and serotonin, but the nature of their communication with colonic afferents remains unclear. Using optogenetic techniques in which channelrhodopsin (ChR2) is targeted specifically to the colon epithelial cells, we are able to activate these cells without the simultaneous activation of primary afferents that occurs with application of mechanical and chemical stimuli onto the colon. In an *ex vivo* preparation, we isolated the distal colon and intact pelvic nerve and recorded the activity of single fibers. Our studies show that optogenetic activation of the epithelium can directly initiate robust action potential firing in colonic afferents of different functional classifications. We further showed through pharmacology that ATP is an important chemical messenger in this epithelial-nerve communication. Application of ATP receptor antagonists decreased or abolished action potential in over half of the afferents that responded to epithelial cell activation. With additional studies targeting other receptors on primary colonic afferents, we seek to further elucidate the mechanisms of epithelial cell-derived activation of colonic afferents and its relation to pain. Furthermore, we will investigate how this communication changes during a state of chronic inflammation as seen in inflammatory bowel disease. Thus, better understanding of the epithelial-neuronal interaction will reveal potential targets for treatment of intestinal pain.

Title: Acute colitis alters the functional properties of mouse lumbosacral dorsal horn neurons - an *In vivo* study

Authors: *K. E. FARRELL, S. KEELY, B. A. GRAHAM, R. J. CALLISTER;
Univ. of Newcastle, Callaghan, Australia

Abstract: Aim of investigation: Chronic abdominal pain is a debilitating symptom of Inflammatory Bowel Disease (IBD) that often persists in the absence of active inflammation. While the mechanisms responsible for the development of chronic pain in these patients are unknown, preclinical evidence suggests plasticity within the spinal cord dorsal horn (DH) is involved. We currently know very little about the *functional properties* of DH neurons that

receive inputs from viscera, in particular their intrinsic properties or the synaptic inputs they receive. This is important, as the functional properties of DH neurons ultimately shape their output and thus, pain transmission to higher centers. We therefore developed an *in vivo* mouse preparation to study the functional properties of DH neurons that receive inputs from the colon in a model of acute colitis.
Methods: Colitis was induced in male mice (C57Bl/6J, 6-7 wks) using an intracolonic administration of TNBS (200µl; 2.5% TNBS in 50% ethanol), while they we under isoflurane anesthesia (2-3%). Five days following the induction of colitis, mice were anesthetised (isoflurane 1-3%) and a laminectomy was performed to expose the L6-S1 spinal segments. In vivo patch-clamp recordings were then made in the superficial DH (lamine I-II) using potassium gluconate internal. Neurons with inputs from the colon were identified using noxious colorectal distension (CRD; 80 mmHg). Convergent cutaneous receptive fields were also assessed using brush or pinch of the hind paw and/or tail. A series of protocols were then applied to measure the intrinsic and synaptic properties of recorded DH neurons.
Results: A significantly larger proportion of DH neurons responded to CRD following colitis compared to controls (32% vs. 11%; $P < 0.05$). While a majority of neurons in both conditions exhibited predominately subthreshold responses to CRD, the nature of these responses (i.e. amplitude and duration) differed. Likewise, the number of DH neurons that had cutaneous receptive fields increased following colitis (83% vs. 49%; $P < 0.05$). Interestingly, this increase in cutaneous responses was mostly observed in CRD non-responsive DH neurons. Surprisingly, colitis resulted in more hyperpolarized resting membrane potentials in both CRD responsive and non-responsive DH neurons compared to controls.
Conclusions: Acute colitis can alter the responses of DH neurons to both visceral and cutaneous stimulation, and result in changes to their intrinsic properties such as resting membrane potential. Importantly, these changes occur universally within the DH, suggesting that the entire dorsal horn “network” is sensitised by visceral inflammation.

Title: Pharmacological effects of different substances in the dextran sulfate sodium (DSS) - induced colitis model in the mouse

Authors: *D. PUSHETT, C. LE CUDENNEC, V. CASTAGNÉ;
Porsolt SAS, Le-genest-saint-Isle, France

Abstract: Ulcerative colitis and Crohn's disease are major forms of inflammatory bowel disease (IBD), which affect millions of people worldwide, however the options for treating IBD are still unsatisfactory. A murine colitis model induced by Dextran Sulfate Sodium (DSS) is an animal model of IBD commonly used to address the pathogenesis of IBD. This mouse model presents many similarities with human ulcerative colitis, as it results from inflammation and damage of gastrointestinal tract and includes clinical signs such as abdominal pain, diarrhea, rectal bleeding and weight loss. We evaluated the effects of DSS in mice (C57/Bl6 strain) and we also evaluated the effects of substances currently used in the clinic for their analgesic and/or anti-inflammatory activities.
Colonic inflammation was induced with DSS administered in drinking water of mice over a period of one week. Animals were monitored at different time-points for their pain response to tactile stimulation (electronic von Frey probe applied to the abdomen) and different observations (posture and eye closure) performed in absence of external stimulation. Macroscopic histological observations were also performed after sacrifice to score local inflammation. We also tested indomethacin, 6-thioguanine and sucralfate for their potential topical site-protective effect and/or analgesic activity. The 3 drugs were orally administered once a day during the DSS-treatment period.As can be expected, after administration of DSS, the main features of colitis included loss of body weight, gastrointestinal inflammation, bloody feces and visceral pain. However, the intensity of these clinical signs as well as their kinetics showed some variability between successive experiments. The effects of the evaluated substances, selected for their analgesic and/or anti-inflammatory effects described in the literature were weaker than expected.
Experimental colitis induced by DSS is a good animal model to study the mechanisms underlying the pathogenesis of IBD. However the lack of efficacy of the treatment evaluated in the present study confirms the variability of efficacy of current treatments, and suggests that the predictive validity of the model should be improved in order to use it in the context of drug development.

Title: Visceral pain: identification of limbic circuitry using *In vivo* optogenetics

Authors: *R. LATORRE[1], A. C. JOHNSON[1], C. O. LIGON[1], B. GREENWOOD-VAN MEERVELD[1,2,3];
[1]Oklahoma Ctr. For Neurosci., Oklahoma City, OK; [2]Dept. of Physiol., Oklahoma Univ. Hlth. Sci. Ctr., Oklahoma City, OK; [3]Dept. of Veteran Affairs, Oklahoma City, OK

Abstract: Introduction: Chronic visceral pain emanating from the internal thoracic, pelvic or abdominal organs is a complex condition that is inadequately managed despite its prevalence. Stress is known to worsen visceral pain though activation of limbic brain regions, such as central nucleus of amygdala (CeA) and the medial prefrontal cortex, which modulate the hypothalamic pituitary adrenal axis activation. We have previously shown that activating the CeA, by repeated psychological stress or stereotaxically placed corticosterone micropellets, induces visceral pain through corticotropin releasing hormone receptor-1 mediating mechanism in the bed nucleus of stria terminalis (BNST). Our experimental goal is to apply an optogenetics approach to explore neural limbic circuitry modulating visceral pain in freely moving rats. Methods: We employed *in vivo* optogenetics using stereotaxic adenoassociated virus vector injections of channelrhodopsin (ChR) or halorhodopsin into the CeA and fiber optic cannulae implantation in the BNST in male Fischer 344 rats. Visceral pain behaviors were assessed via visceromotor response (abdominal contractions) to graded isobaric colorectal distension (20, 40 or 60 mmHg/10 min with 10 min rest between pressures). Following transcardial perfusion fixation, the brain was collected and processed for immunofluorescence and histological verification of neuronal phenotype and virus vector expression compared to non-infected control rats. Results: Eight weeks after injection of the virus vector we found a robust expression of the fluorescent reporter protein within the neuronal cell bodies at the site of injection in the CeA and within fiber bundles at the BNST. Histology revealed neuronal viability, an absence of inflammatory infiltrate, and no morphological alterations in the infected brain areas compared to controls. Immunofluorescence targeting GABAergic and glutamatergic neurons showed no neurochemical changes between infected neurons and controls. Preliminary behavioral studies suggest that ChR stimulation of CeA terminals in the BNST increases visceral pain responses in non-stressed rats (# of abdominal contractions at 20 mmHg: 5.8 ± 1.2 to 17.0 ± 2.0, $p < 0.01$; 40 mmHg: 15.0 ± 2.8 to 32.6 ± 2.0, $p < 0.001$; 60 mmHg: 23.2 ± 2.6 to 40.6 ± 3.3, $p < 0.001$; two-factor repeated measure ANOVA with Bonferroni post-hoc comparisons). Conclusion: By directly manipulating neuronal activity through optogenetic stimulation, we have demonstrated that a CeA and BNST circuit plays an important role in mediating visceral sensitivity emanating from the colon, and may serve as a target for new therapies treating chronic visceral pain.

Title: Brain signature in irritable bowel syndrome: Connectivity-based classification

Authors: *E. A. VALESTRAND[1], K. F. TEKIE[2], T. HAUSKEN[1], A. LUNDERVOLD[2];
[1]Dept. of Clin. Med., [2]Dept. of Biomedicine, Univ. of Bergen, Bergen, Norway

Abstract: An important network in the irritable bowel syndrome (IBS) brain is the *salience network*, integrating information of sensory, emotional and cognitive nature, and contributing to complex brain functions such as self-awareness and social behavior. Using multimodal MR imaging, the IBS brain can be evaluated structurally and functionally. By combining jointly these measurements in a machine learning framework, we can better understand the IBS brain connectivity and integrity.

In our study, comprising 15 IBS patients and 14 healthy controls (HC), we used anatomical MRI, resting state fMRI, and diffusion MRI to perform a connectivity classification of the IBS and HC brains. Regions, obtained from automated brain segmentation (FreeSurfer), included the insula, amygdala, dorsal anterior cingulate cortex, lateral and medial orbitofrontal cortex, and rostral and caudal middle frontal cortex. Altogether 14 nodes within or associated with the salience network were identified in each subject. As a structural connectivity measure between pairs of nodes we used mean fractional anisotropy (FA) of the connecting tracts (DSI Studio). To assess functional connectivity, we used the Pearson correlation between the mean voxel time courses of the corresponding nodes (the CONN toolbox).

For pattern classification we employed a three-layer feed-forward neural network (ANN) classifier (*caret* in R). For analysis we extracted altogether 51 features derived from the 14-node, undirected weighted graphs of structural and functional connectivity. To assess the performance of the binary classifier, we used a series of 100 hold-out repetitions keeping 70% of the observations for training (10-fold cross validation, repeated 10 times) and the remaining (4 HC and 4 IBS) for testing at each repetition.

We obtained a mean classification accuracy of 0.628 (SD 0.144), mean sensitivity 0.665 (SD 0.175), and mean specificity 0.590 (SD 0.172). No connectivity metric or node could be singled out as the most important for discrimination between the IBS and HC brains, and successful classification was rather due to a signature of multiple features associated with the salience network.

We conclude that patients with IBS seem to have altered brain connectivity within the salience network. The finding of such patterns, making it possible to discriminate between the IBS brain and the healthy brain with a sensitivity of ~65% and specificity of ~60% (confirmed by random forest classification), is highly interesting both at a diagnostic and a mechanistic level and will be further explored in a larger imaging study of IBS.

Title: Urothelial barrier dysfunction increases the excitability and firing of bladder afferent sensory neurons

Authors: N. MONTALBETTI, A. RUED, F. KULLMANN, *M. D. CARATTINO;
Med., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Interstitial cystitis/bladder pain syndrome (IC/BPS) is a chronic disorder characterized by voiding dysfunction and pain in the bladder and/or pelvis in the absence of proven urinary infection or other noticeable pathology. While the etiology of IC/BPS remains unknown, compelling evidence indicates that increased urothelial permeability to urine constituents plays an important role in the onset of the disease. Significantly, the message for claudin-2 (Cldn2), a tight junction-associated protein, was found to be upregulated at least ninety fold in bladder biopsies from IC/BPS patients. Consistent with this finding, the overexpression of Cldn2 in the bladder urothelium increased the permeability to small charged solutes, triggered an inflammatory process in the bladder mucosa and lamina propria, reduced bladder wall compliance, and increased voiding frequency. To determine whether the changes in bladder activity observed in rats with reduced urothelial barrier function result from altered afferent activity, we conducted patch-clamp studies with acutely isolated bladder sensory neurons harvested from bladders transduced with adenoviruses coding for GFP (control) or Cldn2. We found that ~ 30% of the bladder sensory neurons from rats transduced with Cldn2, but not GFP,

displayed spontaneous activity. The overexpression of Cldn2 in the urothelium reduced the resting membrane potential, reduced the action potential threshold, reduced the rheobase, and increased the action potential duration of tetrodotoxin-sensitive (TTX-S) bladder afferent neurons. Moreover, the overexpression of Cldn2 in the urothelium increased the response of bladder sensory neurons with TTX-S action potentials to suprathreshold electrical stimulus. These findings indicate that increased tight junction permeability induces sensory adaptation and that this process contributes to the bladder hyperreflexia observed in rats transduced with Cldn2. To determine whether increased urothelial paracellular permeability produces noxious stimulation of the bladder afferent pathways, we examined ERK activation in spinal cord segments receiving bladder input. We observed a significant increase in pERK/ERK ratio in spinal cord segments receiving hypogastric and pelvic nerve input, consistent with the notion that Cldn2 overexpression activates nociceptive pathways. In summary, our studies suggest that as a result of a leaky urothelium, the diffusion and accumulation of urinary solutes in the bladder interstitium sensitizes bladder afferents, which promotes voiding at low filling volumes and pain.

Title: 15d-PGJ_2 activates peripheral PPAR gamma and opioids receptors to reduce inflammatory muscle pain

Authors: *D. S. DOS SANTOS[1], J. T. CLEMENTE-NAPIMOGA[3], B. K. TAYLOR[4], M. G. OLIVEIRA-FUSARO[2];
[1]Lab. of studies of pain and inflammation, UNICAMP, Piracaia, Brazil; [2]Lab. of studies of pain and inflammation, UNICAMP, Limeira, Brazil; [3]Lab. of Orofacial Pain, State Univ. of Campinas, Piracicaba, Brazil; [4]Dept. of Physiol., Univ. of Kentucky, Lexington, KY

Abstract: Peroxisome proliferator-activated receptor gamma (PPARγ) receptors are emerging as a promising target for the treatment of inflammatory and neuropathic pain. As with administration of peripherally-acting opioid receptor agonists, peripheral administration of PPARγ agonists reduces behavioral signs of persistent pain. However, the contribution of

peripheral PPARγ activation to muscle pain and its modulation by opioid receptors remains unknown. The aim of this study was to determine whether activation of peripheral PPARγ receptors by the endogenous ligand 15d-PGJ_2 reduces inflammatory muscle pain in rats in an opioid receptor-dependent manner. Inflammatory muscle hyperalgesia was induced by injection of carrageenan into the gastrocnemius muscle. Mechanical muscle hyperalgesia was quantified with a Randal Sellito pressure analgesimeter, applied to the gastrocnemius muscle. Male Wistar rats were used and methods were approved by the Ethics Committee in Animal Research of the UNICAMP (protocol n. 3919-1). To investigate the contribution of PPARγ receptors to muscle pain, 15d-PGJ_2 was injected into gastrocnemius muscle 30 min before carrageenan. As 15d-PGJ_2 can exert both PPARγ-dependent and PPARγ-independent effects, we pretreated rats 30 min. prior to 15d-PGJ_2 with either vehicle or GW9662, a selective PPARγ receptors antagonist. To test the hypothesis that 15d-PGJ_2 recruits opioid analgesic system, Naloxone, a non-selective opioid receptor antagonist, was injected into gastrocnemius muscle 30 min. before 15d-PGJ_2. Carrageenan (100μg) produced mechanical muscle hyperalgesia 3 h after its injection ($p<0.05$, T test). 15d-PGJ_2 (1, 10 and 100ng) prevented the mechanical muscle hyperalgesia induced by carrageenan when injected in the ipsilateral muscle in a dose-dependent manner ($p<0,05$, ANOVA, Tukey test) but not in the contralateral muscle ($p>0.05$). Pre-treatment with GW9662 (3 or 9 ng) or Naloxone (0.1 or 1μg) reversed the anti-hyperalgesic effect of 15d-PGJ_2 in a dose-dependent manner ($p<0,05$, ANOVA, Tukey test, n=4). GW9662 or Naloxone didn't alter the nociceptive threshold when injected alone ($p>0,05$, T test, n=4). These data demonstrate that 15d-PGJ_2 increases mechanical response thresholds in the carrageenan model of inflammatory muscle pain. This anti-hyperalgesic effect is dependent on activation of peripheral PPARγ and opioids receptors. We speculate that activation of PPARγ leads to the subsequent activation of peripheral opioid receptors, leading to inhibition of inflammatory muscle pain. We conclude that local PPARγ receptors are important pharmacological targets for the pharmacotherapy of inflammatory muscle pain.

Title: Fibromyalgia syndrome: Cold stress reveals altered metabolic activity and thermoregulation

Authors: *J. D. PASLEY[1,2], J. V. PARDO[3], J. T. LEE[3], M. G. NUNEZ[4], R. C. LARSON[4], A. A. LARSON[4];

Abstract: Fibromyalgia syndrome (FMS) is a chronically painful condition characterized by a wide variety of symptoms including impaired sleep, tactile and musculoskeletal hyperalgesia, and a high sensitivity to stress. However most studies are conducted in the absence of intentional stress. This report describes responses of these individuals to cold, a stress that is widely reported to enhance their symptoms that is also easily applied and controlled, to better reveal their unique responses compared to healthy normal controls. FMS patients had higher T-scores and critical scores on the PDSQ test than controls. Patients did not differ from control subjects in their reported physical activity during the previous week but slept less during the 24 hr prior to cold but not to warm tests. Their Pittsburgh Sleep Quality Indexes indicated a poorer quality of sleep and more difficulty getting to sleep. Their self-reported pain intensity and degree of unpleasantness of the pain was greater than controls at all times before and after exposure to either warm or cold. They also scored higher to sensory and affective pain in the McGill Pain questionnaire than controls. Body temperatures did not differ prior to cold exposure and all subjects had lower skin temperatures on their extremities after 3 hr of cold. However, skin temperatures on the arm and calf of patients with FMS were not as low as controls in response to the cold. Forehead temperatures did not differ between groups and core body temperatures did not decrease in either group. Circulating blood glucose did not differ between groups prior to cold exposure, but patients with FMS had lower blood glucose than controls in response to the cold stress. Based on the importance of brown adipose tissue (BAT) during responses to stress, we examined ci-BAT using 18F-fluorodeoxyglucose PET/CT. Under warm conditions, BAT activity was the same and very consistent in both control and FMS subjects. After cold exposure, BAT activity was much more variable within and between groups. Together these data indicate that pain is a consistent symptom of fibromyalgia that is not dramatically affected by a short-term cold stress, however, metabolic activity and temperature regulation differ in patients with FMS compared to controls when exposed to a cold stress.

Title: Mechanistic distinctions between cancer-induced ongoing pain and movement-triggered breakthrough pain

Authors: J. GENTRY, M. DEARBORN, J. HAVELIN, I. IMBERT, *T. E. KING;
Biomed. Sci., Univ. of New England, Biddeford, ME

Abstract: Cancer-induced bone pain is described as moderate to severe ongoing pain that is often controlled by extended release opioids. Many patients also experience transient episodes of severe pain that "breaks through" medication controlled ongoing pain. Breakthrough (BT) cancer pain requires the use of rapid onset opioids. Understanding of mechanisms promoting bone cancer pain has been challenging due in part to limitations in preclinical pain measures. We developed and characterized new measures of cancer-induced ongoing pain using a rat model in which breast cancer cells are injected and sealed into the tibia. Ongoing pain was assessed using the motivational drive to seek pain relief using conditioned place preference whereas BT pain is measured using motivational drive to avoid a chamber paired with movement triggered pain. Systemic administration of MOR agonists (morphine, DAMGO) blocks tumor-induced ongoing pain. In contrast, systemic administration of the DOR agonist, deltorphin II failed to block tumor-induced ongoing pain. In contrast, movement-triggered BT pain is blocked by administration of the DOR agonist, deltorphin II, at the dose that failed to block ongoing pain. We have demonstrated that ablation of TRPV1 expressing nociceptive terminals in the dorsal failed to block BT pain whereas ablation of IB4 expressing fibers blocked BT pain. These observations suggest that DOR agonists may block movement-induced BT pain through actions on IB4 expressing fibers whereas MOR agonists block tumor-induced ongoing pain through actions on TRPV1 expressing fibers. **Acknowledgements:** This work was supported in part by an NIH COBRE grant P20GM103643.

Title: Contributions of DEET to a rat model of gulf war illness pain

Authors: *B. Y. COOPER[1], T. J. NUTTER[2], R. D. JOHNSON[3], L. FLUNKER[2];
[2]Oral Surgery, [3]Physiological Sci., [1]Univ. Florida, Gainesville, FL

Abstract: Introduction. Veterans of the 1991 Gulf War commonly reported a delayed onset joint, muscle and other deep tissue pain. The Research Advisory Committee on Gulf War Illness (GWI) has determined that pesticides may have contributed to the development of the symptoms of GWI (Binns et al., 2008). We developed a rat model of GWI pain based upon a 60 day exposure to permethrin (P), chlorpyrifos (CP) and pyridostigmine bromide (PB; Nutter et al., 2015). In the present report, we combined behavioral and molecular approaches to examine the contribution of DEET to the development of the joint and muscle pain of GWI.
Methods. Juvenile male rats, weighing between 90 and 110 g, were exposed to various combinations of P (2.6 mg/kg; topical), CP (120 mg/kg; subcutaneous (SC)), PB (13 mg/kg; oral gavage), and DEET (400 mg/kg; topical) for 30 days. Using an identical administration schedule, control group rats received only vehicle exposures (topical ethanol, SC corn oil, water by gavage). All rats underwent behavioral testing before, during and after chemical exposures (hindlimb pressure withdrawal; open field activity (movement distance, movement rate and resting duration). Molecular studies were conducted to assess the influence of acute DEET on nociceptors. In molecular studies, young adult rats weighing 90-150 grams were anesthetized and decapitated. Whole cell clamp experiments were conducted on excised dorsal root ganglion neurons that were identified as muscle or vascular nociceptors using the method of Scroggs and Cooper (Cardenas et al., 1995; Petruska et al., 2002).
Results. When exposed to all 4 compounds, rats exhibited reduced open field activity (movement distance and rate) that resembled a myalgia or arthralgia 9-12 weeks after dosing had ceased ($p<.02$ and $p<.004$). When exposed to only 3 compounds, activity changes failed to materialize in the absence of PB or CP but persisted in the absence of permethrin (movement; $p<.05$); moreover, when PB was removed, rate decreases were significantly lessened relative to exposure to all 4 chemicals ($p<.05$). Molecular studies indicated that DEET significantly inhibited $Na_v1.9$ amplitude ($p<.04$; vascular nociceptors) but had no effect on K_v7 or $Na_v1.8$. The influence DEET on $Na_v1.9$ only occurred at relatively high doses that are not likely *in vivo* (100 μM).
Conclusions. DEET makes a significant contribution to a robust deep tissue pain syndrome in a

rat model of GWI pain. PB was required for, and CP contributed to, motor activity changes while permethrin did not play a role at 12 weeks-post exposure. DEET might exert its influence through inhibition of $Na_v1.9$.

Title: TrkA signalling is critical for the initiation of osteoarthritis pain in the monoiodoacetate model

Authors: *J. D. VALENTE[1], L. CALVO[3,4], J. C. AREVALO[3,4], M. MALCANGIO[2]; [1]Wolfson CARD, [2]Wolfson Ctr. for Age-Related Dis., Kings Col. London, London, United Kingdom; [3]Dept. of Cell Biol. and Pathology, Inst. of Neurosciences Castilla y León, Univ. of Salamanca, Salamanca, Spain; [4]Inst. of Biomed. Res. of Salamanca, Salamanca, Spain

Abstract: Nerve growth factor (NGF) is a neurotrophin required during development for survival and growth of sympathetic and sensory neurons. In adulthood NGF can regulate excitability of small diameter sensory neurons that transmit noxious information from periphery to CNS. Administration of NGF produces pain hypersensitivity in humans and animals. Furthermore, endogenous NGF levels are elevated in painful conditions, including knee joints of osteoarthritis (OA) patients, where pain management is often unmet. Anti-NGF treatment of OA patients results in significant analgesia, but also severe side effects such as increase incidence of bone necrosis. Collectively, these data suggest that NGF has a role in causing and augmenting pain in osteoarthritis. In the aim to understand the participation of NGF/TrkA signalling in OA pain, we studied the development of OA-like pain in mice carrying a mutation in the TrkA neurotrophin receptor (P782S) (TrkA KI mice). WT and TrkA KI mice were injected intra-articularly in the knee joint with 0.7 mg MIA and nociceptive behaviour, namely hind paw mechanical thresholds and weight bearing changes, were monitored for 28 days. Immunohistochemical analysis of CGRP and pERK expression in dorsal root ganglia (DRG) and Iba1, p-p38 MAPK and c-fos expression in the dorsal horn of the spinal cord were performed at days 7 and 28 post-MIA injection. TrkA KI mice developed MIA-induced mechanical allodynia faster than WT mice within the first week of MIA injection, and by day 28 allodynia was

comparable to WT mice. Moreover, at a 0.7 mg MIA dose administered, TrkA KI, but not WT mice developed weight bearing deficits over the course of the study. In perfuse-fixed DRGs, 7-day after MIA injection we observed an increased number of CGRP positive neurons, mainly large cells, as well as activation of sensory neurons (p-ERK). These changes were significantly amplified in TrkA KI mice. Furthermore, dorsal horn neuron activation (FOS positive cells) and microglial response (Iba-1 and p-p38 positive cells) were both significantly higher in the spinal cord of TrkA KI compared to WT spinal cords at 7 but not 28 days after MIA injection. This study suggests that increased TrkA signalling secondary to alteration in receptor trafficking results in increased excitability of sensory neurons and dorsal horn neurons and in a faster onset of pain-related behaviour, in a model of OA. Collectively, these data suggest an important role for TrkA signalling in the initiation of OA related pain.

Title: Characterization of nociceptive fibers in back of a patient with chronic pain

Authors: M. BACKONJA[1], *D. C. YEOMANS[2], M. KLUKINOV[3], M. NEMENOV[4,3];
[1]Neurol., Univ. of Wisconsin, Madison, WI; [3]Anesthesia, [2]Stanford Univ., Stanford, CA;
[4]LasMed, Mountain View, CA

Abstract: Physiological characteristics of nociceptive fibers in patients with chronic pain are not known. This is a report of a case study to address that gap. Patient is a 58-year-old man who was involved in a motor vehicle accident six months earlier, which left him with chronic upper back pain. Clinical evaluation yielded negative imaging, leading to diagnosis of musculoskeletal pain and sensory examination revealed altered perception of cold in the area of pain but no evidence for neurological sensory deficits. The area of abnormal sensory perception was used as a study site with diode laser selective stimulation and the area of back not affected by pain served as a control site. The hand was used as an additional control site, which has a larger normative data set. To assure a systematic study, stimulation was conducted in a grid pattern using A-delta stimulation and C-fiber stimulation protocols in the test and control sites. Stimulation of control back sites produced a standard hot pain sensation during C-fiber stimulation while the same stimulus produced stinging for the abnormal pain testing site. The threshold stimulation power was 5-10% higher for the back sites compared to hand site. It is of note that, though A delta

painful stimulation resulted in pricking pain when tested at the hand control site, this stimulus type rarely produced pain when applied to either back site. In conclusion, this case study demonstrates that gain in function in musculoskeletal pain can be discriminated by an abnormal function of cutaneous C-fibers. Receptive fields of heat sensitive A-delta fibers are much more sparse in the upper back and for that reason much more difficult to study.

Title: The neuropsychological mechanisms of memory bias in chronic pain

Authors: E. VACHON-PRESSEAU[1], S. BERGER[1], A. T. BARIA[1], T. ABDULLAH[1], T. J. SCHNITZER[1], *A. V. APKARIAN[2];
[1]Northwestern Univ., Chicago, IL; [2]Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: Several studies have demonstrated that memories for painful events are often inaccurate and generally overestimated. The magnitude and direction of the discrepancy between remembered pain and actual pain are dependent upon many factors. Redelmeier and Kahneman initially demonstrated that patients' memories of the amount of discomfort reported after a minimally invasive procedure was determined primarily by the intensity of pain at both the procedure's worst and most recent episodes, a phenomenon now known as the "peak-end rule". Such memory biases have also been documented in chronic pain patients, with evidence that long-term pain is remembered less accurately than acute pain. In the present study, we examined how discrepancies between actual pain and remembered pain relate to specific morphometric measurements of the hippocampus and propose a model accounting for memory bias in chronic pain patients.
51 chronic low back pain (CBP) patients were asked to use a smart-phone/computer application

to monitor daily fluctuations in pain intensity and mood over a 2-week period. Upon finishing this rating period, patients were asked to remember the average pain they experienced over the last week and complete an anatomical magnetic resonance imaging (MRI) scan. As hypothesized, CBP participants showed a memory bias in the reporting of their previous pain, with their recalled pain of the last 7 days being significantly higher than their average spontaneous pain ($t = 5.96$, $p<0.0001$). This memory bias was associated with shape displacement in the posterior hippocampus where outward displacement correlated with higher recalled pain ($r = 0.44$, $p = 0.015$). Multiple regressions demonstrated that the peak pain ($ß = 0.36$, $p = 0.02$), the average pain over the previous week ($ß = 0.39$, $p = 0.01$), the mood at the end of the rating period ($ß = -0.17$; $p = 0.089$), and the vertex displacement in the posterior hippocampus ($ß = 0.3$, $p = 0.003$) were independent contributors explaining about 60% of recalled pain ($R^2 = 0.62$, $F(4, 43) = 17.82$, $p <0.0001$).
Our results demonstrate that CBP patients experience memory biases according to the peak-end rule and anatomical properties of the hippocampus. Because pain, especially in its chronic form, remains a subjective experience, better understanding the mechanisms of memory bias in chronic pain patients will help improve accuracy of pain measurements and ultimately improve treatment and management of chronic pain.

Title: Refined global intrinsic pain circuits of posterior insula and S2 in non-human primate brain using high-resolution functional magnetic resonance imaging

Authors: *R. WU, F. WANG, P.-F. YANG, L. M. CHEN;
Dept. of Radiology, Vanderbilt Univ., Nashville, TN

Abstract: Our sub-millimeter resolution fMRI, in combination with microelectrode electrophysiological recordings, has identified regions selective for nociceptive heat processing in the posterior insula (pIns) and the secondary somatosensory cortex (S2) of new world monkeys. These observations led us to hypothesize that pIns is a high-order nociceptive

information processing and integrating center that receives nociceptive inputs from S2 nociceptive region. This S2-pIns circuit serves as core center(s) for integrating sensory and affective aspects of nociceptive information via other distinct brain circuits. To test this hypothesis, in this study we first mapped the whole brain regions that are engaged in processing nociceptive heat stimuli, and then used high-resolution resting state fMRI signals to delineate and refine the global intrinsic functional connectivity circuits of these two proximal regions. Four squirrel monkeys have been studied so far. In each subject, nociceptive heat (47.5 ^{o}C) evoked fMRI activations were mapped with both a 3 cm diameter surface coil and a whole brain volume coil at 9.4 T under anesthesia. Nociceptive heat evoked activations were identified in many brain regions, including primary somatosensory (S1) subregions, S2, Insula, thalamus, anterior cingulate cortex (ACC), primary motor cortex (M1), and prefrontal cortex. Using the heat evoked fMRI activation foci in pIns and S2 as the seeds, voxel-wise whole-brain resting state functional connectivity analysis was performed. We found that pIns and S2 were strongly connected to each other, and each region was also part of two distinct functional networks: (1) the pIns-ACC network, and (2) S2-sensorimotor network. In network 1, the most robust connectivity was observed among bilateral insula and ACC with moderate connectivity with posterior cingulate cortex. In network 2, we observed strong connectivity among bilateral S2, bilateral M1, and bilateral S1 cortices. Our study provides evidence for the existence of two distinct and intrinsic functional circuits for S2 and pIns, as well as their joint connection via the S2-pIns circuit. We propose that the S2-pIns circuit serves as key center(s) for integrating sensory and affective aspects of nociceptive inputs in primate brain. The presence of robust and distinct functional connectivity networks under anesthesia underscores the fundamental roles of these functional circuits in processing nociceptive information.

Title: Pain perception in pediatric patients with cerebellar resection: psychophysical results of an ongoing fMRI study

Authors: *K. E. SILVA[1], J. ROSNER[1], N. J. ULLRICH[2], C. CHORDAS[3], L. BECERRA[1], P. MANLEY[3], E. A. MOULTON[1];

Abstract: INTRODUCTION: Recent evidence suggests that the cerebellum plays a role in affective processing, in addition to motor coordination. Imaging studies demonstrate cerebellar activation in individuals experiencing experimental or clinical pain. Moreover, resection of tumors located in the cerebellum in pediatric patients can result in affective and cognitive deficits. However, the consequences of such anatomical disruption on pain sensation and pain processing are unknown. This may be of particular importance in children, as it may alter sensory development into adulthood. The goal of this study is to evaluate the effect of cerebellar resection on the processing of pain. Preliminary findings indicate that damage to the cerebellum may influence pain perception. **METHODS:** Six pediatric patients who were treated with surgery only for a cerebellar tumor (mean age = 14.3 ± 4.1) and six age-, gender-, race- and handedness-matched healthy controls (mean age = 14.5 ± 4.0) were evaluated using quantitative sensory testing and magnetic resonance imaging which included diffusion tensor imaging, resting state and event-related functional MRI scans. Psychophysical measures assessed included heat and cold detection thresholds (HDT, CDT), heat and cold pain thresholds (HPT, CPT), and cold pain tolerance using a cold pressor task. **RESULTS:** A preliminary evaluation of the data thus far indicates a difference in the variability of HPT and CPT between patients and controls. This variability was not detected in measures of HDT or CDT. Similarly, the cold pressor task shows that pain sensitivity appears to mirror cold pain tolerance. **PRELIMINARY CONCLUSIONS:** The differences in pain sensitivity between patients and controls are presumed to result from damage to the cerebellum, potentially interfering with the modulation of pain pathways. Analysis of the preliminary imaging data is underway and recruitment is ongoing.

Title: Brain circuitry underlying sex differences in deep tissue pain sensitivity in chronic low back pain

Authors: I. MAWLA[1], J. LEE[1], A. ORTIZ[1], J. GERBER[1], E. PROTSENKO[1], J. KIM[1], H. KIM[1], S.-T. CHAN[1], *M. L. LOGGIA[2], R. EDWARDS[1], A. WASAN[1], C. BERNA[1], J. KONG[1], T. KAPTCHUK[1], R. L. GOLLUB[1], B. ROSEN[1], V. NAPADOW[1];

Abstract: Women suffer from a higher prevalence, incidence, risk, and severity of chronic pain compared to men. Past studies have reported robust sex differences in several evoked pain measures. However, the brain circuitry subserving chronic pain sex differences is largely unknown. In the current study, 34 women and 29 men suffering from chronic Low Back Pain (cLBP) underwent BOLD functional MRI (fMRI) scans of their brain in a 3T scanner. In a block-design experiment, we delivered deep tissue pressure pain stimuli, via cuff pain algometry, to the left lower leg. The cuff pressure stimulus was percept-calibrated to achieve a target pain intensity rating of ~40 on a scale of 0-100. There were 6 painful stimuli, each preceded by an anticipation cue and, 8 seconds later, followed by a pain intensity rating scale. A whole brain T2*-weighted BOLD fMRI pulse sequence was used (TR=3s, TE=30ms, flip angle=90, axial acquisition, voxel=2.6x2.6x3.1mm). At the subject level, GLM regressors modeled the pain anticipation cue, cuff pressure onset, cuff pressure plateau, and cuff pressure offset, while head motion, rest period between pressure and rating, and the rating period itself were included as covariates of no interest. Parameter estimates and variances were passed on to mixed-effects group level analyses, which calculated group maps and compared male and female cLBP patients (FLAME 1+2, FSL, $Z>2.3$ voxelwise threshold, cluster correction $p<0.05$). Cuff pressure to achieve target ratings was greater ($p=0.02$) for male (184±67mmHg, M±SD) compared to female (149±51mmHg) subjects, indicating a sex difference in sensitivity to pain stimulation. fMRI results showed that for pain onset, male cLBP subjects demonstrated greater activation in ipsilateral secondary somatosensory cortex/inferior parietal lobule and posterior insula; and contralateral lateral prefrontal cortex, compared to female cLBP subjects. No sex differences were found for brain activity at cuff pressure plateau. For cuff pressure offset, male subjects deactivated medial prefrontal cortex more robustly than female subjects. These results corroborate previous findings, demonstrating differences in sensorimotor, self-regulatory, and emotion processing brain circuitry in pain processing between men and women. Additionally, for chronic pain patients, brain response to stimulus onset and offset may more readily differentiate male and female patients, contributing to higher pain sensitivity reported by female cLBP patients.

Title: Altered theta oscillation at anterior insula in women with primary dysmenorrhea during pain-free state

Authors: *P.-S. LEE[1], Y.-S. CHEN[2], C.-H. TU[3,4], H.-T. CHAO[5], J.-C. HSIEH[3,4], L.-F. CHEN[3,4,1];

Hosp., Taipei, Taiwan; [5]Dept. of Obstetrics and Gynecology, Taipei Veterans Gen. Hosp., Taipei, Taiwan

Abstract: Theta oscillation has been reported to reflect memory integration and to dominate in resting state of patients with severe and chronic neurogenic pain. Evidence from our recent studies suggests that menstrual pain is associated with maladaptive functionality of pain modulatory system, especially trait-related changes in the resting-state brain activity. In this work, we aimed to further examine whether menstrual pain was associated with theta oscillations in the resting brain of women with primary dysmenorrhea (PDM) during pain-free phase. Forty-six PDM and 46 healthy female controls (CON), a subset of the participants from our previous genetic association and behavioral studies of PDM being eligible for neuroimaging studies, were included in the present study. The magnetoencephalographic (MEG) signals with 3-5 minutes of eye-open resting state were recorded using a 306-channel MEG system (VectorviewTM, Elekta-Neuromag, Helsinki, Finland) during their 12th-16th day of the menstrual cycle (periovulatory phase, POV). All subjects were assessed with a standardized clinical evaluation protocol including gynecological examination and psychological assessments. The source image of theta oscillatory activity for each individual was estimated by using the beamforming approach. A voxel-wise two-sample t-test was performed for group comparison, using a cut-off of $p < 0.01$ (uncorrected; cluster size $k > 50$ voxels). Spearman's correlation analyses between

psychological/pain experience assessments and the mean theta power of the voxels in each cluster with significant group difference were further conducted. The results demonstrated that PDM exhibited increased theta oscillations in the left ventral anterior insula (vAI), left middle temporal gyrus, and right inferior temporal gyrus. No correlation was found. As a part of the pain matrix, the vAI plays an important role in visceral representation and emotional component of pain experience. This area is also a key region of the salience network, mediating default mode network and affective information processing. Our recent resting-fMRI study reported trait-related hypoconnectivity of DMN-salience network in PDM. The findings of increased theta oscillation in vAI suggest systematic alteration of affective processing in pain-free stage, possibly encoding the prolonged salience of pain and manifestation of chronicity.

Title: Machine learning approaches to discriminate clinical pain states from ASL brain imaging data in chronic low back pain patients

Authors: J. LEE, I. MAWLA, J. GERBER, A. ORTIZ, E. PROTSENKO, J. KIM, H. KIM, S.-T. CHAN, M. L. LOGGIA, R. EDWARDS, A. WASAN, C. BERNA, J. KONG, T. KAPTCHUK, R. L. GOLLUB, B. ROSEN, *V. NAPADOW;
Martinos Ctr. for Biomed. Imaging, Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Machine learning (ML) approaches for classification of pain have typically been applied to healthy individuals experiencing evoked, nociceptive stimuli. A wide gap exists between such efforts and the ability to predict the presence and/or severity of clinical pain in individuals who have chronic pain disorders. Our fMRI study applied previously validated procedures to increase clinical pain in chronic low back pain (cLBP) patients, and applied ML algorithms to attempt to classify the increased pain state using arterial spin labeling (ASL) brain imaging data.

Thirty-nine cLBP patients (18 male, 37±11 yrs) performed individualized low back pain exacerbation maneuvers. Regional cerebral blood flow (rCBF) was assessed before and after maneuvers using pseudo-continuous ASL (6 minutes, TR/TE=3800/15 ms, label duration=1500 ms, post label delay=1200 ms) at 3T. Imaging data were preprocessed to remove cardiorespiratory artifacts and head motion, and whole-brain normalized. Patients' rCBF data were registered to the MNI152 template and contrasted pre- versus post-maneuvers to guide ML analysis. Multivariate classification techniques (k-nearest neighbor (k-NN); support vector machine (SVM), with linear- and rbf-kernel) were applied to discriminate increased pain from rCBF data, and searchlight algorithms were used to localize optimal brain subregions for such discrimination.

Maneuvers significantly increased clinical pain intensity for all cLBP patients (pre-maneuver=29.0±23.7, post-maneuver=53.8±24.1, $p<0.0001$, on a 0-100 scale). Maneuvers increased rCBF in bilateral thalamus and decreased rCBF in bilateral post-central gyri (SI) ($p<0.05$, paired t-test, cluster corrected), which were then selected for ML classification to discriminate pain states. In SI, the k-NN (classification accuracy=69%) and SVM (linear kernel, accuracy=68%) algorithms provided best discrimination accuracy, and rCBF decrease in the SI face area was optimal for discrimination on searchlight analysis. In thalamus, the k-NN classifier showed higher classification accuracy (63%) than SVM (linear kernel=58%, rbf kernel=51%), with activation of left ventrolateral nucleus showing optimal discrimination on searchlight analysis.

Low back pain exacerbation maneuvers effectively increased clinical pain intensity in all LBP patients, and rCBF was increased in thalamic and decreased in SI somatotopic subregions with non-back/leg cortical representations. Machine learning techniques were successfully applied to discriminate lower versus higher pain states, and preliminary results suggested optimal discrimination in specific thalamic and S1 subregions.

Title: Impaired communication with the insular cortex is associated with a persistent awareness of pain in patients with complex regional pain syndrome

Authors: *S.-H. CHOI[1,2], J.-H. KIM[3], J. H. JANG[2], J.-Y. YUN[2], D.-H. KANG[1,2];
[1]Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of; [2]Seoul Natl. Univ., Seoul, Korea, Republic of; [3]Samsung Med. Ctr., Seoul, Korea, Republic of

Abstract: Complex regional pain syndrome (CRPS) is characterized by a continuing pain which has a devastating impact on the quality of life. In this long-lasting subjective experience of the pain, the insular cortex can be contributory to constant perception of the pain. We investigated resting-state functional connectivity of the insular cortex with the other brain regions in patients with CRPS. Twenty-five patients with CRPS and 25 matched healthy controls underwent functional magnetic resonance imaging at rest. With each seed regions of anterior and posterior insular cortices, we compared the resting-state functional connectivity strength between the two groups. Patients with CRPS appeared to have decreased functional connectivity with the anterior and posterior insular cortices in postcentral gyrus, cingulate, inferior frontal, and dorsomedial prefrontal cortices. Additionally, more decreased functional connectivity between the anterior insula and right postcentral gyrus was associated with more severe pain perception in patients with CRPS (with the sensory sub-scores of Short Form McGill Pain Questionnaire, r = -.517, p = .023; with present pain intensity score, r = -.420, p = .046). These findings suggest that the disconnection between the somatosensory cortical function of sensory perception and the insular function of awareness may play a significant role in a persistent experience of regional pain, which is not in a specific nerve territory or dermatome.

Title: Different modulation of the descending control during pain and itch

Authors: *R. RINGLER[1], V. VIEROW[2], M. RANK[2], K. DETMAR[3], R. LOOSE[3], H. O. HANDWERKER[2], C. FORSTER[2];

[1]Univ. of Technol. Amberg-Weiden, Weiden, Germany; [2]Inst. of Physiol., Erlangen, Germany; [3]Dept. of Radiology, Clin. Ctr. of Nuremberg, Nuremberg, Germany

Abstract: Many studies using fMRI dealt with the processing of pain and itch as a multidimensional approach. The quality of pain and itch is processed in a "cerebral network" and a large amount of that network meanwhile is identified. The aim of this work was to explore with the help of fMRI whether itch and pain are processed in identical or different cerebral networks and how the connectivity within these networks change from the default mode to pain and itch, respectively.

18 healthy subjects participated on two separated psychophysical pre-examinations. For pain the skin of the forearm was pretreated by topical application of capsaicin (0,05% for 30 minutes). Then two heat stimuli each lasting 3 min with 5 minute break in between were applied to this site. This lead to a thermal hyperalgesia and heat pain was applied 1 degree above the pain threshold. Itch was applied by iontophoresis of histamine into the skin of the volar forearm. Recording of the sensation by a visual analogue scale (VAS, 0: no itch; 30: desire to scratch; 100: maximal conceivable itch). In two fMRI sessions itch and pain were assessed using a classical connectivity fMRI-design (EPI, 1.5 T Siemens Espree). The first run was without stimulation to detect the subject default mode network. During the second fMRI sequence itch or pain was applied. The itching or painful sensation lasted during the whole fMRI.

For calculations of the connectivity seed regions (thalamus, PAG and posterior insular cortex) were defined. The mean MRI time courses signals were z-transformed and Pearson's correlation coefficients (r) were calculated between the seed regions and other ROIs. In a 2nd level analysis contrasts were calculated between resting state and itch or pain condition and between itch and pain.

During pain the connectivity of the PAG with most of the brain areas decreased as compared with baseline. The only exception is a small area in the posterior part of the anterior cingulate cortex (pACC) where a significant increase of the connectivity could be found. During itch connectivity reverses and increases. Interestingly, caudal to pACC another region adjoins with the reverse connectivity pattern.

These findings show that the descending control via the PAG is modulated differently during pain and itch and the source of this different modulation seem to be within the medial system including ACC and insular cortex.

Title: Tai chi modulates the impaired resting state functional connectivity of the ventral striatum in fibromyalgia

Authors: *J. KONG[1], F. CUI[1], E. WOLCOTT[2], K. JORGENSON[1], A. ORTIZ[1], W. HARVEY[2], C. WANG[2];
[1]Psychiatry, Massachusetts Gen. Hosp., Charlestown, MA; [2]Tufts Med. Ctr., Boston, MA

Abstract: Introduction The striatum, a component of the basal ganglia, is involved in diverse functional domains including movement, cognition, and reward. Recently, studies have shown that the striatum is also involved in the neuropathology of chronic pain. Studies suggest that Tai Chi, a mind-body exercise, has clinically important benefits for chronic pain; nevertheless, the underlying mechanism remains unclear. This study aims to explore whether Tai Chi can modulate the resting state functional connectivity (rsFC) of the striatal subregions in fibromyalgia (FM) patients. To accomplish this, we first compared the rsFC of the striatum of FM patients to that of the matched healthy controls, then examined how Tai Chi practice modulated the striatal rsFC after 3-months of Tai Chi exercise. **Method** We conducted a 3-month, non-randomized comparison trial of Tai Chi involving FM patients and healthy controls matched on age, gender, and body mass index. The 60-minute group sessions occurred twice-weekly. Each subject participated in two identical fMRI scanning sessions at baseline (Scan 1) and after 3 months of Tai Chi intervention (Scan 2). Using a 3T Siemens MRI system, 8-minute resting state fMRI data were collected. We also administered the Revised Fibromyalgia Impact Questionnaire (FIQR) before and after the fMRI scans. Seed-based rsFC was analyzed with CONN. We divided striatum into six subregions as seeds: dorsal caudate (DC), ventral caudate (superior) (VSs), ventral caudate/nucleus accumbens (inferior) (VSi), dorsal rostral putamen

(DRP), dorsal caudal putamen (DCP), and ventral rostral putamen (VRP). A threshold of voxelwise $p< 0.005$ and $p< 0.05$ FDR corrected was applied. **Results** Twenty-one FM patients and twenty healthy controls completed the study and included in data analysis. There were no significant between-group differences in age and gender. Baseline rsFC analysis showed that compared to matched healthy controls, FM patients showed 1) decreased rsFC between left VSi and right temporoparietal junction, and increased rsFC between left VSi and bilateral medial orbital prefrontal cortex; and 2) increased rsFC between left VSs and right postcentral gyrus and middle cingulate cortex. All above rsFC deviations observed at baseline normalized after Tai Chi practice. After Tai Chi interventions, there were significant improvements in the general FIQR scores ($p < 0.001$). **Conclusions** Our results suggest that in FM patients, Tai Chi can significantly modulate the left ventral striatum rsFC over 12 weeks. The reward system may be involved in the Tai Chi-induced improvement of fibromyalgia-related symptoms.

Med. Oncology, Univ. of Michigan, Ann Arbor, MI

Abstract: Patients with head and neck cancer often experience a significant decrease in their quality of life during chemoradiotherapy (CRT) due to treatment-related pain, which is frequently classified as severe. Transcranial direct current stimulation (tDCS) is a method of non-invasive brain stimulation that has been frequently used in experimental and clinical pain

studies. In this pilot study, we investigated the clinical impact and central mechanisms of twenty primary motor cortex (M1) stimulation sessions with tDCS during seven weeks of CRT for head and neck cancer. From 48 patients screened, seven met the inclusion criteria and were enrolled. Electroencephalography (EEG) data were recorded before and after tDCS stimulation as well as across the trial to monitor short and long-term impact on brain function. The compliance rate during the long trial was extremely high (98.4%), and patients mostly reported mild side effects in line with the literature (e.g., tingling). Compared to a large standard of care study from our institution, our initial results indicate that M1-tDCS stimulation has a pain relief effect during the CRT that resulted in a significant attenuation of weight reduction and dysphagia normally observed in these patients. These results translated to our patient cohort not needing feeding tubes or IV fluids. Power spectra analysis of EEG data indicated significant changes in α, β and γ bands immediately after tDCS stimulation and, in addition, α, δ and θ bands over the long term in the seventh stimulation week ($p < 0.05$). The independent component EEG clustering analysis showed estimated functional brain regions including precuneus and superior frontal gyrus (SFG) in the seventh week of tDCS stimulation. These areas colocalize with our previous positron emission tomography (PET) study where there was activation in the endogenous μ-opioid system during M1-tDCS. This study provides preliminary evidence demonstrating the feasibility and safety of M1-tDCS as a potential adjuvant neuromechanism-driven analgesic therapy for head and neck cancer patients receiving CRT, inducing immediate and long-term changes in the cortical activity and clinical measures, with minimal side-effects.

Title: Cerebral and autonomic encoding of the location and intensity of tonic pain

Authors: *M. M. NICKEL[1], E. S. MAY[1], L. TIEMANN[1], M. POSTORINO[1], S. TA DINH[1], J. GROSS[2], P. SCHMIDT[1], M. PLONER[1];

Abstract: Ongoing pain is the key symptom of chronic pain syndromes. Although converging evidence indicates that the brain plays a central role in the development and maintenance of chronic pain, the cerebral substrates of ongoing pain are largely unknown yet. We have previously shown that the cerebral encoding of objective stimulus intensity and subjective pain intensity of ongoing pain dissociate within 10 minutes of painful heat stimulation. We further observed that subjective pain intensity was selectively encoded by prefrontal gamma oscillations. Here, we further investigated the cerebral and autonomic correlates of ongoing tonic pain in 52 healthy subjects using EEG, continuous pain ratings and autonomic measures. To disentangle the encoding of the location and intensity of ongoing pain, we applied 10 min of tonic heat stimulation of varying intensity to the left and right hand, respectively. A conjunction analysis of right and left hand stimulation revealed that subjective pain intensity was encoded by gamma oscillations (30-100 Hz) in the prefrontal cortex independent of the stimulation side. Gamma oscillations increased with increasing pain intensity. Conversely, the contrast right vs. left hand stimulation revealed a spatially specific encoding of objective stimulus intensity in sensorimotor areas contralateral to the stimulation side by alpha (8-13 Hz) and beta (14-29 Hz) oscillations. Alpha and beta activity decreased with increasing stimulus intensity. The analysis of autonomic measures showed that skin conductance levels and the frequencies of nonspecific skin conductance responses were significantly related to objective stimulus intensity but not to subjective pain intensity. Taken together, these results confirm that gamma oscillations and the medial prefrontal cortex play a crucial role in the encoding of tonic, ongoing pain and encode subjective pain intensity independent of pain location. In contrast, alpha and beta activity over contralateral sensorimotor areas encode objective stimulus intensity in a spatially specific manner. The stronger relationship of autonomic responses to stimulus intensity suggests that autonomic responses reflect lower level stimulus characteristics and are at least partially independent of the subjective pain percept. These findings extend the understanding of the brain mechanisms of ongoing pain as a key symptom of chronic pain syndromes.

Title: Spontaneous oscillations in low back pain patients

Authors: *M. JUNG, A. ORTIZ, K. JORGENSON, J. KONG;
Dept. of Psychiatry, Massachusetts Gen. Hosp., Harvard Med. Sch., Charlestown, MA

Abstract: Introduction: Low back pain (LBP) is one of the leading causes of disability in the USA. Despite numerous magnetic resonance imaging (MRI) studies and investigative methods used, the pathophysiology of LBP in the brain remains unclear. Recent studies in resting state functional magnetic resonance imaging (rsfMRI) have suggested that integration of brain function occurs within multiple frequency bands, each associated with different neural manifestations. Thus, low frequency fluctuation (LFF) ranges can be further divided into several distinct bands, among which are slow-4 (0.027 - 0.073 Hz) and slow-5 (0.01-0.027 Hz). These bands mainly reflect neuronal fluctuations and their amplitude in gray brain matter. The aim of this study is to explore 1) amplitude of low-frequency fluctuation (ALFF) differences between LBP patients and healthy controls (HCs) across different bands; and 2) ALFF changes in LBP patients when the intensity of endogenous LBP is increased.
Methods: A total of 36 right-handed subjects were recruited. RsfMRI data were collected using a 3.0 T MRI scanner. All LBP patients were scanned two times, before and after exercise maneuvers, aiming to increase the intensity of LBP. RsfMRI data from 17 adults with LBP (mean age, 36.84 ± 9.07 years) and 19 adult HCs (mean age, 36.84 ± 9.07 years) were included in data analysis. We calculated ALFF in 2 low-frequency bands: slow-4 and slow-5 Hz using a Data Processing Assistant for Resting-State fMRI (DPARSF) toolkit. The statistical threshold for contrasts was uncorrected $p < 0.001$ with 20 continuous voxels.
Result: Compared with the HCs, the LBP group showed increased ALFF values in the supplementary motor area (SMA) of slow-4 and in the middle temporal gyrus of slow-5. However, decreased ALFF values of slow-4 and slow-5 were detected in the middle occipital gyrus. When compared to the post maneuver rsfMRI data, the pre-maneuver LBP group showed

increased ALFF values of slow-4 in the pre-central gyrus (PreG) / paracentral lobules (ParaL) and in the postcentral gyrus, but decreased slow-4 values in the dorsal prefrontal cortex. There was a significant correlation between slow-4 ALFF values in the SMA and the changes in slow-4 ALFF values in the PreG/ParaL in LBP patients.
Conclusions: Our findings suggest that LBP patients with different endogenous LBP intensities have different spontaneous oscillations across different frequency bands. Our results endorse the value of distinguishing the slow-4 and slow-5 bands in chronic pain studies.

Title: Determining effect of chronic pain using EEG source imaging analysis of sickle cell disease patients

Authors: *M. CASE[1], S. SHIRINPOUR[1], Y. DATTA[1], S. NELSON[2], K. GUPTA[1], B. HE[1]; [1]Univ. of Minnesota, Minneapolis, MN; [2]Children's Hosp. and Clinics of Minnesota, Minneapolis, MN

Abstract: Sickle cell disease (SCD) is a blood disorder that affects approximately 100,000 Americans. An abnormality in sickle hemoglobin causes the cells to form stiff sickle shapes which can block blood vessels. Ischemia causes many complications, but the most common symptom in SCD patients is chronic pain. Chronic pain treatment often involves the use of opioids. However, this treatment method can be ineffective because patients may be under-treated due to the risks associated with opioids. An objective method is needed to help quantify pain to help improve pain treatment in SCD patients. The goal of this study was to explore using electroencephalography (EEG) to identify potential biomarkers of chronic pain in sickle cell disease. Ten SCD patients and ten healthy controls were recruited. All patients gave written informed consent and all experimental procedures were approved by the IRB of the University of Minnesota. EEG data was recorded during resting state. Patients rated their pain on the day of recordings on a scale from 1 to 10. An averaged two second epoch that was filtered into the

alpha band was used to perform EEG source imaging. The source analysis was performed using the sLORETA algorithm and the moving dipole solution. The power of the EEG was also assessed across different frequency bins to assess any differences between controls and patients. Healthy controls showed sources located in the prefrontal cortex and precuneus/posterior cingulate areas. All of these areas are associated with the default mode network (DMN). The SCD patients showed source localizations in thalamus and unilateral activation in the insula. The insular cortex and thalamus have been implicated to be involved in pain processing. Both sLORETA and moving dipole solutions had similar source locations for most of the subjects. SCD patients had statistically more power in the delta, theta, and alpha bands when compared to controls ($p < 0.05$). The results of this EEG analysis suggest that controls and SCD patients have different resting state sources. No patients were experiencing an acute pain crisis at the time of EEG recordings, indicating these differences most likely reflect chronic pain. This indicates that EEG reflects chronic pain and that EEG data can be used to find differences between patients and controls. EEG is a non-invasive imaging method that is cost-effective and easy to implement compared to other non-invasive imaging methods such as fMRI. Our results indicate the potential for an EEG-based method to quantify pain in SCD which will be more beneficial to patients as fMRI data is expensive to obtain and is also burdensome for the patients. Funding: NIH U01-HL117664 and NSF IGERT DGE-1069104.

Title: Effects of spinal cord injury on nociceptive heat evoked fMRI responses in cervical spinal cord of monkeys

Authors: *L. CHEN, P.-F. YANG, F. WANG;
Radiology and Inst. of Imaging Sci., Vanderbilt Univ., Nashville, TN

Abstract: Our previous fMRI studies of cervical spinal cord demonstrated that bilateral dorsal and ventral horns were all actively engaged in the processing of nociceptive heat and innocuous tactile inputs from hand (Yang et al., J Neurosci., 2015). Additionally, after unilateral injury to

cervical spinal cord, horn-horn functional connectivity, as measured with resting state fMRI signals, was weakened on the spinal segments below the lesion, and only on the lesion side (Chen et al., PNAS, 2015). These observations led us to hypothesize that the strengths of intrinsic functional connections between spinal horns are indicative of spinal cord functional state. The integrity and maintenance of proper horn-horn functional connectivity are essential for execution of spinal functions, such as processing of incoming nociceptive inputs. To test this hypothesis, in this study we investigated how traumatic injury (i.e., section) to cervical spinal cord injury affects spinal fMRI responses to nociceptive heat and innocuous tactile stimulation of digits and resting state functional connectivity in monkeys under anesthesia. Two squirrel monkeys were studied under isoflurane anesthesia thus far. All MRI scans were performed on an Agilent 9.4 T MRI scanner. Five high-resolution structural transverse images with MT contrast, covering C5-C8 spinal segments that received afferents from digits, were acquired to maximize the grey-white matter contrast within spinal cord. T2* weighted fMRI data were acquired using a fast gradient echo with identical imaging plan prescription. For each subject, multiple fMRI runs were obtained during nociceptive heat stimulation of digits 2 and 3, and also at rest, within each imaging session. Nociceptive heat (47.5 ^{o}C) stimuli (21 s on/30 s off blocks) were delivered via a Medoc thermal probe. MRI data obtained before and weeks after unilateral spinal cord lesion of the dorsal column were quantified and compared. Image pre-processing and statistical analysis were done with custom Matlab scripts and AFNI software. Prior to spinal cord injury, nociceptive heat stimulation of two digits elicited fMRI response in all four horns, but with strongest response in ipsilateral dorsal horn across multiple adjacent spinal segments. Four weeks after a unilateral lesion of the dorsal column, identical nociceptive heat stimulation evoked fMRI response only in slices above the lesion site. The locations of heat responses, however, appeared to be shifted to the middle section between dorsal and ventral horns within the grey matter. Nociceptive and tactile response magnitudes appeared to be weaker than those obtained before lesion.

Title: Neural habituation to painful stimuli is modulated by dopamine: evidence from studies using EEG and pharmacological fMRI

Authors: *E. M. BAUCH[1], C. ANDREOU[2], N. BUNZECK[1,3];
[1]Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [2]Ctr. for Gender Res. und Early Detection, Basel, Switzerland; [3]Dept. of Psychology, Univ. of Lübeck, Lübeck, Germany

Abstract: Pain perception dependents on the absolute magnitude of the pain (absolute coding) but it is also influenced by contextual predictions (context-dependent coding). We investigated the temporal dynamics (EEG) and brain regions (fMRI) involved in absolute and context-dependent coding of pain as well as their link to dopaminergic neuromodulation (placebo/haloperidol). Context-dependent coding was associated with a frontal ERP effect at ~600ms that was pinpointed to the insula; and absolute coding was associated with a frontocentral ERP effect at ~600ms, that was source localized to the left postcentral gyrus. Importantly, in the placebo condition activity in postcentral gyrus increased linearly with shock magnitude only in the beginning of the experiment and subsequently habituated. In contrast, when the dopaminergic system was blocked by haloperidol, absolute coding was also present at the end of the experiment. Together, our findings suggest that dopaminergic neuromodulation plays an important role for the habituation to painful stimuli over time.

Title: Neural and behavioral changes in coping with acute pain after Cognitive Behavioral Therapy: a randomized controlled trial

Authors: A. KUBICKI[1], *M. SHPANER[1], D. A. SEMINOWICZ[2], N. D. LA ROSA[1], J. BISHOP[1], A. FRENCH[1], E. MCCALLION[3], J. MANTEGNA[1], F. J. KEEFE[4], M. R. NAYLOR[1];

Abstract: Chronic pain is a complex physiological and psychological condition, characterized by hypersensitivity to noxious stimulation, and likely caused by persistent changes in the central and peripheral nervous systems. We hypothesized that the CNS abnormalities can be reduced with Cognitive Behavioral Therapy (CBT), and that the development of better coping skills as a result of such training will influence perceptual and neural responses to acute pain. Functional neuroimaging (echo planar fMRI on a 3T Phillips Achieva magnet) during an acute pain task was performed in patients with chronic musculoskeletal pain before and after an eleven-week CBT intervention (n=58), as well as a matched (ages 19-72, both genders) active control group of patients who received educational materials (n=38). Inclusion criteria consisted of a minimal pain level of 4 on a 10-point scale for at least 1 year. Prior to scanning, we determined a moderate pain level for each participant (7 on a 10-point scale), which we held constant at follow-up. The acute pain task consisted of two runs using induced thermal pain, with five 20-second pain blocks each. Participants were instructed to "attend to the pain" in the first run and to "decrease the pain" (cope) in the second run. To investigate the impact of CBT on the neural responses to acute pain, we compared differences between groups across time. Compared to the control group, CBT led to significant improvements in clinical measures of pain, mental health, pain catastrophizing, and self-efficacy for coping with chronic pain. After therapy, participants in the CBT group relied more heavily on relaxation techniques when coping with acute pain, compared to control group participants. The CBT group also had lower acute pain unpleasantness ratings following intervention, although these changes were not significantly different from the control group. We observed significant changes in the dorsal somatosensory stream (contralateral S1, S2, premotor cortex, superior parietal lobule as well as the dorsolateral prefrontal cortex) when coping with pain in the CBT group compared to control group. Prefrontal changes correlated with changes in catastrophizing. These results add to mounting evidence that CBT is a valuable treatment option for chronic pain, and its effects might be mediated by neuroplasticity associated with coping during ongoing pain.

Title: High density electroencephalography and automated classification of pain perception

Authors: *S. COOMBES, G. MISRA, W.-E. WANG;
Univ. of Florida, Gainesville, FL

Abstract: Previous experiments show that oscillatory power in theta, alpha, beta, and gamma activity are associated with the translation of brief (5 ms) pain eliciting sensory stimuli to the subjective perception of pain. Conventional studies have focused on electrodes over sensorimotor cortex, but recent evidence shows that when pain-eliciting stimuli and subjective perception are concurrent for 10 minutes, pain perception is only associated with increases in gamma power in medial prefrontal cortex. What is not clear, however, is whether concurrent sensory input and subjective perception that lasts a few seconds is sufficient to elicit changes in oscillatory power in medial prefrontal cortex, and whether oscillatory activity in this region can be used to classify pain states. Developing a short duration experimental pain paradigm that assesses medial prefrontal cortex function is attractive because this region is implicated in many chronic pain states. In addition, developing models that use neurological signals to classify pain states remains an important goal in the field of pain research. In the current study we combine high-density EEG with a paradigm in which a 4 second sensory stimulus and the subjective perception of pain are concurrent. We collected data from 30 healthy adult subjects. We implemented a novel unconstrained whole brain analysis approach in source space and used machine learning to determine whether power in specific regions and specific frequencies could be used to classify experimentally evoked high and low pain states. Our analyses revealed that high as compared to low pain perception lead to increases in theta and gamma power in medial prefrontal cortex and reductions in beta power in sensorimotor cortex. A gaussian kernel SVM classifier found a leave-one-out cross validation accuracy of 89%, with gamma power in medial prefrontal cortex and beta power in sensorimotor cortex contributing most to the classification. Our findings show that short duration EEG experimental pain paradigms can provide a window into medial prefrontal cortex function and that pain intensity can be classified using EEG data in source space with a leave-one-out cross validation accuracy of 89%.

Title: Effects of relationship and gender difference on pain

Authors: *H. MAEOKA, A. MATSUO, M. HIYAMIZU, S. MORIOKA;
Kio Univ., Koryo-Cho, Kitakatsuragi-Gun, Nara, Japan

Abstract: [Introduction] The perception of pain varies depending on one's mental state of aversion or unpleasantness, and relationship with others. There are also gender differences in pain sensitivity, and women are said to have a lower threshold and tolerance to pain than men. To date, sufficient study concerning the impact of the relationship with others and the gender difference on the sensitivity of pain including the brain function has not been conducted. In the present study, we used electroencephalogram (EEG) to examine the influence of human relationships and gender difference on pain. [Materials and Methods] The subjects were 28 healthy university students and the experimenter was a woman who gave pain stimulus. The subjects were divided into 4 groups: high intimacy group of 6 men, high intimacy group of 8 women, low intimacy group of 7 men and low intimacy group of 7 women. The measurement procedures consisted of first evaluating the intimacy and anxious, followed by a rest of 2 minutes. Then, a painful stimulus to the forearm for 40 seconds and a rest of 30 seconds were repeated thrice, followed again by a rest of 2 minutes. During this time, EEG and electrocardiography (ECG) were measured simultaneously. The pain thresholds of the forearm, pain intensities to pain stimulus, and unpleasantness as well as anxious were measured before and after measurement. EEG were analyzed by exact low resolution brain electromagnetic tomography (eLORETA), and the rate of change of each evaluation parameter before and after measurement were calculated and compared. In addition, the results of high and low intimacy groups were compared, and their relation to anxious was investigated. [Results] The rate of change of pain thresholds increased significantly in high intimacy men compared with low intimacy men. The rate of change increased significantly in high intimacy men and women in comparison with low intimacy men and women. EEG analysis findings revealed a decrease of α waves in the insular cortex during pain stimulation in the low intimacy group. [Discussion] The results of the present study revealed that the rate of change of pain thresholds increased significantly in the high intimacy groups. Previous studies have reported that it is easier to get more social support from familiar people, and it is thus thought that people in high intimacy groups, where familiar persons are close by, felt better emotional support. Furthermore, the results of EEG analysis revealed a response of the insular cortex during pain stimulation in the low intimacy groups. It appears that the low intimacy groups experienced more unpleasantness and anxious in addition to a decreased rate of change of the thresholds.

Title: Chronic pain patients show regional gray matter atrophy across the affective regions: a voxel-based morphometry study

Authors: T. LI, E. IKEDA, H. KOBINATA, S. ZHANG, T. OTA, K. MAKITA, *J. KURATA; Anesthesiol., Tokyo Med. and Dent. Univ. Hosp. of Med., Tokyo, Japan

Abstract: Regional atrophy in cerebral gray matter was reported in chronic pain (CP) patients from specified etiologies, such as chronic low back pain and fibromyalgia. Here we examined gray matter changes in CP patients across various etiologies to search for a common fingerprint, and sought for its association with behavioral variables.[Methods] We recruited 17 CP patients (age 42.5 ± 10.8 years; 10 females) and 17 healthy control (HC) subjects (41.8 ± 12.2; 9 females). All the subjects were right-handed and abstained from alcohol and caffeine 24 hours before the experiment. From each subject we recorded various psychophysical parameters such as short-form McGill Pain Questionnaire, painDETECT, Pain Catastrophizing Scale, Beck Depression Inventory, and a visual analogue scale (VAS, 0-10 cm) of current pain intensity. We also examined, using a Peltier-type thermal stimulator (Medoc, Israel) with a 30 mm-diameter probe attached on the left volar forearm, a thermal pain threshold at the VAS of 6 (Tv6). We performed a set of multimodal magnetic resonance imaging including resting-state functional and high-resolution T1-weighted anatomical imaging for each subject on a 3.0 T MRI scanner. MR images were analyzed with SPM12 (Welcome Trust Centre for Neuroimaging, UK). Correlation analysis was performed with SPSS 23.0 (IBM, USA).[Results] After correction for age and gender as covariates, CP patients, compared with HC subjects, showed decreased regional GMV in the right primary somatosensory cortex, right premotor cortex, right ventral posterior cingulate cortex (vPCC), left subgenual anterior cingulate cortex (sgACC), left primary motor cortex, and right anterior insula (AI); and increased regional GMV in the right angular gyrus and left precuneus ($P_{unc.} < 0.001$, $k > 19$ voxels). CP patients, but not HC subjects, showed a pronounced age-dependent decrease of GMV in those regions except for the sensorimotor areas ($P < 0.05$). In CP patients, Tv6 was positively correlated with total and regional GMV at the angular gyrus ($P < 0.05$). No correlations were found between any of the behavioral measures and morphometric changes.[Conclusion] CP was associated with gray matter atrophy at the primary sensorimotor areas and hypertrophy at the sensory association areas, which implies possible plastic changes in higher-order processing of nociceptive information. More

importantly, CP was also associated with atrophy at the core regions concerned with affective processing pain, such as vPCC, sgACC, and AI. Functional significance of those alterations will further be determined with functional connectivity analysis of resting-state fMRI data sets.

Title: Investigating the influence of prior information on the neural processing of pain using drift diffusion modelling

Authors: ***K. WIECH**[1], F. EIPPERT[1], J. VANDEKERCKHOVE[2], J. ZAMAN[3], I. TRACEY[1]; [1]Univ. of Oxford, Oxford, United Kingdom; [2]UC Irvine, Irvine, CA; [3]Univ. of Leuven, Leuven, Belgium

Abstract: Expectations have been shown to modulate the perception of pain. Using a drift diffusion model, we recently showed that this influence of prior information on pain processing is primarily based on biased perceptual decision rather than altered sensory processing. However, if a high-intensity stimulus was unexpectedly applied, sensory processing was accelerated, indicating sensory gain ('pop-out'). Here, we investigated the neural mechanisms underlying both types of bias.
In a probabilistic cueing paradigm, healthy participants were presented with one of three visual cues per trial: (1) A cue that was followed by high-intensity stimulation in 80% of the trials and a low intensity stimulation in 20% of trials ('80/20'), (2) a cue that signalled the delivery of a high-intensity stimulus in 20% and of a low-intensity stimulus in 80% of trials ('20/80') and (3) a cue that signalled the same probability for both intensities ('50/50'). Participants indicated as quickly as possible whether a low or high-intensity stimulus had been applied. Brain responses to cue and stimulus delivery were recorded using a 3T MRI scanner. Individual model parameters for shift in prior (indicating biased decision-making) were used as a covariate of cue-related brain

response and individual parameters of sensory gain were correlated with brain responses during stimulus delivery.
A shift in prior towards the high-intensity boundary following the presentation of the '80/20' cue was negatively correlated with activation in right dorsolateral prefrontal cortex (DLPFC). This cue-related DLPFC engagement was related to activation in the PAG during stimulus delivery but only if the expected high intensity stimulus was applied. A shift towards the low intensity boundary during presentation of the safe '20/80' was positively related to right DLPFC activity. Increase in sensory gain during 'pop-out' scaled with engagement of left amygdala which showed increased functional connectivity with the PAG during stimulus application.
Our results indicate that the engagement of the right DLPFC when relevant information becomes available but prior to stimulus delivery 'buffers' against biased perceptual decision-making. Its link to PAG activation during subsequent stimulus delivery resembles known descending pain modulation implemented through DLPFC and PAG in cognitive pain modulation. Accelerated processing of unexpectedly aversive stimuli involves the amygdala and its cross-talk with the PAG. The convergence of both types of bias in the PAG as the key subcortical relay station for incoming noxious information highlights its pivotal role in expectancy-related changes in pain processing.

Title: Persistence of pediatric post-traumatic headache (PTH) and disturbances in regional cerebral blood flow

Authors: *H. SANTORO[1], D. HODKINSON[1], P. SERRANO[1], M. O'BRIEN[2], A. LEBEL[1], R. BURSTEIN[3], L. BECERRA[1], D. BORSOOK[1];
[1]Anesthesiol., Boston Children's Hosp., Waltham, MA; [2]Div. of Sports Med., Boston Children's Hosp., Boston, MA; [3]Anesthesiol., Beth Israel, Boston, MA

Abstract: Introduction: Children suffering from concussion/mild traumatic brain injury often experience persistent post-traumatic headache (PTH). Surprisingly little is known about the pathogenesis of PTH, although shared pathophysiology with that of the brain injury is suspected. These changes may lead to negative outcomes in PTH patients, including the disruption of normal development and increased risk of pain chronification.
Aims & Objectives: To characterize the clinical features of post-traumatic headache (PTH), and determine its effect on regional cerebral blood flow (rCBF).
Methods: *Participants:* 12 PTH patients and 22 healthy controls were recruited for the study (age range 14-18 years). Patients were identified at Boston Children's Hospital and scanned within the range of 16-351 days post-concussion/mTBI. *Headache Characteristics:* A retrospective PTH attack report, including the prevalence of headache type and characteristics, along with cognitive, autonomic and sensory symptoms, was collected. *Image acquisition:* Participants were scanned on a 3T MRI scanner. High-resolution T1-weighted anatomical scans were acquired for image registration. Quantitative rCBF measurements were performed using pseudo-continuous arterial spin labeling (pCASL) [PLD=1.3sec, LD=1.5sec, GE-EPI, TR/TE= 3870/12, FOV=220mm, matrix=64x64, 26 slices, slice thickness = 5mm]. *Image processing:* Data were pre-processed using SPM8. Group-wise changes in rCBF were calculated using random effects two-sample t-test.
Results: *Symptom profile:* Persistent headaches were described as stabbing (25%), exacerbated by exertion (17%), and have characteristics of tension-type (17%), cluster (8%), migraine (8%), or other (25%) headaches. Other associated symptoms included cognitive (90%), autonomic (70%) and sensory (80%) deficits. *Blood flow measurements:* Statistical comparisons between healthy controls and PTH patients revealed significant rCBF increases in several areas, including insula, basal ganglia, and limbic system.
Discussion: PTH in children seldom occurs in isolation and is normally accompanied by several clinical symptoms. These neurological deficits suggest a widespread disruption in brain function, which could be driven by altered mechanisms of resting brain perfusion. Whether or not there is a causal and temporal relationship between rCBF and headache symptomatology remains to be confirmed in prospective studies. The ASL technique may be used to reliably measure successful brain recovery in pediatric PTH patients, thus providing a useful clinical diagnostic marker.

Ctr., Boston, MA; [5]Departments of Anesthesiol. and Psychiatry, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA; [6]Dept. of Psychiatric Neuroimaging, Massachusetts Gen. Hosp. Dept. of Psychiatry, Charlestown, MA

Abstract: Introduction Expectation can significantly modulate pain perception. In this study, we investigated whether boosting expectancy can enhance acupuncture treatment effect in subjects with osteoarthritis of the knee (knee OA) as measured by Knee injury and Osteoarthritis Outcome Score (KOOS), and explored its underlying mechanism using resting state functional connectivity (rsFC). **Methods** Patients with knee OA were randomized to boosted acupuncture (Boost), standard acupuncture (Acu) or treatment as usual control (TAU). Each subject in the two acupuncture groups received a total of 6 sessions within one month. Each subject participated in two identical fMRI scanning sessions (treatment 1 and 6) including a 6-minute resting state fMRI used for this analysis. In the Boost group, expectancy manipulation was applied during two scan sessions, i.e. subjects were told that stimuli of identical experimental heat pain would be applied before and after acupuncture. In fact, the heat pain intensity was lowered surreptitiously after treatment to boost subjects' expectation. In the Acu group, subjects were told that we reduced the pain intensity after treatment. Subjects in the TAU group experienced the identical procedures as the Acu group except no acupuncture. Seed-based rsFC was analyzed with CONN. Histological atlas distributed along with FSL for laterobasal (LB), centromedial (CM), and superficial (SF) nuclei were used as seeds. A threshold of voxelwise $p< 0.005$ and $p< 0.05$ FDR corrected was applied. **Results** 54 subjects (19 Boost, 18 Acu and 17 TAU) completed both fMRI sessions. The ANCOVA in KOOS pain subscale indicated that the Boosted Acu significantly increased (improvement) compared to Acu ($p = 0.011$) and TAU groups ($p = 0.005$). The Acu and TAU groups were not significantly different. The rsFC analysis showed that compared to Acu, Boost Acu produced a significant rsFC increase between 1) the right CM and bilateral pregenual anterior cingulate cortex (pACC), medial prefrontal cortex

(MPFC), and right angular gyrus; 2) left CM and right dorsal lateral prefrontal cortex (DLPFC), MPFC, right insula, putamen, thalamus; and 3) right SF between bilateral precentral and postcentral gyrus. Compared to TAU. Boost Acu produced significant rsFC increases between 1) right CM and right ventral striatum (VSt), putamen, and hypothalamus; and 2) right LB and bilateral subcallosal cortex and right orbital prefrontal cortex. **Conclusions** Our results suggest that expectancy can significantly enhance clinical improvement through modulation of multiple networks including CM, the reward network (ventral striatum), and pain descending pain modulation systems (ACC & MPFC).

Title: Brain connectivity patterns provide insight into the mechanism of visual hypersensitivity in fibromyalgia

Authors: *T. E. LARKIN, JR[1,2,3], C. M. CUMMIFORD[2,3,1], E. ICHESCO[2,4], S. E. HARTE[2,5], D. J. CLAUW[2,5], R. E. HARRIS[2,5];

Abstract: Introduction: Patients with fibromyalgia (FM), a chronic centralized pain disorder, show increased hypersensitivity to multiple sensory stimuli, including light. The insula may play a role in multisensory integration as activity in this region is amplified during both pain and visual stimulation in FM. However, it is unknown whether these findings are related to insula connectivity at rest and/or during visual stimulation. Here, we examined differences in functional connectivity during visual stimulation versus rest, as well as longitudinally in FM.
Methods: 15 female FM patients underwent fMRI at baseline and 4 weeks after a sham treatment. Functional connectivity during an evoked visual stimulus task and resting state was

measured. Whole brain connectivity to 4 anterior insula seeds, we previously identified as showing enhanced activations with this visual stimulus in FM, was performed using SPM8 and the Conn Toolbox. Subject-specific connectivity maps for each seed were entered into group analyses to measure changes in connectivity at baseline and longitudinally. We also performed Group Independent Component Analysis using the GIFT toolbox to assess lateral visual network (LVN) connectivity. Results were deemed significant at a false discovery rate cluster-level corrected p-value < 0.05 derived from a voxel-wise uncorrected p-value < 0.001. Post-hoc correlations were performed between connectivity and unpleasantness ratings (20-point Gracely Box Scale) following visual stimulation in SPSS 22 ($p < 0.05$).
Results: At baseline, insula connectivity to the precentral/postcentral gyrus and cuneus were increased during visual stimulation. Increased connectivity between the insula and the precuneus, a region of the Default Mode Network, was positively correlated with unpleasantness ratings of the visual stimuli ($r^2 = 0.527$). Post-sham treatment, we found that decreases in insula connectivity to the inferior frontal gyrus ($r^2 = 0.881$), precentral gyrus ($r^2 = 0.894$), and mid occipital lobe ($r^2 = 0.866$) were positively correlated with decreases in unpleasantness ratings between the two time points. Further, we found increased connectivity between the LVN and insula at rest, absent of visual stimulation. ($p < 0.05$).
Conclusion: These data suggest that the insula cortex is involved in the processing of aversive visual stimuli in FM as ratings of visual unpleasantness were positively associated with connectivity to this structure. We speculate that longitudinal changes in sensory integration within the insula may be related to modulation of the underlying pathology in FM. Connectivity data in pain-free controls is needed to confirm this hypothesis.

Title: Behavioral responses to noxious stimuli shape the perception of pain

Authors: *E. S. MAY[1], L. TIEMANN[1], P. SCHMIDT[1], M. M. NICKEL[1], N. WIEDEMANN[1], C. DRESEL[2], M. PLONER[1];
[1]Dept. of Neurol. and TUM-Neuroimaging Ctr., Technische Univ. München, Muenchen, Germany; [2]Ctr. for Neurosci., The Feinstein Inst. for Med. Res., Manhasset, NY

Abstract: Pain serves vital protective functions, which crucially depend on appropriate behavioral responses to noxious stimuli. However, pain has mostly been conceptualized as a perceptual phenomenon. In this common perception-centered concept of pain, it is thought that a noxious stimulus induces a percept which, in turn, induces a behavioral response. In view of the utmost relevance of protective behavioral responses, we here considered an alternative, action-oriented concept of pain in which behavioral responses do not exclusively depend on perception but themselves shape the perception of pain. We tested this hypothesis in a simple behavioral experiment in which 55 healthy human subjects performed speeded behavioral reactions and provided perceptual ratings of brief noxious and tactile stimuli to their right hand. As expected, intensity ratings increased and reaction times decreased with increasing stimulus intensity for both stimulus types. To further explore the relationships between stimulus intensity, behavioral responses, and perception, we performed multi-level moderated mediation analyses. These analyses revealed that behavioral responses are significantly involved in the translation of a noxious stimulus into the perception of pain. This involvement was significantly stronger for painful than for non-painful stimuli, as shown by a stronger mediating role of action in the stimulus-perception relationship for pain than for touch stimuli. A subsequent control experiment with an additional 35 healthy subjects and randomized instead of block-wise presentation of pain and touch stimuli fully replicated these results. Together, these findings strongly indicate a pain-specific contribution of action to perception and thereby advocate a novel action-oriented concept of pain. Such a concept parallels recent concepts of emotions, which also emphasize a central role of reactions and actions in the emergence of emotional feelings. Furthermore, our results might entail important implications for the understanding and treatment of chronic pain. The modulation of pain behavior and underlying brain circuits might not only alleviate the consequences of pain but also influence an important determinant of pain perception.

Title: Relationship between the pain and brain activity during illusory kinesthesia in patients after surgery for a distal radius fracture.

Authors: *R. IMAI[1], M. OSUMI[2], S. MORIOKA[2,3];
[1]Kio Universsity, NARA, Japan; [2]Neuro Rehabil. Res. Center, Kio Univ., NARA, Japan; [3]Grad. Sch. of Hlth. Sciences, Kio Univ., Nara, Japan

Abstract: [Introduction] We showed that illusory kinesthesia by vibratory tendon stimulation on acute stage after surgery for a distal radius fracture reduces pain (Imai, 2015). It has been reported that activation of motor-related regions of the brain inhibits pain (Maarrawi, 2013), but it has not been verified that the region of the brain related to illusory kinesthesia is really activated during illusory kinesthesia in patients after surgery for a distal radius fracture. Therefore, we used brainwaves to investigate whether the motor-related regions of the brain can be activated through an illusory kinesthesia with vibratory tendon stimulation the day after surgery for a distal radius fracture. [Method] Subjects were 6 patients who had undergone surgery for a distal radius fracture. We used a hand massager (YCM-20,70Hz) for vibration stimulus. The illusory kinesthesia was conducted with a vibration stimulus on the extensor digitorum muscle at the wrist joint of the non-affected hand. The intervention period was 7 days. Pain at rest, movement pain and illusory kinesthesia were all evaluated using a Visual Analogue Scale(VAS) on day one and after 7 days of vibration stimulus. We used electroencephalograph(Biosemi) to measure brainwaves, the electrodes were arranged according to the 10-20 system with 32ch, and the sampling frequency was set to 1024Hz. EMSE Suite (Source Signal Imaging) was used for analysis and the power spectrum analysis at rest and during vibration stimulation targeted the C3, Cz and C4 regions. The high-α wave band was set at around 2Hz of each subject's peak value, the ERD value {(exercise-rest)/rest)} was calculated, and Spearman's rank correlation coefficient was used to calculate the correlation between pain at rest and pain on movement. Level of significance was set as 5%. [Results] An illusory

kinesthesia was elicited in 6 subjects. The pain at rest decreased from 60.8±25.7mm (mean±SD) to 13.8±15.9mm (mean±SD), while movement pain decreased from 68.0±17.0 mm (mean±SD) to 29.8±17.6 mm (mean±SD). High-α was decreased in C3, Cz and C4ch during vibration stimulus compared to during at rest. Also, a significant negative correlation was seen in the C3, Cz and C4ch ERD value and the level of change in pain at rest ($p<0.05$). [Conclusion] During illusory kinesthesia in patients after surgery, attenuation of α-waves, which are related to execution of movement was seen in the bilateral sensorimotor areas of C3, Cz and C4ch. Also, a negative correlation was seen in the C3, Cz and C4ch ERD value and the amount of change in pain at rest. These results suggest that sensorimotor areas activated by the illusory kinesthesia may be involved in improvement of pain.

Title: Treatment variability affects placebo responses through prediction error signaling

Authors: *A. GRAHL, C. BÜCHEL;
Dept. of Systems Neurosci., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: Placebo effects and concomitant hypoanalgesia exemplifies the substantial influence of expectations on treatment outcomes. We investigated the influence of variability in prior experience and expectations on placebo effect magnitudes by using a Bayesian-like experimental manipulation and fMRI.
BOLD responses of 63 healthy male subjects ($N_{group1/2}$ = 31/32) were compared by applying heat pain. As placebo treatment, transcutaneous electrical nerve stimulation (TENS) was introduced as a putative method for pain treatment. During conditioning, both groups' placebo compared to the control condition temperature was lowered. Via different temperature variation across trials, one group experienced the placebo treatment as constant (certain, SD = 0°C) the other as variable hypoanalgesic (uncertain, SD = 0.57°C). During test, the influence of both treatments (certain/uncertain) on the placebo effect was investigated via 22 identical heat stimuli (11 placebo TENS/11 control no TENS).
Pain ratings in the placebo compared to the control condition were significantly lower only in the

certain group. On the neural level, this variability modulated placebo effect was reflected by decreased amygdala and anterior cingulate cortex activity in the certain compared to increased activity of the same areas in the uncertain group during early pain anticipation. For heat pain, an activation increase for placebo in the uncertain compared to the certain group was observed in the PFC, insula, and substantia nigra (SN). Furthermore, increased SN activity of the uncertain group was correlated with individual pain rating variability in placebo conditioning and may reflect involvement of dopaminoceptive structures.
Activation of dopaminoceptive structures such as the SN has been linked to appetitive prediction error coding (Seymour et al., 2005) which is more pronounced in the uncertain group's placebo condition. In summary, treatment variability can influence the effect of expectation in the perception of painful stimuli and seems to be mediated by differences in prediction error signaling.

Title: Sex differences in the functional connectivity of insular cortex during colorectal distension

Authors: *Z. WANG[1], Y. GUO[1], E. A. MAYER[3], D. P. HOLSCHNEIDER[2];
[1]Psychiatry & Behavioral Sci., [2]Psychiatry & Behavioral Sci., Neurology, Biomed. Engin., Univ. of Southern California, Los Angeles, CA; [3]Medicine, Physiology, Psychiatry and Biobehavioral Sciences,Center for Neurobio. of Stress, UCLA, Los Angeles, CA

Abstract: BACKGROUND: The insular cortex plays a critical role in visceral pain processing and shows sex differences in functional activation during noxious visceral stimulation. Much less is known at the circuit level regarding functional interactions both within the insula and between the insula and other parts of the brain. AIM: To characterize sex differences in insular functional connectivity (FC) in rats during noxious colorectal distension (CRD). **METHODS:** Functional connectivity analysis was applied to a published data set consisting of 4 groups: male/control, male/distended, female/control, and female/distended. Cerebral blood flow mapping was performed using ^{14}C-iodoantipyrine autoradiography in awake, nonrestrained rats. Forty regions of interest (ROIs) were defined anatomically to represent the granular, dysgranular, and agranular insular cortex along the anterior-posterior axis. A 40x40 inter-regional correlation matrix was calculated for each group to characterize intra-insular FC, which was further analyzed with graph theoretical tools. Representative insular ROIs were chosen for seed correlation analysis to examine sex differences in their global FC patterns. **RESULTS:** Both control females and males showed strong intra-insular FC with females showing higher density (fraction of connections to possible connections) at 54% compared to males at 32%. Clear functional segregation was seen along the anterior-posterior axis. Denser FC was observed anteriorly in females but posteriorly in males. During CRD, intra-insular FC density decreased greatly to 25% in females, and modestly to 26% in males. A loss of long-range connections was apparent. New functional organization was characterized in both males and females by a functionally connected mid-insular cluster and primarily short-range FC along the anterior-posterior axis of the insula. Seed correlation analysis revealed complex sex- and CRD-related differences in insular FC with other brain areas. In particular, during CRD, sex differences were noted in FC of the anterior agranular insular cortex with the medial prefrontal cortex and with the periaqueductal gray, suggesting sex differences in the affective and modulatory aspects of visceral pain processing. **CONCLUSIONS:** Functional connectivity analysis revealed important

sex differences in the functional organization of the insular cortex and in its interaction with other areas in the pain circuit. These findings bring new insights into understanding at the circuit-level sex differences in visceral pain processing.

Title: Acute pain perception is associated with decreased modularity of brain functional networks

Authors: *M. N. BALIKI[1,2], B. PETRE[2], M. A. FARMER[2], A. VANIA[2];
[1]Rehabil. Inst. of Chicago, Chicago, IL; [2]Physiol., Northwestern Univ., Chicago, IL

Abstract: Theories of pain perception are traditionally based on regional nociceptive activity and do not account for brain integrative mechanisms that must underlie conscious perceptions. More recent human neuroimaging studies are beginning to explore how functional brain networks interact and are modulated by pain perception. While many functional network properties have been identified during rest and task states, it remains unclear how pain perception impacts the intrinsic brain network architecture. Here we tested the extent of brain network changes that can reflect acute pain perception, using graph theoretical analysis applied to functional connectivity data.
Twenty healthy subjects (9 females) were scanned at rest, during a pain, and visual rating tasks. Following preprocessing images were registered into standard MNI space and subsequently down-sampled to 5850 voxels with size of 6x6x6 mm. Brain networks were constructed from the functional correlation between all voxels at various threshold (2 - 10% density). We compared global and local brain network properties between the 3 scans.
Similar to previous reports, brain networks during task and resting state were highly similar. Only modularity was significantly lower during pain, compared to the visual and resting state scans, at all thresholds ($F=19.53$, $p<0.01$). Furthermore modularity exhibited a strong association with the number of voxels activated (glm) in pain ($R = -0.81$, $p< 0.001$), but not visual task. Local differences in connectivity were limited to the dACC, which showed 40% increase in edges for pain ($F = 45.02$, $p < 0.001$). Finally, We tested the validity of our results in an

independent group of female subjects (n = 11) during painful and nonpainful mechanical vulvar stimulation. Only modularity correctly classified painful and non-painful scans (ROC=0.87, $p<0.01$), while activity contrast (glm), dACC connectivity (ROC=0.52, p=0.84) and the Neurological Pain Signature (ROC = 0.57, p =0.74) did not.
Our results provide compelling evidence that pain perception is associated with increased information integration throughout the brain, resulting in decreased modularity, and modularity seems to be a more specific brain parameter related to pain perception than measures used in the past. However, more studies are required to account for the differentiable aspects of pain perception, such as saliency, attention, anxiety, and intensity, and their relationships to modularity changes during pain. Our findings point to a possible mechanism supporting brain integrative nature of pain perception.

Title: Simultaneous fMRI mapping of nociceptive pathways in brain and spinal cord of non-human primates

Authors: *P.-F. YANG, F. WANG, L. CHEN;
Inst. of Imaging Sci., Vanderbilt Univ., Nashville, TN

Abstract: Nociceptive signals originated from peripheral skin (e.g., hand) ascend to brain via spinal cord and lead to pain perception in conscious subjects. Pain modulation also occurs in parallel at each information relay station along the pathway. The two nociceptive ascending and descending systems interact constantly in mediating pain perception in a context dependent manner. To date, even though spinal cord and brain interact constantly during nociceptive processing, the vast majority of *in vivo* pain studies have focused on either the spinal cord or the supra-spinal regions, mainly due to a lack of effective tools. Thus, the ability to monitor the entire nociceptive pathways in action noninvasively, particularly in primates, will have unprecedented impact for basic and clinical pain research. Recently, few studies in humans have showed promise that simultaneous mapping of pain response in the brain and spinal cord can be achieved. Building upon our previous successful high-resolution multi-parametric MRI and

fMRI studies of the nociceptive pathways/circuits in the spinal cord and the brain of monkeys at 9.4T (in separate sessions), this study aims to: (1) implement novel magnetization transfer (MT) contrast MRI to visualize spinal grey and white matter structures, and (2) optimize fMRI imaging protocols to map simultaneously nociceptive heat evoked fMRI responses and intrinsic functional connectivity of the entire pain system from the cervical spinal cord to the entire brain. Three monkeys have been scanned so far on a 9.4T Varian INOVA scanner under isoflurane anethesia. fMRI data during noxious heat stimulation of distal finger pads of digits 2&3, as well as at rest, were acquired with a custom volume coil and multi-shot EPI sequence. fMRI signals underwent a series of pre-processing procedures, including physiological noise correction, slice timing and motion corrections, and regression of CSF and muscle signals. Resting state fMRI data (300 volumes) were band pass filtered (0.01-0.1 Hz) for further analysis. With proper maintenance of animal's physiological condition, we were able to detect stimulus-evoked fMRI activation in the spinal cord dorsal and ventral horns and regions in the brain. When a seed was placed at the right motor cortex, functional connectivity was detected in multiple brain regions and the ventral horn of the cervical spinal cord. Our preliminary results show the feasibility and potential of simultaneous brain and spinal cord MRI/fMRI for investigating the functional connectivity between brain and spinal regions involved in nociceptive processing at a fine spatial resolution that has not been previously achieved.

Title: Neural network of dysesthesia symptoms produced by sensorimotor incongruence in healthy volunteers. A functional connectivity analysis

Authors: *O. KATAYAMA[1], M. OSUMI[2], R. IMAI[1], T. KODAMA[2,3], S. MORIOKA[1,2]; [1]Dept. of Neurorehabilitation, Grad. Sch. of Hlth. Sciences,Kio Univ., Nara, Japan; [2]Neuro Rehabil. Res. Center, Kio Univ., Nara, Japan; [3]Fac. of Hlth. Sciences, Kyoto Tachibana Univ., Kyoto, Japan

Abstract: Objectives. Pathological pain is caused by sensorimotor incongruence. Several studies on healthy subjects clearly indicate that dysesthesia, similar to pathological pain, is caused by sensorimotor incongruence. There are some reports about the cortical mechanisms of the dysesthesia caused by sensorimotor incongruence. However, only a few of these neural network

reports exist. In this study, we aimed to clarify the neurophysiology of the neural network by analyzing the functional connectivity on the electroencephalogram (EEG).
Methods. Eighteen healthy subjects were recruited. The subjects were instructed to place their left limb such that it was reflected in a mirror and aligned in the sagittal plane and place their right limb behind the mirror. They were asked to perform the flexion/extension exercises with their elbows: moving elbows simultaneously (Congruence condition), moving elbows unsymmetrically (Visual incongruence condition), and moving only the left elbow, while the right one was moved by the experimenter (Proprioception incongruence condition). We recorded the EEG activity, and the participants were asked to rate the intensity of their dysesthesias on Numerical Rating Scale (NRS) in every condition. For functional connectivity analysis, we used exact-Low Resolution Brain Electromagnetic Tomography (eLORETA).
Results. The NRS scores among the three conditions showed significant effects in peculiarity (χ^2=18.98, P = 0.000), and in nausea (χ^2 =13.24, P = 0.001) in the Friedman test. The post-hoc test showed that peculiarity in the Visual and Proprioception incongruence conditions were significantly higher than in the Congruence condition ($p < 0.016$). Nausea in the Proprioception incongruence condition was significantly higher than that in the Congruence condition ($p < 0.016$). When comparing subjects with incongruence in proprioception causing peculiarity and subjects with no peculiarity, we observed a strong functional connectivity on the beta band between the bilateral anterior cingulate cortex ($t = 3.292$, $p < 0.05$). Finally, between subjects with nausea and without nausea, on the beta band, there is a strong functional connectivity ($t = 3.188$, $p < 0.05$) between the bilateral ventromedial prefrontal cortex and the right anterior cingulate cortex.
Conclusions. The present study revealed that peculiarity and nausea were caused by the Proprioception incongruence condition. Furthermore, we confirmed that subjects with dysesthesia have strong activity on the neural network in the brain region linked to emotions. Consequently, we suggest that these neural networks are related to the occurrence of dysesthesia.

Title: Active vibrissal sensing in arboreal environments

Authors: *K. ARKLEY, B. MITCHINSON, T. J. PRESCOTT;
Dept. of Psychology, Univ. of Sheffield, Sheffield, United Kingdom

Abstract: Navigating through tree canopies is a skill that many small mammals such as rodents are expert in. The biomechanics of the body during arboreal locomotion is well studied, however, very little is known about the sensing strategies used to extract information about the local environment in order to inform the placement of safe footfalls or general body posture. There is some evidence to suggest the vibrissae (whiskers) provide an advantage for such locomotion, for instance i) small nocturnal and arboreal mammals have longer and more densely packed facial vibrissae than ground-dwelling or burrowing mammals; ii) vibrissae are present elsewhere on the body, such as on the wrists; iii) rodents employ their vibrissae to determine the distance of gaps in order to cross them. Here we present the first direct evidence that rats adapt their vibrissal sensing strategies in order to sample the position and diameter of "branches" during arboreal locomotion. Animals were filmed in high-speed at 500 fps from the side (dorsoventral view) and from the front (rostral view) whilst freely exploring a vertical pegboard maze (1 m x 1 m) in search of food rewards. Pegs were interchangeable, with 10 cm spacing vertically and horizontally between each. We compared the position and movement of the vibrissae and head whilst animals crossed gaps of different distances, onto branches (pegs) of differing diameter. Rats were capable of actively manipulating the angle of their vibrissae in the dorsoventral plane in order to make as many contacts with the substrate as possible, such that the ventral-most vibrissa retract as the rat moves closer to the branch, resulting in an asymmetry between the dorsal- and ventral-most vibrissae. Furthermore, as determined from the rostral-view, rats adopted a strategy of pointing the vibrissae down towards the ground when travelling along narrow branches, but increasing this angle to point upwards toward the ceiling as branch diameter increased. This maximal contact strategy allowed the animal to trace the outline of the branch, whilst sampling the area the forepaws will subsequently land.

Title: What tactile information do trigeminal projection pathways convey during behavior?

Authors: *V. PREVOSTO[1,2], F. WANG[1];
[1]Neurobio. department, [2]Biomed. Engin., Duke Univ., Durham, NC

Abstract: Whisker-evoked tactile sensation is a prime modality for rodents to appraise their environment. Afferent facial tactile inputs are first distributed and processed through brainstem trigeminal circuits, before being further integrated at higher levels. While the functional organization of the trigeminal brainstem is broadly understood, little is known about the physiological responses of neurons in diverse behavioral contexts, let alone the role played by specific projection pathways during behavior. We set out to tackle these issues through a two-pronged strategy, which involved
a) inducing the expression of ChR2 (a light-activated cation channel) in thalamic-projecting trigeminal neurons, in order to identify ("phototag") those neurons during extracellular recordings in behaving mice, and
b) recording from the principal or spinal trigeminal nuclei (PrV, SpV respectively) with multi-channel optrodes while mice learned to perform complementary sets of behavioral tasks.
ChR2 expression in trigeminal projection neurons was achieved by injecting a lentiviral vector coding for the Cre protein (Lenti-Cre) in Ai32 mice, which genome has been altered to enable Cre-dependent ChR2 expression. In addition, the viral vector was conferred the ability to propagate retrogradely, through pseudotyping with a rabies-derived fusion glycoprotein. The retrograde Lenti-Cre could thus transfect and induce ChR2 expression in neurons that specifically target the injected region. The viral vector was injected in known thalamic projection zones of PrV or SpV output neurons, namely VPM or Po. Optrodes were built by combining home-made tetrode arrays or single-wire multi-electrode arrays together with a fiber optic cannula and (optionally) a microdrive system. After habituating mice to behavioral setups, selected subjects were sequentially injected with the retrograde Lenti-Cre, implanted with an optrode and finally trained on behavioral tasks.
In order to study differential recruitment of trigeminal output pathways according to behavioral context, we trained mice on two separate tasks, the first involving sensory discrimination (texture detection task), and the second based on sensory localization (gap crossing task). Overall, this experimental strategy enables the study of basic physiological properties (sensory tuning) of ascending trigeminal pathways in behaving animals, as well as to explore potential contextual response modulation of the neurons contributing to those pathways. We will discuss whether and how sensory tuning may be selectively modulated at this early stage across specific ascending pathways during diverse exploratory behaviors.

Title: New ways to wiggle whiskers: optogenetic control of whisker movement and active sensation

Authors: *D. J. MARGOLIS[1], S. PARK[2], A. BANDI[2], C. R. LEE[2];
[1]Cell Biol. & Neurosci., [2]Rutgers Univ., Piscataway, NJ

Abstract: The mouse whisker-to-barrel cortex system is an important model system in neuroscience. During natural behaviors, mice actively move their whiskers to touch and palpate objects of interest. Active sensation is difficult to control experimentally. We explored stimulation of whisker movements using mouse lines that express channelrhodopsin-2 (ChR2) in facial muscles, peripheral nerves, or a combination of muscle and nerve. High-speed videography was used to quantify the angle change of whisker protractions evoked by optical stimulation of the whisker pad in mice expressing ChR2 in facial muscles. Larger amplitude whisker protractions could be elicited by higher light intensities in a linear fashion. Longer duration light pulses at maximal intensities elicited larger amplitude whisker protractions that peaked after durations of approximately 60 ms. Stimulation at various frequencies revealed stronger adaptation (decreased movement amplitude with subsequent pulses) at high frequencies. Electrophysiological recordings of sensory cortex multiunit spiking activity and local field potentials showed that peripheral optogenetic stimulation evokes cortical signals with longer latency than responses to mechanical whisker stimulation. Furthermore, behavioral experiments showed that mice can detect peripheral optogenetic stimulation. Our results establish a paradigm for non-invasive optogenetic control of whisker movements which will be useful for studies of sensorimotor integration in the mouse whisker-to-barrel cortex system.

Title: Motor cortex-directed movement of the mystacial vibrissae through pre-motor neurons in the spinal trigeminal nuclei

Authors: *N. MERCER LINDSAY[1], P. M. KNUTSEN[2,4], D. GIBBS[3], H. J. KARTEN[3], D. KLEINFELD[2];

Abstract: Context dependent coordination of orofacial motor actions into a behavior involves a convergence of reflexive circuits, sensory feedback, and motor commands onto pre-motor and motor circuits in the brainstem. The spinal trigeminal nuclei (SpV) are known to receive primary sensory input and contain pre-motor neurons that project onto facial motor neurons (Takatoh et al. *Neuron* 2013; Matthews et al. *J Comp Neurol* 2015). Here, we explore the role of descending projections from vibrissa motor cortex (vMCx) onto SpV pre-motor neurons in controlling movement of the mystacial vibrissae and potential filtering of peripheral sensory information. Using a combination of modern viral techniques, we show that vMCx projections to SpV are concentrated in the region containing premotor neurons. Preliminary evidence indicates that the vMCx preferentially innervates somatotopically within SpV. Optogenetic activation of trigeminal projecting vMCx neurons evokes vibrissa movement. We conclude that vMCx projections to SpV, along with those from vibrissa primary somatosensory cortex (Matyas et al. *Science* 2010), integrate with primary sensory inputs to modulate vibrissae motor output. Modulation is likely through control of the set-point of vibrissa position.

Title: Vibrissa motor cortex activity suppresses contralateral whisker movement

Authors: *C. L. EBBESEN, G. DORON, C. LENSCHOW, M. BRECHT;
BCCN Berlin, Berlin, Germany

Abstract: Anatomical, stimulation and lesion data point to a role of vibrissa motor cortex in the control of whisker movement. Motor cortex is classically thought to play a key role in movement generation, but most studies have found only weak correlations between vibrissa motor cortex activity and whisking. The exact role of vibrissa motor cortex in motor control remains unknown. To address this question we recorded vibrissa motor cortex neurons during various forms of vibrissal touch, all of which were associated with increased movement and forward positioning of whiskers. Free whisking, palpation of objects and social touch all resulted in similar vibrissa motor cortex responses: (i) Population activity decreased. (ii) The vast majority (~80%) of significantly modulated single cells decreased their firing. (iii) Rate-decreasing cells were the most strongly modulated cells. To understand the cellular basis of this decrease of activity, we performed juxtacellular recordings, nanostimulation and in vivo whole-cell recordings in head-fixed animals. Social facial touch - a strongly engaging stimulus - resulted in decreased spiking, massively decreased cell excitability and a ~1.5 mV hyperpolarization in vibrissa motor cortex neurons. To assess how activation of vibrissa motor cortex impacts whisking we performed intracortical microstimulation, which led to whisker retraction, as if to abort vibrissal touch. Finally, we blocked vibrissa motor cortex. A variety of inactivation protocols resulted in increased contralateral whisker movements and contralateral whisker protraction, as if to engage in vibrissal touch. Surprisingly, our observations collectively point to movement suppression as a prime function of vibrissa motor cortex activity.

Title: Biomechanical coupling of frictional movements at the tip of a vibrissa to its base.

Authors: ***M. OLADAZIMI**[1,2,3], T. PUTELAT[4], C. SCHWARZ[2,3], R. SZALAI[4], A. CHAMPNEYS[4];

Brain Res., Tuebingen, Germany; [4]Dept. of Engin. Mathematics, Univ. of Bristol, Bristol, United Kingdom

Abstract: Rats collect tactile information about their surrounding environment while actively rubbing and taping their whiskers against objects. The nature of the physical signals that rats use for the discrimination of surface textures is still poorly understood. We investigated the mechanical modalities of the signal transference from the whisker's tip and object contact zone to the base and mechanoreceptors interface. To this end we extracted the spatiotemporal evolution of the local curvature of plugged rat vibrissae from their motion acquired by high-speed and high resolution videography (>2 kHz frame rate). The vibrissa were mounted on a rotating axis and swept by a stepper motor at different angular velocities and distances across sandpaper surfaces of different grades. Our measurements suggest that dynamic friction, expressed as stick-slip movements of the vibrissa tip, is converted to bending waves propagating along the whisker towards its base. We constructed a mathematical model, which converts local curvature into moments along the vibrissa shaft. We found that the bending moment variations are transmitted (quasi) instantaneously from tip to base and are strongly amplified. In a second approach we aimed at explicitly modelling the tip contact zone, giving rise to frictional movements, and linking it to a model of the conically tapered shaft. Preliminary results showed good agreement of these model outcomes with the previously observed torque amplification.

Title: A new dimension in multiple whisker tracking: imaging and tracking whisking behaviour in 3D

Authors: *M. S. LOFT, M. H. EVANS, S. FOX, R. S. PETERSEN;
Fac. of Life Sci., Univ. of Manchester, Manchester, United Kingdom

Abstract: During natural active exploration, rodents rhythmically move their whiskers against objects in their surroundings. This behaviour is commonly studied by high-speed imaging of the whiskers in the horizontal plane (bird's eye view). However, whisker movement has a substantial 3D component and involves torsional rotation. Moreover, whisker-object contact can cause movement and bending with a vertical component. Our aim was to get comprehensive insight into how this important sensory system operates by imaging the whiskers in 3D. To this end, we filmed awake mice whisking in 3D and developed computer vision software to extract the 3D kinematic /mechanical whisker information from the videos.
Head fixed male C57BL/6 mice (trimmed to either one row or one arc of whiskers) were encouraged to whisk either in free air, against a smooth metal pole, or against a textured surface. The whiskers were illuminated using high-power infrared LED arrays and imaged using high-speed cameras (1000frames/sec) in both horizontal and vertical (coronal) planes. In order to calibrate the two views, a known object was moved within the field of view and the data used to calculate the mapping from real world 3D coordinates to the horizontal and vertical projections. All videos collected were successfully calibrated. The 3D trajectory of each target whisker was tracked using an extension of our 2D whisker tracker ('WhiskerMan'; (Bale et al., 2015, Campagner et al., 2016)). This tracker differs from other trackers in using temporal information to obtain robust to whisker cross-over events. The new algorithm represents the proximal segment of each target whisker as a 3D, quadratic Bezier curve and fits parameters to data from the two (calibrated) image planes.
Using this approach it was possible to image a large proportion of the whisker array including Greek whiskers β-δ, and rows B-E within arcs 1-4. The new algorithm successfully tracked four whiskers simultaneously both in free air and during touch, with only occasional errors from whisker cross-over events. For each whisker, it was possible to obtain a 3D description, including azimuthal and elevation angles, torsional rotation and 3D curvature.

All experimental procedures were approved by the United Kingdom Home Office authorities and the University of Manchester ethical review.

Title: Diverse strategies underlying active tactile discrimination in head-fixed mice: a novel, three-choice object localisation task

Authors: *M. H. EVANS[1], D. CAMPAGNER[1], S. FOX[1], K. CHLEBIKOVA[1], D. PETTIFER[1], M. D. HUMPHRIES[1], K. SVOBODA[2], R. S. PETERSEN[1];
[1]Fac. of Life Sci., Univ. of Manchester, Manchester, United Kingdom; [2]Janelia Res. Campus, Howard Hughes Med. Inst., Ashburn, VA

Abstract: Sensation is an active process. Animals purposively move their sense organs - eyes, hands, antennae or whiskers - to optimise information accumulation towards a goal. In the past, active sensing was difficult to study, but advances in high-speed videography and image processing have made rigorous study feasible.
To gain more insights into the computational nature of active sensing we developed a novel three-choice object location discrimination task for head-fixed mice.
Water-restricted mice were trained to use their whiskers to sense the location of a pole presented in one of three anterior-posterior locations, while whisker motion was imaged at 1000 fps. Mice were trained to lick from a left reward port if the pole was posterior; to lick from a right reward port if the pole was central; and to withhold licking if the pole was anterior. To solve the task mice had to sample at least two of the three locations with their whiskers, and subsequently discriminate differences in experienced mechanical variables or sensorimotor contingencies (early or late touch in the whisking cycle).

Each mouse's exploration strategy was mapped at millisecond resolution over hundreds of behavioural sessions using machine learning algorithms applied to the high-speed video data. To date we have analysed task behaviour in more than 50,000,000 video frames.
Mice (n=6) performed ~200 trials per behavioural session, achieving stable high performance (>75% correct) with a full whisker array in < 20 behavioural sessions, a single row of whiskers in 22-44 sessions (10 mice) and a single whisker in 25-63 sessions. Performance fell to chance after whiskers were trimmed to the level of the fur. Mice used an active strategy, exploring a region of space with their whiskers encompassing both rewarded pole locations - touching the pole when it was presented in one of the two rewarded locations with equal probability, and frequently touching the pole in the `no-go' location. This strategy differs from that displayed by naive mice, and mice trained in two-choice object localisation (O'Connor et al 2010, Guo et al 2014). Task-level differences in whisker movement strategy and sensory inputs imply that mice actively direct whisker movements to meet task demands.

Title: Discrimination of tactile regularity : a novel 2-alternative forced-choice task in the rat

Authors: P. KEREKES, A. DARET, D. SHULZ, *V. EGO-STENGEL;
CNRS, Gif-sur-Yvette, France

Abstract: Learning to discriminate sequences of stimuli in the temporal and spatial domains is fundamental in certain sensory-guided behaviors. Neurons from the primary somatosensory cortex (S1) code for spatial (Jacob et al., 2008) and temporal sequences of stimuli (Webber & Stanley, 2004). However, in behavioral studies, the simultaneous discrimination of tactile gratings has not been yet explored. Here we asked if tactile gratings can be discriminated by rats using their whiskers in a task incompatible with whisking. We developed a two-alternative forced-choice task in an automated modified T-maze. Stimuli were either a surface with no bars

(smooth), or with bars spaced irregularly or regularly. While running at full speed, rats encountered the two discriminanda, placed at random on the right and left sides of the central aisle. They had to turn to the side of the regular grating (rewarded stimulus). During initial phases of learning, reminders of this target stimulus were placed near reward locations. The animal choice, speed, global whisker movement and head direction were tracked during the task. Rats (n=6) learnt to recognize tactile regular bars against smooth surfaces in eight weeks. Clipping the whiskers reduced performance to chance level at the beginning of the session, demonstrating that the rats learnt this task using their whiskers (n=4). However, the performance rose back at the end of the session, indicating that the animals started to develop an alternative strategy independent of the use of whiskers. Inactivation of S1 using muscimol (GABA-A receptor agonist) dropped the performance down to chance level during the first part of the session, showing that activity in S1 is necessary for tactile discrimination (n=3). Similarly to the whisker trimming experiment, the rats performed better than chance at the end of the session. When we introduced the irregular series of bars during one session, 3 rats out of 6 were able to discriminate it from the regular series. Rats solved the task while running at a speed of 107.2 ± 7.7cm/s (mean ± SEM), so that the contact with the stimulus lasted less than one typical whisking cycle. Whisker tracking analysis showed that during successful trials, after the initial contact, the whiskers oriented towards the rewarded stimulus, and ~50ms later the head turned to the side of the rewarded stimulus (n=3). To conclude, the rats were able to discriminate sequences of bars on a surface by scanning the stimuli just once. We showed that the whisker system and S1 activity are involved during the discrimination process. We hypothesize that in S1, a neuronal code based on precise spike timing is underlying this tactile ability.

Title: Layer-specific somatosensory processing in head-restrained mice during exploratory locomotion

Authors: *A. AYAZ, A. STÄUBLE, F. HELMCHEN;
Univ. of Zurich, Zurich, Switzerland

Abstract: We perceive the outside world as a result of continuous sensorimotor interactions. There is increasing evidence that locomotion modulates sensory processing in primary sensory cortices of mice (Niell & Stryker, 2010 Neuron 65, 472-479; Saleem et al.,2013 Nat. Neuroscience 16, 1864-1869; Keller et al., 2012 Neuron *74*, 809-815; Fu et al.,2014, Cell *156*, 1139-1152), however the effect of locomotion seems to be heterogeneous across different sensory modalities (Schneider et al., 2014, Nature 513, 189-194; Fu et al.,2014, Cell *156*, 1139-1152; Sofroniew et al.,2016 eLife 4:e12559). Here, we investigate how animal movements (running and whisking) are integrated with tactile touch stimuli in primary somatosensory cortex (S1) of mice during exploratory locomotion. We focus on differential processing across superficial (layer2/3) and deep (layer5) cortical layers.

In their natural environment rodents navigate through dark tunnels utilizing their whiskers. To mimic this exploratory locomotion behavior we developed a virtual tactile environment, in which mice can run in the dark, along a "wall", on which textures are presented. Mice are head restrained on a treadmill and textures (sandpapers of varying graininess) are presented on rotating cylinders in reach of whiskers. While mice are running and whisking along the "wall" we perform 2-photon calcium imaging of cortical (predominantly excitatory) neurons, expressing the calcium indicator R-CaMP-1.07, in superficial and deep layers of S1. We consider three stimulus conditions: free walk in the absence of somatosensory stimulus; closed loop when the speed of the texture rotation is coupled to the speed of the animal locomotion; and open loop when the speed of the texture rotation is independent of the animal speed on the treadmill. Closed loop sessions also involve brief perturbations by decoupling texture rotation and animal speed.

We found that in both superficial and deep layers, subsets of neurons show increased activity with locomotion. A larger set of neurons were responsive to initial contact of rotating textures. A major difference between layers appears to be the persistence of the response to touch such that in layer 2/3, neurons continue to respond to rotating stimuli whereas the activation of layer 5 neurons is transient and gets suppressed after the initial touch activity. Responses to the perturbations are more infrequent and vary across the population. These results highlight layer-specific differences in the integration of sensorimotor aspects in barrel cortex. We are currently investigating whether sensory stimulus speed and locomotion speed are also integrated differently across layers.

Title: Activation of VIP-expressing interneurons in primary somatosensory cortex in head-restrained mice during exploratory locomotion

Authors: *A. STÄUBLE, A. AYAZ, F. HELMCHEN;
Brain Res. Inst., Univ. of Zurich, Zurich, Switzerland

Abstract: Sensory processing in the neocortex is strongly modulated by behavioral state. In recent years, recordings in head-restrained mice allowed investigation of how animal movements influence sensory processing. In visual cortex (V1) neurons show higher firing rates during locomotion compared to stationary periods (Niell & Stryker, 2010 Neuron 65, 472-479; Ayaz et al., 2013, Current Biology 23, 890-894). Vasoactive intestinal peptide-positive (VIP+) interneurons have a key role in this process: They receive cholinergic long-range inputs from the basal forebrain during running periods, inhibit somatostatin-expressing neurons, and thereby disinhibit pyramidal neurons (Fu et al., 2014, Cell 156, 1139-1152). Similar disinhibitory mechanisms have been found in primary somatosensory cortex (S1) of mice during whisking with inputs arising from vibrissae motor cortex (vM1) (Lee et al., 2013, Nature Neurosci. 16, 1662-1670). Here, we investigated how both of these motor-related aspects (whisking and locomotion) are integrated by VIP+ interneurons in S1 with touch stimuli during exploratory behavior. We developed a naturalistic setting, which simulates moving along a wall in darkness: the head-restrained mouse was allowed to freely run on top of a ladder wheel while sandpaper on a rotating cylinder could be brought in reach of the whiskers. The speed of the rotating texture was either coupled to the animal's speed (closed loop) or decoupled (open loop). Whisker movements were monitored by videography. We used the triple transgenic mouse line VIP-Cre-ztTA-YCX2.60, which expresses the yellow cameleon calcium indicator YX2.60 in VIP+ neurons, and performed 2-photon calcium imaging of VIP+ interneurons through a cranial window. We find that VIP+ interneurons in layer 2/3 show enhanced mean activity during periods of continuous running and whisking compared to stationary periods. Large calcium transients occurred after locomotion and whisking onset but not in response to texture touch. In conclusion, we find strong and positive correlation between explorative behavior and L2/3 VIP+

interneuron activity in mouse barrel cortex. Together with the finding of increased activity in a subset of excitatory neurons (see SfN poster from Ayaz et al.), our results are consistent with an disinhibitory role of VIP+ interneurons in S1 during exploratory behavior.

Title: The role of VPm thalamus in whisker related tactile perception

Authors: *C. WAIBLINGER[1,2,3], C. J. WHITMIRE[1], A. J. SEDERBERG[1], G. B. STANLEY[1], C. SCHWARZ[2,3];
[1]Wallace H Coulter Dept. of Biomed. Engin., Georgia Tech. and Emory, Atlanta, GA; [2]Systems Neurophysiol., Werner Reichardt Ctr. for Integrative Neurosci., Tübingen, Germany; [3]Dept. of Cognitive Neurol., Hertie Inst. for Clin. Brain Res., Tübingen, Germany

Abstract: The rodent ventro-posterior-medial nucleus (VPm) is the primary thalamic station of ascending whisker signals in rodents and traditionally has been viewed as the gateway for lemniscal tactile information destined for the primary somatosensory whisker representation, the barrel cortex. The thalamic gate is thought to be sensitive to general states, like vigilance and sleep. Here we studied whether VPm is involved in modifying tactile signals on short time scales and in a task-dependent manner. We trained head-fixed rats on a Go-NoGo detection of change task which required them to passively detect brief near-threshold amplitude ramp-like whisker deflections of different direction embedded in Gaussian white noise. Our first observation was that VPM single unit coding of kinematic variables was insensitive to ramp direction and did not change between successfully detected trials (hits) or failed trials (misses). However, single- and multi-unit spiking in response to ramps was decreased due to background noise, thereby confirming the role of pre-adaptation on signal detection in the awake animal. Further, evoked spike rates across the recorded population were significantly different between hit and miss trials if background/pre stimulus activity was taken into account. This predictability of the behavioral

choice could be identified seconds before stimulus presentation indicating a systematic reflection of task engagement versus disengagement. As measured from sequences of hit and miss trials, task engagement was tracked by thalamus in a highly dynamic fashion that could change from one trial to another. These results support the notion that the thalamic gate is highly dynamic on a time scale of seconds, and this could serve a role in dynamically gating information flow to generate cortical representation leading to perception.

Title: Thalamic control of cortical sensory representations.

Authors: *P. Y. BORDEN[1], A. D. ORTIZ[1], A. J. SEDERBERG[1], A. E. MORRISSETTE[2], C. WAIBLINGER[1], D. JAEGER[2], G. B. STANLEY[1];
[1]Georgia Tech., Atlanta, GA; [2]Neurosci., Emory Univ., Atlanta, GA

Abstract: The thalamus is a central hub of sensory and motor processing, where thalamic dysfunction has been linked to many complex sensorimotor neurological disorders including Parkinson's Disease, Central Pain, and Schizophrenia. In the context of sensory pathways, very little is known about how ongoing thalamic activity controls feedforward downstream evoked cortical responses. A single cortical neuron is only weakly driven by a single thalamic synapse; therefore, cortical responses require large numbers of temporally synchronized thalamic neurons. Additionally, thalamic activity is highly dynamic, and can range from tonically active to bursting states with varying levels of synchrony across the thalamic population. Furthermore, the majority of inputs to thalamus have been shown to be modulatory in nature, indicating the thalamic state is likely constantly being modulated and tuned by ongoing activity of cortical and subcortical

structures. Here, we used paired recordings of the thalamus and cortex while modulating the thalamic state using optogenetics to determine the role of thalamic activity on evoked cortical response. Specifically, we extracellularly recorded single thalamic neurons from the mouse lemniscal whisker pathway while simultaneously recording cortical responses with widefield volumetric imaging cortical activity using the genetically encoded voltage sensor Arclight. We used AAV delivered hyperpolarizing opsins (Halorhodopsin or eNph3.0) to shift the VPm thalamus into a bursting state while simultaneously measuring thalamic and cortical sensory responses to various whisker velocities under isoflurane anesthesia. At baseline, our results show monotonic increase in S1 cortical volumetric voltage spatiotemporal response with increased single whisker velocity. Through optogenetic hyperpolarization of VPm, we increased the thalamic bursting, while also increasing both thalamic and cortical whisker velocity responses. Thalamic hyperpolarization also caused an overall increase in spatial response and theoretical detectability whisker stimuli. These results suggest a potential role of thalamic state modulation, particularly bursting, as a method to increase cortical response and perception of sensory information.

Title: State-dependent encoding in the thalamocortical circuit. Modeling feature selectivity in different optogenetically induced thalamic states

Authors: *C. WHITMIRE[1], C. WAIBLINGER[1], Y. LIEW[1], C. SCHWARZ[2], G. B. STANLEY[1];

[1]Wallace H Coulter Dept. of Biomedial Engin., Georgia Tech/Emory, Atlanta, GA; [2]Dept. of Cognitive Neurology, Hertie Inst. for Clin. Brain Res., Univ. of Tübingen, Tübingen, Germany

Abstract: It has been posited that the regulation of thalamic firing modes could function as a mechanism for controlling not only how much, but what kind of information is conveyed to downstream cortical targets. Yet how this gating mechanism impacts precise feature selectivity in the thalamocortical circuit remains unknown. Using in-vivo single unit recordings in the rat vibrissa thalamus (VPm), feature selectivity was assessed using white noise whisker stimulation while simultaneously manipulating the firing mode of the neurons using optogenetic hyperpolarization. When stimulated with white noise, both the optogenetically hyperpolarized and baseline responses evoke similar numbers of spikes and show reliable responses to the same temporal features in the noise. However, the firing mode of the thalamus shifts from a tonic encoding scheme to a burst encoding scheme when hyperpolarized. Generalized linear model (GLM) fits of the thalamic activity in different optogenetically manipulated thalamic states revealed clear feature selectivity associated with tonic firing, yet the thalamic bursting activity was not well captured by the standard GLM architecture due to an extreme dependence upon the silence between spiking periods, or spike history. If however, the spike history element of the GLM is modified to capture different spike history dependence of the two firing modes while the feature selectivity is held constant, the predictive capability of the GLM is significantly enhanced. This suggests that the thalamic neurons are encoding the same information (i.e. the feature selectivity is maintained across optogenetically manipulated state conditions) because the synaptic input to the thalamic neurons is unchanged in this paradigm. However, the output of the thalamic neurons, or the spiking activity, is fundamentally different as a function of thalamic state. In this case, the state-dependent thalamic input to cortex may induce significant shifts in cortical feature selectivity and encoding. These results could have broad implications for a more comprehensive coding strategy whereby ongoing sensory stimulation, as experienced constantly in natural sensing conditions, dynamically alters the state of the thalamus to fundamentally shape the functional encoding of the pathway. Dynamic shifts in thalamic state set the stage for an intricate control strategy upon which cortical computation is built.

Title: Brain state and spatiotemporal representations of tactile stimuli in sensory cortex explored with genetically expressed voltage-sensor imaging

Authors: *A. J. SEDERBERG[1], H. J. V. ZHENG[1,2], B. J. HE[3], G. B. STANLEY[1];
[1]Wallace H Coulter Dept. of Biomed. Engin., Georgia Inst. of Technol. & Emory Univ., Atlanta, GA; [2]Max Planck Florida Inst., Jupiter, FL; [3]Departments of Neurology, Neurosci. and Physiology, and Radiology, Neurosci. Institute, New York Univ. Langone Med. Ctr., New York, NY

Abstract: Even under well-controlled experimental conditions, cortical responses to sensory stimulation are variable. Some of this variability arises from input interaction with ongoing cortical activity, which is linked to brain state. In primary sensory cortex, brain state is often described as existing on a continuum from an inactivated state with synchronized depolarizations of individual neurons across broad cortical areas, to an activated state, in which the local field potential (LFP) and sub-threshold membrane potentials are desynchronized. Depending on brain state, evoked and ongoing activity may interact in different modes, either in a near-linear regime in the desynchronized state, or in a nonlinear excitable regime in the synchronized state. Population recordings show that depolarization events (up states) occurring during the synchronized state are coordinated sequences that propagate across cortical columns and layers in diverse trajectories. Such complex dynamics could differentially interact with spatially distributed inputs to a particular cortical region, and taking such factors into account may improve the predictability of cortical activity and provide a clearer link between cortical activation and perception.
Determining how sensory information is processed in a background of structured activity requires recordings with high spatial and temporal resolution over large cortical regions. The recent advent of genetically expressed voltage sensors may provide the needed set of tools for capturing this type of neural activity, and open up doors to chronic imaging during behavior and cell-type specific measurements. However, the relationship of measurements derived from this class of voltage sensors to traditional measurements, like LFP, is not well established. Here, we conducted simultaneous recordings of LFP and voltage imaging of the genetically expressed sensor ArcLight from the somatosensory cortex of the anesthetized rat, during periods of spontaneous and whisker-evoked activity. Evoked responses were detected in the ArcLight signal in single trials, and accounting for local variation in hemodynamics improves detectability. Synchronization was quantified based on the concentration of low-frequency power in the LFP. Preliminary analyses were consistent with previous work: size and spread of evoked responses were state-dependent, with the largest responses observed when sensory stimulation occurred during the down phase of the synchronized state. This work provides a first step to rigorous analysis of the imaged signal across brain states, and opens up possibilities for detailed investigation during behavior.

Title: Spatio-temporal population coding in layer 2/3 of rodent barrel cortex

Authors: *S. MOLDAKARIMOV[1], M. BAZHENOV[2], D. E. FELDMAN[3], T. J. SEJNOWSKI[4];
[1]UCSD/Salk Inst., La Jolla, CA; [2]UCSD, San Diego, CA; [3]UC Berkeley, Berkeley, CA; [4]Salk Inst., La Jolla, CA

Abstract: In the rodent cortex S1, representation of sensory information in layer (L) 2/3 differs significantly from that in L4. L4 neurons receive inputs primarily from single whiskers, thereby forming a cortical map of the whisker pad. In contrast, single whisker deflection elicits responses in distributed neuronal populations that span multiple cortical columns in L2/3, revealing "salt-and-pepper" tuning of L2/3 neurons, when neighboring cells are more likely to respond to different whiskers. Response properties of L2/3 neurons to whisker stimulation also differ significantly from those of L4 neurons. While L4 neurons have rather reliable responses, whisker stimulation only evokes low-probability spiking in the majority of L2/3 neurons. Still, surprisingly, a small fraction of L2/3 neurons have relatively higher response probabilities. These laminar differences pose challenges for standard theories of sensory encoding, since most theories are based on topographically-organized receptive fields and employing rate coding by populations of local neurons.We have developed a cortical network model, based on important known features of L2/3 circuits. The model, consisting of 2D network of excitatory and inhibitory spiking neurons connected via short and long-range synapses, explains how a topographically-organized sensory code in L4 can be transformed into a distributed code in L2/3, in agreement with the transformation found in vivo. We show that distributed activity in L2/3 can be formed by traveling waves in populations of L2/3 neurons that are directly activated by L4 neurons. Such stimulus-evoked propagation of activity has been observed in the rodent barrel cortex in response to whisker stimulation. The sparseness of the distributed activity is a critical model constrain to explain the observed response properties in L2/3 neurons. Our model predicts that the sparse long-range connections among L2/3 neurons can lead to the skewed, as observed in vivo, distribution of response probabilities in L2/3, when the majority of L2/3 neurons respond sparsely to even their preferred stimuli, but a few L2/3 neurons respond to almost all stimuli. Our study proposes a new population coding theory, in which information could be reliably encoded by spatially distributed populations of sparsely responding neurons formed by propagating waves. The number of responding neurons within any selected area within L2/3 of barrel cortex

could encode intensity of stimulation, e.g., the degree of whisker deflection. Firing rates or precise spike times of individual neurons may not be critical for this encoding mechanism.

Title: Widefield imaging of sensory-evoked and behavior-related cortical activity in GCaMP6 transgenic mice

Authors: *C. R. LEE, M. B. DELROCINI, J. H. FAROOQUI, D. J. MARGOLIS;
Cell Biol. and Neurosci., Rutgers The State Univ. of New Jersey, Piscataway, NJ

Abstract: Advances in fluorescent calcium indicator proteins have allowed imaging of neural activity from specific cell types in various brain regions. We used widefield transcranial imaging in new generation TITL-GCaMP6f reporter mice to measure calcium signals of excitatory neurons across a large portion of the dorsal neocortex covering visual, somatosensory and parts of auditory, motor and association areas. Signal to noise of sensory-evoked responses was high, with spontaneous events reaching up to 30% amplitude and averaged whisker-evoked signals in primary somatosensory cortex (S1) reaching between 5-10% amplitude. Mechanical stimulation of single whiskers in awake, head-restrained mice resulted in early S1 signals followed closely by signals in secondary somatosensory cortex (S2) and motor cortex (M1). In other experiments, simultaneous video recordings of pupil diameter and cortical calcium signals showed a switch in the spatiotemporal dynamics of calcium signals during pupil dilation, involving activation of medial-posterior cortical regions. Our results indicate that new generation GCaMP6f reporter mice enable mapping the functional properties of cortical networks related to sensory processing, arousal, and sensory-driven behaviors.

Title: Is S1 required for active sensory detection-transient versus chronic inactivation of primary sensory cortex

Authors: *Y. HONG, R. BRUNO;
Dept. of Neurosci., Columbia Univ., New York, NY

Abstract: Establishing whether a specific brain area is causally involved in a behavioral task often requires manipulation of the area by inactivation. If the brain area under investigation is determined not to be required for the task, analysis of its neuronal activity would have little meaning. Numerous studies have used inactivation to examine whether primary sensory cortex is required for sensory detection and discrimination, with conflicting results. The discrepancies have been attributed to numerous factors, such as task difficulty, passive versus active sensation, or behavioral response type. Recent work in rodent and bird motor systems has demonstrated that homeostatic regulation of neural activity can reverse deficits caused by chronic inactivation, questioning the validity of concluding necessity from transient inactivation. These issues have yet to be addressed in primary sensory cortex. Here, we examine the effects of transient versus chronic inactivation of rodent barrel cortex in mice performing a simple whisker detection task. Previous reports are contradictory regarding the necessity of barrel cortex for object detection. We find that lesions of S1 resulted in only temporary behavioral deficits, with animals quickly recovering to pre-lesion performance levels. Furthermore, recovery was experience-dependent. Consistent with previous reports, transient inactivation by optogenetic or pharmacological inactivation strongly inhibited behavioral performance. However, when optogenetic inactivation was tested over multiple sessions, inactivation no longer had an effect on behavior, similar to lesions. Together, this suggests that S1 is only transiently required for the behavior. Current work is aimed at determining whether recovery is due to changes in behavioral strategy or

experience-dependent neuronal plasticity, and identifying areas mediating sensory detection in the absence of S1.

Title: Rapid disinhibition during whisker map plasticity is mediated by reduced intrinsic excitability of PV interneurons in mouse S1

Authors: *M. A. GAINEY, D. E. FELDMAN;
Dept. of Mol. & Cell Biol., UC Berkeley, Berkeley, CA

Abstract: In rodent somatosensory cortex (S1), whisker deprivation drives rapid disinhibition that homeostatically maintains whisker-evoked firing rates in L2/3 for several days prior to classical Hebbian weakening of deprived whisker responses (Li et al., 2014). Here we investigate the synaptic and circuit basis of this rapid disinhibition, using PV-Cre/tdTomato mice. 1 d whisker deprivation at P18-21 reduced feedforward L4-L2/3 excitation and inhibition onto L2/3 pyramidal (PYR) cells in ex vivo S1 slices. Inhibition was preferentially weakened, and E-I ratio was increased. This confirms that deprivation rapidly drives disinhibition in L2/3 of S1, as reported in V1 (Kuhlman et al., 2013, Hengen et al., 2013). mIPSCs in L2/3 PYR cells were unaffected. Instead, deprivation reduced L4-evoked spike probability in L2/3 PV interneurons, which mediate feedforward inhibition. We made whole-cell recordings from L2/3 PV neurons to identify the cellular basis for reduced PV spiking. 1 d deprivation did not affect L4-evoked EPSCs, IPSCs, or net PSPs in PV neurons. This contrasts with longer duration deprivation in rats, which reduces L4-evoked excitation on PV cells (House et al., 2011). Vrest, Rinput and other resting properties of PV cells were also unaffected. Instead, 1 d deprivation decreased multiple aspects of near-threshold intrinsic excitability, as evidenced by changes in spike threshold, subthreshold depolarization to current injection, first-spike latency, spike width, and after-hyperpolarization. We are now investigating the specific currents that are regulated by deprivation to produce these effects. Our results indicate that activity-dependent changes in PV

intrinsic excitability (e.g., Dehorter et al., 2015) are engaged in vivo to homeostatically maintain network firing rate in L2/3 of S1. Regulation of PV intrinsic excitability implements network homeostasis on a rapid time scale similar to Hebbian weakening of excitatory synapses, rather than the slower time scale of classical homeostatic synaptic scaling.

Title: Dense statistical connectome of rat barrel cortex

Authors: *D. UDVARY[1], R. EGGER[1], V. J. DERCKSEN[2], M. OBERLAENDER[1];
[1]Max Planck Inst. For Biol. Cybernetics, Tübingen, Germany; [2]Zuse Inst. Berlin, Berlin, Germany

Abstract: Synaptic connectivity is one important constrain for cortical signal flow and function. Consequently, a complete synaptic connectivity map (i.e., connectome) of a cortical area across spatial scales would advance our understanding of cortex organization and function. We present a dense statistical connectome of the entire rat vibrissal cortex based on measured 3D distributions of axons/dendrites/somata of excitatory and inhibitory neurons. By calculating the structural overlap between pre- and postsynaptic cells our model provides quantitative estimates on connectivity measurements like connection probability and number of synapses on cell type, cellular, and subcellular levels. We found that our model reproduces connectivity measurements between thalamic and excitatory/inhibitory neurons reported in paired recordings and light- and electron-microscopic studies. Similarly, intracortical synaptic connectivity of our model matches most connectivity measurements. However, the location and distance between pre- and postsynaptic cells and - in case of slicing experiments - the degree of truncation strongly influences the connectivity. When reproducing electronmicroscopic and in vitro slicing experiments in our model, we found that measurements obtained under the respective experimental conditions are in line with our model's results, but represent only a small fraction of the underlying distribution. The experimental conditions such as the small volume analyzed in

electron-microscopic studies or the truncation of morphologies thus biases the conclusions that are drawn, e.g. an underestimation of the connection probability. Our approach can therefore be used to improve experimental design and seen as a starting point to simulate sensory-evoked signal flow and investigate structural and functional organization of the cortex.

Title: Cell-type-specific temporal dynamics of GABAergic interneurons in mouse barrel cortex during active sensation

Authors: *J. YU[1], A. AGMON[2], K. SVOBODA[1];
[1]HHMI Janelia Res. Campus, Ashburn, VA; [2]West Virginia Univ., Morgantown, WV

Abstract: Different connectivity rules likely underlie the specific roles of different types of GABAergic interneurons during sensory processing. In the barrel cortex, somatostatin-positive interneurons are weakly innervated by thalamocortical afferents but receive facilitating inputs from local excitatory neurons, whereas parvalbumin-expressing fast-spiking interneurons are strongly innervated by thalamocortical afferents. Here we compared the behavior-related dynamics of fast-spiking interneurons (recorded in VGAT-ChR2-EYFP or SOM-IRES-Cre x Ai32 mice) and somatostatin-positive interneurons (recorded in SOM-IRES-Cre x Ai32 mice) in the barrel cortex of mice performing a whisker-dependent object localization task. Loose-seal cell-attached recordings were made in layers (L) 4 and 5; a subset of neurons were morphologically reconstructed. Fast-spiking interneurons responded to both whisker movement and touch. Latencies to touch onset (4-5 ms) coincided with the arrival time of touch-evoked thalamocortical input (4 ms). In contrast, in SOM-ChR2+ neurons of L4 and 5, with relatively broad spike waveforms (peak-to-trough 0.3 - 0.7 ms), touch also reliably elicited action potentials, but with latencies of 10-30 ms, consistent with intracortical excitation. Whisker movement, on the other hand, did not increase the spike rates of SOM+ interneurons and suppressed the spike rates of those with significant spontaneous activity. Thus, different types of GABAergic interneurons are recruited in response to specific sensory inputs and show millisecond-scale temporal difference in response to the same sensory input.

Title: Characterization of dendritic spines in the barrel cortex of mice, strain versus deprivation

Authors: M. A. ESPINOSA[1], C.-C. CHEN[3], *J. C. BRUMBERG[2];
[1]Neurosci. Major, [2]Dept Psychology, Queens Col., Flushing, NY; [3]Dept. of Molecular, Cell & Developmental Biol., Univ. of California, Santa Cruz, Santa Cruz, CA

Abstract: Dendritic spines are small protrusions on the membrane of neuronal dendrites that receive the majority of the neurons' excitatory synaptic inputs. Dendritic spines can take many forms, from short stubby ones to long lollipop like appendages. We sought to characterize the density and morphology of dendritic protrusions (spines and filopodia) in layer 4 pyramidal neurons of C57/Bl6 and CD-1 mice. Employing the Golgi technique which labels a small percentage of neurons, we used light microscopy to morphologically characterize each dendritic protrusion (spine and filopodia) and their relative densities. We classified dendritic protrusions as filopodia, stubby, mushroom or thin type based on their morphological appearance. Our results indicate that spines are found in higher densities approximately 50-70 μm from the soma. Overall spine density was higher in CD-1 versus C57/BL6 mice. At one month of age, the majority of dendritic protrusions in C57/Bl6 mice were filopodia, followed by mushroom, thin and then stubby, whereas CD-1 showed a higher percentage of small stubby spines. Following one month of whisker trimming induced sensory deprivation, spine densities increased in both species. In C57/BL6 mice we utilized Sholl analysis to quantify spines as a function of dendritic location and observed similar morphological distributions on apical versus basilar dendrites. Our results suggest that spines are found in similar distributions on all dendrites and that although spine density varies as a function of species, the impact of sensory deprivation is consistent across species.

Title: Fishing for the molecules and mechanisms that underlie sensory transduction in zebrafish Rohon-Beard cells

Authors: *S. E. LOW, D. MCCLURE, A. J. HUDSPETH;
Lab. of Sensory Neurosci., Rockefeller Univ., New York, NY

Abstract: Cutaneous receptors are charged with discerning various forms and amplitudes of stimuli. For instance mechanoreceptors distinguish between a gentle touch and an annoying pinch. Thermoreceptors must likewise discriminate the soothing effect of menthol from the heat of an open flame. Acuity such as this raises questions regarding how different stimuli are detected and encoded by cutaneous receptors. To gain insight into this process we have turned to zebrafish Rohon-Beard cells, sensory neurons whose cutaneous branches resemble free nerve endings. Our experiments with GCaMP7a have revealed that Rohon-Beard cells constitute a spatially organized population of polymodal sensory neurons that respond to mechanical, thermal, and noxious stimuli. We have additionally found that these neurons segregate into nociceptive and non-nociceptive subpopulations. Exploiting the experimental advantages offered by the zebrafish model system, we also hope to deduce how individual Rohon-Beard cells transduce various stimuli.

Title: Cutaneous mechanoreceptor morphology and immunostaining as potential biomarkers for neuropathy

Authors: *B. D. MCADAMS, G. WENDELSCHAFER-CRABB, W. KENNEDY;
Dept Neurol., Univ. Minnesota, Minneapolis, MN

Abstract: Mechanosensation in skin originates from Merkel cells, Meissner's corpuscles and other receptors. These receptors have known skin distributions, but little is known about structural or chemical variations that may contribute to changes in sensation that occur with disease, injury, or aging. In this study, we describe variations in mechanoreceptor morphologies and chemical phenotypes as determined by immunostaining for synaptic vesicle and other neural proteins in human cutaneous nerve fibers essential for normal skin mechanosensation. Human skin tissues were fixed, sectioned and coimmunostained with antibodies to neural-specific markers, UCHL1, βIIItubulin, neuropeptides and presynaptic proteins. Tissues were then cleared, mounted and imaged with confocal microscopy to determine variations in mechanoreceptor structure and immunostaining. Immunostaining for presynaptic markers was localized in epidermal Merkel cells and dermal Meissner's corpuscles. Merkel cells were distributed differentially in the basal epidermis in hairy skin versus glabrous skin. While most Merkel cells immunostained for both synapsin 2 and SV2, isolated exceptions hinted at different phenotypes. Also, some Merkel cells are apparently uninnervated. Meissner's corpuscles were also found to differentially immunostain for presynaptic proteins. In some Meissner's corpuscles, presynaptic proteins colocalized within a portion of the corpuscle's UCHL1-labeled regions. Similarly, there was also a wide variation in possible conformations of neural innervation of the Meissner's corpuscles. Some flattened out parallel to the epidermal surface, some were perpendicular to the surface and others were mixed. Our results confirm that innervation of cutaneous mechanoreceptors is highly variable ranging from no innervation (for some Merkel cells) and possible disordered innervation present in Meissner's corpuscles to highly ordered and consistent innervation of most mechanoreceptors. The variation in distribution of presynaptic markers within regions of Merkel cells and Meissner's corpuscles may indicate regional variation in activity. Thus, confocal imaging of skin mechanoreceptors provides detailed information regarding potentially critical changes in phenotype that may predict altered sensations from chemotherapy-induced, diabetic, or other neuropathies. Future research on the functional impact of the structural and chemical changes in these mechanoreceptors may lead to a greater understanding of normal function and may provide novel biomarkers for early diagnosis of peripheral sensory neuropathies and novel therapeutic targets.

Title: Mechanotransduction of mouse Merkel cells in whisker hair follicles and effect of paclitaxel on whicker afferent SA1 response

Authors: *W. CHANG[1], H. KANDA[2], J. GU[2];
[1]Univ. of Alabama At Birmingham, Birmingham, AL; [2]Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Somatosensory dysfunction is a common side effect of many chemotherapy drugs. Paclitaxel induced neuropathy symptoms including mechanical allodynia, tingling, numbness and loss of vibration sensation. The paclitaxel-induced sensory disorders are thought to be due to afferent demyelination induced by paclitaxel. It is currently unclear if non-neuronal cells may be involved in paclitaxel-induced sensory dysfunctions. In the epidermis of mammals, Merkel cells are located in mechanically sensitive spots and they are innervated by large diameter afferent fibers. We have recently shown that rat Merkel cells play a critical role in driving electrophysiological tactile responses manifested as slowly adapting type 1 (SA1) impulses. In the present study, we characterized mechanical sensitivity and membrane excitability of mouse Merkel cells. We further investigated effects of paclitaxel on whisker afferent SA1 responses. We found that short treatment of whisker hair follicle with paclitaxel significantly enhanced whisker SA1 responses. Our findings raise a possibility that paclitaxel may affect mechanical transduction and/or membrane excitability of Merkel cells, which subsequently affect electrophysiological tactile responses. **Keywords:** Chemotherapy; Mechanotransduction, Touch, Pain; Paclitaxel; Merkel cell.

Title: A study of somatosensory neuron mechanics using the laser optical trapping system

Authors: *H. KANDA, J. GU;
Dept. of Anesthesiol. and Perioperative Med., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Mechanical stimuli applied to the skin of mammals evoke various sensations such as touch, pressure, vibration and pain. While important progresses have recently been made in understanding mechanotransduction in mammals, how mechanotransduction in somatosensory neurons is regulated remains to be poorly understood. We have recently shown that mechanotransduction mediated by piezo2 channels in somatosensory neurons is strongly associated with static plasma membrane tension, suggesting that somatosensory neuron mechanics may play a critical role in sensing mechanical stimuli. However, membrane mechanics of somatosensory neurons have not been accurately determined so far. To begin to precisely determine the role of somatosensory neuron membrane mechanics in controlling mechanotransduction, we have established the laser optical trapping approach to probe membrane mechanics in cultured dorsal root ganglion (DRG) neurons. With the use of the highly focused laser beam to trap and manipulate microspheres, we were able to pull membrane tethers from DRG neuron membranes and determine some parameters of membrane mechanics including the forces needed to form and elongate membrane tethers. We found that the forces for the formation and extension of the membrane tethers were in the range of 20 to 50 pN, suggesting that these neurons have some degree of stiffness but not highly stiff. Future studies will aim to understand how the membrane mechanics of somatosensory neurons may be altered by biological events including inflammation.

Abstract: At its most fundamental level, touch sensation requires the translation of mechanical energy into mechanosensitive ion channel opening, thereby generating electro-chemical signals. Our understanding of this process, especially how the cytoskeleton influences it, remains unknown. Here we demonstrate that mice lacking the α-tubulin acetyltransferase Atat1 in sensory neurons display profound deficits in their ability to detect mechanical stimuli. We show that all cutaneous afferent subtypes, including nociceptors have strongly reduced mechanosensitivity upon Atat1 deletion, and that consequently, mice are largely insensitive to mechanical touch and pain. We establish that this broad loss of mechanosensitivity is dependent upon the acetyltransferase activity of Atat1, which when absent leads to an increase in cellular rigidity. By mimicking α-tubulin acetylation genetically, we show both cellular rigidity and mechanosensitivity can be restored in Atat1 deficient sensory neurons. Hence, our results indicate that by influencing cellular stiffness, α-tubulin acetylation sets the force required for touch.

Title: Tentonin 3 confers distinct mechanosensitive currents in dorsal root ganglion neurons with proprioceptive fuction

Authors: *G. HONG, H. KIM, J. WEE, H. LU, U. OH;
Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Mechanosensation is a basic function required for the survival of vertebrates. Touch sensation or proprioception requires the transduction of mechanical stimuli into electrical signals by mechanoreceptors in the periphery. These mechanoreceptors are equipped with various transducer channels. Although Piezo1 and 2 are mechanically activated channels with rapid inactivation, MA molecules with other inactivation kinetics have not been identified. Here we report that heterologously expressed Tentonin3 (TTN3) is activated by mechanical stimuli with distinctly slow inactivation kinetics. Genetic ablation of *Ttn3* markedly reduced slowly adapting neurons in dorsal-root ganglion neurons. The mechanically-activated TTN3 currents were inhibited by known-blockers of mechanosensitive ion channels. Moreover, TTN3 was localized in muscle spindle afferents. *Ttn3*-deficient mice exhibited the loss of coordinated movements and abnormal gait. Thus, TTN3 appears to be a component of a mechanosensitive channel with a slow inactivation rate and contributes to motor coordination. Identification of this gene advances our understanding of the various types of mechanosensations including proprioception.

Title: The mechanotoxin GsMTx-4 inhibits the Stretch-Activated BK channel through the mechanism specific to mechano-gating

Authors: *Q. TANG[1], M. TANG[2], H. LI[1], X.-R. DU[1], Y.-J. FENG[1], X.-D. TANG[1], F.-F. ZHANG[1], S.-X. KE[1], P. DONG[1], M. SOKABE[3], Z. ZHANG[1];
[1]Anesthesiol., Xuzhou Med. Univ., JIangsu, China; [2]Dept. of Pathology, Affiliated Hosp. of Southwest Med. Univ., Luzhou, China; [3]Nagoya University, Grad. Sch. of Med., Nagoya, Japan

Abstract: The peptide toxins, mechanotoxin 4 (GsMTx-4) isolated from *Grammostola spatulata*, has been widely used to identify mechanically activated (MA) channels in sensory system including in neurons, but the mechanism by which how peptide specifically acts on the mechano-gating remains unknown. One difficulty in studying the mechanism of mechanotoxin action is that the mechano-gate on many MS channels is not known. By studying a stretch-activated (SA), large conductance (BK) (SAKca) channel expressed in CHO cells, here we show that the inhibitory effect of GsMTx-4 requires the mechano-sensitive domain located between RCK1 and RCK2 domain in BK channel. We show that 15 mins later following the back-filling of GsMTx-4 in the pipette, 0.5 μM GsMTx-4 inhibits 93% of SAKca channel current at -50 mV in the excised inside-out configuration, where the deformation of cell membrane automatically generates membrane tension under the pipette tip. In addition, Kinetic studies show that stretch increases the mean open time of the channels and decreases the slowest time constant of the closed-time distributions, whereas GsMTx-4 reversed the both effects. We previously identified the STREX-exon located between the RCK1 and RCK2 domains is responsible to the mechano-gating in SAKca channel. We found that under the same conditions, even a 20-fold higher concentration of GsMTx-4 had no effect on STREX-del-mutation in the ranges of voltages tested, convincing that GsMTx-4 inhibits SAKca channel requires the mechano-gating domain of STREX-exon. These results may provide novel insights on the fundamental mechanism of GsMTx-4 action on MS channels.

Title: Pressure induced mechanostimulation on patch clamped PC-12 cells provides access to drug discovery on Piezo currents

Authors: *T. KNOTT, J. ZHANG;
R&D, Cytocentrics Inc., San Antonio, TX

Abstract: Mechanosensation plays critical roles in many physiological processes, including sensing gentle touches in Merkel cells and sensory neurons, lineage choice in neural stem cells, and blood vessel development. Piezo ion channels, with Piezo1 and Piezo2 as the two mammalian isoforms, are essential for the initiation of mechanosensation. However, the observed mechanical sensitivity of Piezo varied by cell types and stimulating methods. In this study, using CytoPatch hands free patch clamp that precisely controls both magnitudes of pressure (holding, pipette and suction pressure) and application duration (to milliseconds), we investigate the activation mechanisms of Piezo channels, and apply our assays to screen chemical compounds for activating or blocking Piezo channels. We have successfully recorded mechano-stimulating rapidly-inactivating inward Piezo currents on PC-12 cells that have been previous suggested to endogenously expressing Piezo channels. Currents of 100 nA to 400 nA were recorded in response to 50 ms and 100 ms pressure-step stimulation of 50-150 mbar. Standard errors of repetitive stimuli were below 5% of the mean. Mock application did not alter the current size. We will further investigate the current-pressure relationships in PC-12 cells and sensory neurons and apply the assays to screen chemical compounds for activation or blockage of Piezo channels. This study will have great implication in drug discovery for human diseases linked to disrupted mechanosensation due to altered Piezo inactivation.

Title: A combined technique for retrograde tracing and transcriptome analysis: zeroing in on specific neural populations based on peripheral target

Authors: *G. R. SCHMIDT-MCCORMACK[1], A. KANTHASAMY[1], N. D. JEFFERY[2]; [1]Biomed. Sci., [2]Vet. Clin. Sciences, Biomed. Sci., Iowa State Univ., Ames, IA

Abstract: Changes in neural activity subsequent to injury of non-neural tissue can have profound implications for the treatment of orthopedic injuries. However, much of the previous information on these changes is derived from systems-level analysis, but connections

between neurons at all levels can affect the overall observed changes in sensation and mobility. Further study on the underlying components of the system can help to provide a basis for understanding the systematic consequences of injury. Here we focus on the changes in specific sets of cells directly contacting the affected tissue by developing a protocol for identifying and analyzing these neurons separately from surrounding neurons of different targets in a rodent model. Primary sensory neurons are taken from the dorsal root ganglia (DRG), and motor neurons are taken from the ventral horn of the spinal cord (VH). We are optimizing the integration of (i) retrograde tracing, (ii) tissue dissociation and single cell collection, and (iii) RNA-Seq. Ideally, the use of single-cell RNA-Seq will allow us not only to look at changes in the transcriptome, but to separate neurons into different subtypes based on previously described transcriptional markers. Dissociation and isolation need to be quick, due to the quick decay of mRNA. Our preliminary results suggest that previously reported DRG dissociation protocols are compatible with these analytical approaches.

Title: Compartmentalized co-cultures for studying interactions between central and peripheral nervous systems in various pain states

Authors: *N. VYSOKOV, S. B. MCMAHON, R. RAOUF;
IoPPN, King's Col. London, London, United Kingdom

Abstract: The aim of the project is to recapitulate in a dish aspects of neuronal circuitry involved in transmission and processing of pain signals. Traditional mixed co-cultures and co-cultures in Campenot chambers offer very limited possibilities in manipulating the components individually. Here we utilise microfluidic isolation to compartmentalise cultured rat embryonic E16 dorsal root ganglion (DRG) cells and cells of the spinal cord dorsal horn (DH). This technology enables us to investigate the physiological effects of peripheral sensitisation on the cells of spinal cord dorsal horn and how this affects their responses to stimuli.
In triple-compartment co-culture we show that DRG axons can cross the microfluidic barriers from “DRG” compartment into a “periphery” compartment as well as into a “spinal cord”

compartment thereby forming synapses with the DH cells. Electrical and chemical stimulations of the DRG axons in the "periphery" elicit physiological responses from DH cells observed by ratiometric Ca^{2+} imaging. The response is due to signal transmission from DRG cells to DH cells, since same stimuli are unable to generate a response in the DH cells when the DRG cells are absent from the system or when the DRGs (but not the microfluidically isolated DH cells) are blocked by 5 mM lidocaine. The versatility of the device allowed us to pharmacologically block $Na_V1.7$ and $Na_V1.8$ pre-synaptic to the DH cells and observe the reduction in signal transmission efficacy. Moreover, to evaluate the electrophysiology of DH cell response to peripheral stimulation of DRG axons, we developed a modification of the microfluidic isolation device, which allows patch pipettes to access the neurons in the "spinal cord" compartment.
Thus, the microfluidically compartmentalised co-culture system is a versatile and robust system for dissecting the effects of peripheral manipulations on the physiology of DH cells. With the importance of involvement of central nervous system in chronic pain, the model presented here can be used for screening of CNS-targeting drugs prior to testing in animals.

Title: Knockout of Nav1.6 in DRG neurons contributes to amelioration of mechanical allodynia

Authors: *L. CHEN, A. M. TAN, Z. PENG, J. HUANG, X. CHENG, S. G. WAXMAN, S. D. DIB-HAJJ;
Yale Univ. / VA Healthcare CT, West Haven, CT

Abstract: Sodium channels are major contributors to increased excitability of primary afferents following nerve injury. Such hyperexcitability is a key driver of neuropathic pain. Extensive studies have focused on peripheral-specific sodium channels Nav1.7, Nav1.8 and Nav1.9, as well as Nav1.3, a channel that is up regulated after nerve injury. In this study, we investigated the contribution of Nav1.6, the major sodium channel at nodes of Ranvier in myelinated axons and which is also expressed in unmyelinated C-fibers, to excitability of DRG neurons and neuropathic pain. Since global Nav1.6 knockout mice are juvenile lethal, we investigated how Nav1.6 contributes to mechanical allodynia by knocking out Nav1.6 with either Nav1.8-directed or adeno-associated virus (AAV)-mediated Cre-Lox recombination system. We used the spared nerve injury (SNI(t)) model of neuropathic pain, in which the common peroneal and the sural

branches of the sciatic nerve were transected and the tibual branch was kept intact. Within 1 week of SNI, mice developed mechanical allodynia, which was sustained for up to 6 weeks. With the aid of a td-tomato reporter line, we showed that Nav1.8-directed Nav1.6 knockout is restricted to Nav1.8-positive neurons, whilst intrathecal AAV-Cre injection knocks out Nav1.6 in 50 to 80% of neurons irrespective of Nav1.8 expression. We also confirmed that knockout of Nav1.6 reduces the TTX-S current in both small- and large-diameter DRG neurons. We found that Nav1.8-directed Nav1.6 knockout mice develop SNI-induced mechanical allodynia normally, while AAV-mediated Nav1.6 knockout partially yet significantly attenuates SNI-induced mechanical allodynia as early as two weeks following AAV injection. Consistent with behavioral phenotype, we observed that AAV-mediated Nav1.6 knockout significantly reduces Nav1.6 accumulation at nodes of Ranvier (A-fibre specific) adjacent to the site of nerve injury. Preliminary data also suggested that AAV mediated Nav1.6 knockout reduced excitability of large-diameter neurons 6 weeks after nerve injury. Taken together, these data are consistent with a role of Nav1.6 and large-diameter Aβ neurons in neuropathic pain.

Title: Voltage gated sodium channel NaV1.6 is expressed in muscle spindles.

Authors: *D. I. CARRASCO, T. C. COPE;
Applied Physiol., Georgia Inst. Of Technol., Atlanta, GA

Abstract: Understanding has advanced significantly, but remains incomplete for the molecular mechanisms underlying transduction and encoding of mechanical stimulation by muscle spindles. In particular, the ion channels underlying sustained repetitive firing occurring during static muscle stretch are unknown. Insight was gained into this phase of firing behavior from its interruption by acute treatment of the antiepileptic drugs Riluzole and Phenytoin. Although both drugs have multiple modes of action, the only commonality between them is that both inhibit sodium persistent inward current (NaPIC). NaV1.6 is known to be required for the generation of repetitive firing in many other systems and was recently localized in slowly adapting

mechanosentive receptors of the skin and the gut. The present study was undertaken to determine whether NaV1.6 is also present in muscle spindles. NaV1.6 immunoreactivity tested in soleus muscle spindles of adult rats, cats and mice was found concentrated in the heminodes that precede unmyelinated nerve endings and that are the presumed site of spike encoding of receptor potentials. NaV1.6 was also present in the sensory endings. These findings open the possibility that NaPIC participates in mechano-sensory transduction and encoding.

Title: Cortical encoding of tactile roughness in primate primary somatosensory cortex (S1)

Authors: W. YAÏCI[1], *E.-M. MEFTAH[2], C. E. CHAPMAN[1];
[1]Neurosciences, Univ. de Montréal, Montréal, QC, Canada; [2]Neurosciences, Univ. De Montreal, Montreal, QC, Canada

Abstract: We recently showed that a proportion of texture-sensitive neurones in the S1 cutaneous hand representation have properties consistent with them playing an important role in the encoding of tactile roughness intensity: their discharge rates are broadly tuned across a wide range of SPs (spatial periods), independent of tactile scanning speed (Bourgeon et al. 2016). We also identified a number of neurones that showed changes in discharge restricted to a smaller range of SPs, and suggested that they may play a role in discriminating changes in tactile roughness. Curiously, however, these neurones did not seem to be more sharply tuned for changes in raised dot spacing than those that were broadly tuned as would be required to explain the human ability to discriminate small changes in the spacing of tactile elements in the order of μm. We also noted, however, that texture-related signals were substantially higher in the population of neurones tested with non uniform textured surfaces (first half of the surface with a small SP, 1.5mm; second half with SPs up to 8.5mm), as compared to those tested with uniform SPs (2 - 8 mm). Moreover, the slopes of their regressions (rate vs SP) were steeper. In this study,

we pursued this observation by recording the discharge of 95 texture-sensitive neurones in 2 alert monkeys as a wide variety of textured surfaces were displaced under their fingertips. Recordings were restricted to neurones with a cutaneous receptive field on the digits in contact with the surfaces (D3, D4). Four series of 4 surfaces (rectangular arrays of raised dots) were prepared from flexible letterpress. The first half of each surface had a standard SP, S; the second half had a modified, M, SP: 1) S/M, 1/1-8.5 mm; 2) 1/1-1.6mm; 3) 2.5/2.5-3.7mm; 4) 3.5/3.5-5.3mm. Surfaces were attached to a drum that was rotated under the fingertips at 60 mm/s. Monkeys performed a diversionary task (visual discrimination) during data acquisition. We hypothesized that the SP encountered over the S portion of the surface would modify the subsequent response to the M surfaces. Our results show that a large proportion of neurones (81/95) in the cutaneous hand representation (areas 3b, 1 and 2) showed a marked amplification of their texture-sensitivity as a function of the roughness of the S surface. We interpret these results as providing evidence of a dynamic gain change as a function of the SP encountered over the first half of the surface. This mechanism can dynamically extend the working range of S1 neurones, consistent with the highly developed abilities of humans to discriminate small change in tactile roughness.

Title: Human tactile afferent responses to skin strain patterns caused by fingertip shearing

Authors: *A. BARREA[1], E. JAROCKA[2], P. LEFÈVRE[1], J.-L. THONNARD[1], B. B. EDIN[2], B. P. DELHAYE[3];

[1]Univ. Catholique De Louvain, Louvain-la-Neuve, Belgium; [2]Umeå Univ., Umeå, Sweden; [3]Dept. of Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL

Abstract: Strain patterns are produced in the skin when a fingertip is pressed against a surface and then loaded tangentially. These strains can be precisely measured using a recently developed method (Delhaye et al. 2016), evolve during increasing loading and are specific to the loading direction. Although tactile afferents are known to respond to such strain changes, it has not been previously possible to relate their responses to specific skin strain patterns.
To fill this gap, we have combined the novel method to investigate strain patterns in fingertips with microneurography recordings. While recording single tactile afferents from human fingertips (right index or middle finger), a servo-controlled transparent flat surface was moved perpendicular towards the finger pad in single trials, made contact and reached a preset normal force that was kept constant during the trial. After a short delay, the surface was moved horizontally with a constant speed (5.5 mm/s) first in one direction (ulnar, radial, distal or proximal) for 8 mm and then in the opposite direction for 12 mm. The movement amplitudes were thus large enough to ensure eventually full sliding between the fingertip and the surface in both directions. The trial ended when the surface was retracted from the finger (total trial duration: 6 s). Two different frictional conditions were obtained using a glass surface, covered or not with RainOff, a transparent coating markedly reducing the surface-skin friction. Position and forces exerted on the finger were recorded at 1 kHz during the trials. At the same time, fingerprint deformations were monitored with a high-speed (50 fps) and high-resolution (1,200 dpi) camera, allowing derivation of surface strains in the fingertip.
We recorded responses from 19 afferents that had receptive fields at least partially within the contact area between the surface and the fingertip (6 SAI, 11 FAI and 2 SAII). The simultaneous recording of fingerprint images and tactile afferent responses allowed us to investigate the precise timing of neural responses to strains induced by tangential fingertip loadings commonly experienced during dexterous manipulation. Most of the afferents showed a strong response to the onset of the movement, and some displayed continuous discharges during the whole transition from sticking to sliding of the whole contact area. Both the frictional condition and the stimulation direction strongly influenced the afferent responses.

Abstract: Perception as well as encoding of sensory stimuli depend on several recurrent networks spanning multiple brain areas. In rats, for example, neurons in prefrontal cortices show reciprocal connections to primary and secondary somatosensory cortex, temporal higher-order sensory areas such as rhinal cortices, as well as to primary and secondary motor cortex. Prefrontal cortex is associated with executive functions and is therefore likely to be important for modulating the information processed in these different loops.
In the current study, we are investigating how prefrontal cortex integrates and processes information from primary sensory areas in context of the sensorimotor loop. In ketamine anesthetized Long Evans rats expressing channelrhodopsin-2 in primary somatosensory cortex, we used an array of epidural micro-LEDs to excite principal neurons in different barrels in distinct spatiotemporal patterns. Simultaneously, we recorded local field potentials, single and multi-unit responses in primary motor cortex, secondary motor cortex, orbitofrontal, or prelimbic cortices using high density silicon probes with up to 128 channels. Our setup represents a novel system to probe neural dynamics with multi-channel parallel stimulation and readout.
We are currently analyzing the data to understand how much information is conveyed to downstream areas about the spatial temporal structure of activity in primary sensory areas.

Title: Unified framework for the perception of stimulus intensity and stimulus duration in humans and rats

Authors: *A. TOSO, A. FASSIHI, F. PULECCHI, M. E. DIAMOND;
Cognitive Neurosci., SISSA, Trieste, Italy

Abstract: The nervous system can extract multiple perceptual features from a single sensory stream. Presented with a tactile vibration, for instance, we perceive both its intensity and its duration. How are different dimensions of a single stimulus read out from the brain to generate separate perceptual properties? Are the dimensions independent or else interacting? Here we present behavioral experiments, in both human and rats, to determine whether, and how, stimulus intensity and duration interact in the perception of both features. In the first experiment, subjects receive two vibrations (Stim1 and Stim2) delivered either to their fingertip (humans), or whiskers (rats). Vibrations are normally distributed velocity noise, defined by mean speed and by stimulus duration. They are rewarded for detecting the relative mean speeds of Stim1 and Stim2, an intensity comparison. Humans and rats both show progressive improvement as vibration duration increases, provided Stim1 and Stim2 are of equal duration. In contrast, unequal duration of Stim1 and Stim2 leads to a perceptual bias corresponding to an overestimate of the intensity of the longer stimulus. In the second experiment, we implemented a duration comparison task using the same stimulus set: subjects are rewarded for detecting the relative durations of Stim1 and Stim2. Humans and rats then over-estimate the duration of the higher-intensity stimulus. Thus, longer feels stronger (Experiment 1) and stronger feels longer (Experiment 2). In Experiment 3, in order to quantify the interaction of perceived duration and intensity, we designed a task in which human subjects have to estimate either the duration or the intensity of single vibrations by scaling their judgment through a slider. This experiment reveals that both the percepts - duration and intensity - are generated using “universal” variables simultaneously. We thus propose a unified model that supports the idea that a common network can dynamically extract duration or intensity from the same vibration in a task-dependent manner. In behaving rats, neurons in the barrel (primary somatosensory) cortex do not show the temporal integratory properties that could explain the duration-intensity perceptual confound. In contrast, premotor cortex neurons do express the computations inherent to the model and confirm that both intensity and duration of the stimuli are encoded by the same neural population.

Title: Encoding of whisker mechanics and kinematics in trigeminal ganglion neurons of the rat.

Authors: *N. E. BUSH[1], A. E. T. YANG[2], L. A. HUET[2], S. A. SOLLA[3], M. J. Z. HARTMANN[4];
[1]Interdepartmental Neurosci. Program, Northwestern Univ. - Chicago, Chicago, IL; [2]Mechanical Engin., Northwestern Univ., Evanston, IL; [3]Physiology; Physics and Astronomy, Northwestern Univ., Chicago, IL; [4]Mechanical Engineering; Biomed. Engin., Northwestern Univ., Evanston, IL

Abstract: Tactile information available to the rat vibrissal system begins as external forces that cause whisker deformations; these in turn excite mechanoreceptors in the follicle. Despite the fundamental mechanical origin of tactile information, primary sensory neurons in the trigeminal ganglion (Vg) have often been described as encoding the kinematics (geometry) of object contact. Here we aimed to determine the extent to which Vg neurons encode the kinematics vs. mechanics of contact. We used models of whisker bending to quantify mechanical signals (forces and moments) at the whisker base, while simultaneously monitoring whisker kinematics and recording the activity of single Vg units in both anesthetized rats and awake, body restrained rats. We employed a novel manual stimulation technique to deflect whiskers in a way that decouples kinematics from mechanics, and used Generalized Linear Models (GLMs) to show that Vg neurons more directly encode mechanical signals during whisker deflection.

Abstract: Supra-granular layers of sensory cortex exhibit sparse spiking activity. In the rodent vibrissal cortex, a small fraction of neurons in layer 2 and 3 (L2/3) respond to whisker deflections under anesthetized and behaving conditions. Here, we combined whole-cell recording and two-photon imaging in urethane anesthetized mice and quantified the synaptic and spiking responses of L2/3 neurons to a range of stimulus intensities that included a “sharp” stimulus to mimic high-velocity whisker slips during object or texture palpation. Stimuli consisted of 11 “standard” deflections (amplitudes; 0-2.8 degrees, peak velocities; 0-1.21 degree/ms) and the sharp deflection (amplitude; 3.6 degree, peak velocity; 3.82 degree/ms). These deflections were applied to the left whisker-pad in a pseudorandom order for 25 trials each (2s inter-trial-intervals). Whole-cell recording confirmed the sparse response to the regular range of stimulation: although all recorded cells received the sensory signal as postsynaptic potentials (PSPs), only a small fraction (3 out of 11) produced spikes to the strongest standard stimulus. The sharp stimulus on the other hand evoked strong and fast-rising PSPs, resulting in reliable spiking activity. The threshold of these evoked spikes was on average 10.8 mV lower than spontaneous spikes ($p<0.001$, n=11 neurons). Across all electrophysiological recordings (whole-cell: n=11, and loose cell-attached n=26) similar transition from sparse to dense spiking was observed: only 8 cells out of 37 (21.6%) were responsive ($p<0.05$) to the standard stimulus with the highest peak velocity, but the sharp stimulus (3.82 degree/ms) produced significant spiking response in 34 out of 37 cells (91.9%). Reliable spiking was also observed when the sharp stimulus was delivered to a single whisker in recordings form L2/3 of the corresponding cortical column targeted by intrinsic signal optical imaging (n=31, 74% responsive). Evoked spikes were highly reliable across trials with an average jitter of 1.73 ms and Fano factors close to the theoretical minimum. Functional imaging confirmed the dense activation; 1574 out of 1640 cells (~96%) produced a significant response to the sharp stimulus (delivered to the whisker-pad) while 647 cells (~39%) were responsive to the standard deflection at the highest peak velocity

(1.21 degree/ms). Our results indicate that sparse coding depends on the choice of stimulus; a "dense" population response emerged in L2/3 when a high-velocity stimulus was delivered to a single whisker or the whole whisker-pad.

Title: Neural representation of contact pressure in primary somatosensory cortex

Authors: *T. CALLIER, S. J. BENSMAIA;
Univ. of Chicago, Chicago, IL

Abstract: Tactile signals from the hand are critical to our ability to grasp and dexterously manipulate objects. Information about contact pressure is a key component of sensory feedback in guiding object interactions. Indeed, we apply just enough pressure so that we do not drop an object and no more. In the present study, we examined how pressure is encoded in primary somatosensory cortex (S1) of non-human primates (NHPs). To this end, NHPs performed a pressure discrimination task in which they judged which of two ramp-and-hold indentations delivered to their skin was stronger. While the animals performed the task, we recorded the responses evoked in S1. First, we found a linear relationship between indentation depth and evoked firing rates. Second, neurometric analysis revealed that the performance of the NHPs was well predicted by the neuronal responses under most circumstances. Third, we observed that neuronal responses were highly dynamic during the stimulus: phasic responses at stimulus onset and offset were much stronger than were the sustained responses during the hold phase. In fact, information theoretic analysis revealed that nearly all of the information about indentation depth was conveyed by the phasic responses evoked during the stimulus transients. Fourth, we confirmed that the distribution of neural activity over the cortical surface varied consistently based on the locus of stimulation, yielding clear and detailed somatotopic maps of the hand representation in S1. Neural activity was centered on one or a few points and decayed with distance from these "hot zones." Importantly, the location of these hot zones remained constant, but the area of activation increased systematically with increases in indentation depth.
In conclusion, information about pressure is encoded in both the strength of the response at the hot zone and in the size of the activated neuronal population, with greater pressure recruiting more neurons. Furthermore, the response to a simple ramp-and-hold indentation is highly

dynamic, with most of the information conveyed during the stimulus transients. The default approach to restoring somatosensation in upper-limb neuroprostheses is to implement a linear mapping between the output of sensors on the prosthesis and strength of electrical stimulation delivered to the brain. The present findings can be used as a blueprint to develop stimulation approaches that more closely mimic the neural correlates of changes in pressure, which should result in more intuitive and informative feedback about object contact.

Title: Coding of edge orientation in afferent responses of macaques

Authors: *A. K. SURESH, B. P. DELHAYE, H. P. SAAL, S. J. BENSMAIA;
Univ. of Chicago, Chicago, IL

Abstract: Experiments with non-human primates (NHP) have shown that many neurons in primary somatosensory cortex are tuned for the orientation of edges indented into or scanned across the skin, drawing a strong analogy with their counterparts in primary visual cortex. In a recent study, however, the responses of individual mechanoreceptive afferents, measured in humans, have also been found to carry information about edge orientation. In the present study, we sought to (1) investigate whether orientation signals are also found in afferent responses in NHPs and (2) explore how these signal might contribute to downstream orientation tuning. To this end, we recorded the activity evoked in cutaneous mechanoreceptive afferents when edges were indented into or scanned across their receptive field on the glabrous skin of the hand. First, we show that monkey afferents exhibit complex receptive field structure, consisting of multiple hot spots, as is the case with their human counterpart. Second, we confirm that information about the orientation of edges indented or scanned across the skin can be extracted from the timing of afferent responses. Third, we find that orientation signals in tactile afferents are often highly dependent on stimulus features other than orientation, for example stimulus amplitude, in contrast to their counterparts in somatosensory cortex. Finally, we implement a computational

model to assess the degree to which peripheral edge tuning might contribute to the robust orientation tuning observed in cortex and find that this contribution is modest. We then speculate as to possible functions of the complex receptive field structure of mechanoreceptive afferents.

Title: Dynamics of motion signals in the primary somatosensory cortex

Authors: *F. PIRSCHEL, J. E. WINBERRY, S. J. BENSMAIA;
Univ. of Chicago, Chicago, IL

Abstract: When we manipulate an object, neural signals from the hand convey information about its size, shape, and texture. If the object is moving relative to the skin, information about the speed and direction of the motion is also transmitted. These signals play a key role in our ability to dexterously manipulate objects as evidenced by the deficits that are observed when somatosensory feedback is eliminated, either experimentally or as sequela of disease.
In previous experiments on the neural basis of tactile motion perception, we identified a subpopulation of neurons in primary somatosensory cortex (S1) whose responses were tuned both for stimulus orientation and for motion direction. In the present study, we investigated the time course over which information about these two stimulus features evolves in the multiplexed responses of these S1 neurons. To this end, we scanned gratings or bars in different directions across the fingertip of Rhesus macaques while recording the responses evoked in S1 neurons. We found that tuning for stimulus orientation emerged consistently earlier than did tuning for stimulus direction. While orientation tuning peaks around 50 ms after stimulus onset, direction tuning increases over the first 200 ms of movement. Thus, responses from the same neurons seem to reflect both stimulus properties at different moments in time. We discuss the potential mechanisms underlying these dynamics and their sensory consequences.

Title: The transformation of texture representations from somatosensory periphery to cortex

Authors: J. D. LIEBER, H. P. SAAL, Z. M. BOUND-SINGER, A. I. WEBER, *J. E. WINBERRY, S. J. BENSMAIA;

Abstract: Our sense of touch endows us with an exquisite sensitivity to surface texture. One of the remarkable aspects of tactile texture processing is that it operates over 6 orders of magnitude in element sizes, from the smallest discernible elements (on the order of 10s or nanometers) to the largest elements that can fit on a fingertip, measured in tens of millimeters. This wide range of scales is accommodated by distributing information across three types of mechanoreceptive afferents, each sensitive to surface elements over different spatial scales. The coarsest textural features, those on the order of millimeters, are conveyed in the spatial pattern of activation in slowly adapting type 1 (SA1) afferents. Finer features, ranging in size from microns to nanometers, are conveyed in the temporal spiking patterns of rapidly adapting (RA) and Pacinian corpuscle associated (PC) afferents. PC afferents are especially notable for their ability to phase-lock to vibrations as high as 1000 Hz. It is unknown to what extent these peripheral streams of information are integrated to achieve a unitary sensory experience of texture.
To investigate how these peripheral representations of texture transform as they ascend the somatosensory neuraxis, we scanned a large set of natural and artificial surfaces across the fingertip of Rhesus macaques while recording the responses evoked in single-units in primary somatosensory cortex (areas 3b, 1 and 2). Most cortical responses showed evidence of integration across multiple streams of afferent information. For example, many neurons were characterized by both complex spatial receptive fields (indicative of input from the spatial pattern of activation across SA1 afferents) as well strong at the offset of indentations (a signature of RA and PC input). In striking contrast to the main population however, we found a small subset of neurons that appeared to be driven solely by PC responses. In contrast to the rest of S1, these neurons preserved some of the finely timed spiking patterns found peripheral texture responses. S1 appears to use both convergence and segregation as strategies to extract texture information from peripheral representations.

Title: High-dimensional representation of hand movements in sensory and motor cortices

Authors: *J. GOODMAN, JR[1,2], G. A. TABOT[2], A. K. SURESH[2], N. G. HATSOPOULOS[2], S. J. BENSMAIA[2];

Abstract: The hand is complex. With over 20 degrees of freedom, it is difficult to coordinate and track all the joints that make up a hand to achieve the fluid movements that we can effortlessly produce. One theory to explain how the brain solves the motor control problem is that the nervous system, rather than controlling each degree of freedom individually, pulls a smaller number of strings to co-activate stereotyped combinations of muscles, or synergies. To investigate this synergy hypothesis and its applicability to the hand, we train monkeys to grasp a variety of objects that vary widely in shape and size and hence evoke myriad grasping strategies. As each monkey performs this task, we track the joints of the hand while simultaneously recording single-unit spiking activity from primary somatosensory and motor cortices. We then use supervised machine learning (linear discriminant analysis) to determine the degree to which the kinematics and associated neuronal responses depend on what object is grasped. First, we find that both the kinematics and the neuronal responses are highly object specific. Second, the pattern of confusions by the classifier are similar when classification is performed based on kinematics or neuronal responses. Third, as expected, motor responses convey object-specific information earlier than do the kinematics, which in turn are informative earlier than are the sensory responses. Fourth, to classify objects based on kinematics or neuronal responses requires many more dimensions than would be expected based on the synergy hypothesis. Indeed, classification based on nine principal components is significantly poorer than classification based on all dimensions. In other words, even those kinematic dimensions that account for little variance and are dismissed as noise in a typical principal components analysis seem to be under volitional control and systematically encoded in M1 and S1 responses. These results argue against the interpretation of the synergy hypothesis that postulates that motor control is simplified by a reduction in the dimensionality of volitionally controlled limb movements.

Title: Decoding motion speed from the responses of tactile afferents

Authors: *B. P. DELHAYE[1], A. I. WEBER[2], S. J. BENSMAIA[1];
[1]Dept. of Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL; [2]Grad. Program in Neurosci., The Univ. of Washington, Seattle, WA

Abstract: Movement is a hallmark of haptic exploration: to make out the shape of an object, we move our hands across it. When we use a tool, we need to be aware of its movements in the hand. Much experimental attention has been devoted to understanding how the direction of tactile motion is encoded in the somatosensory system. Here, we investigate how tactile speed is encoded in the nerve. We and others have shown that human subjects can scale speed at which objects move across their skin. One hypothesis is that speed is encoded in the strength of the response, given that afferent firing rates increase monotonically with increases in scanning speed. However, the firing rates of nerve fibers are also strongly modulated by surface texture. Here, we investigate the possibility that tactile speed is computed in a way that is analogous to visual speed: from correlated but phase-shifted responses across afferents with nearby receptive fields (i.e., via Reichardt detectors). To this end, we analyze measured and simulated neuronal responses to scanned textures. First, we confirm that afferent firing rates are poor predictors of tactile speed given their strong texture dependence. Second, we show that pairs of afferents of the same type produce correlated albeit somewhat idiosyncratic responses to textures. We then examine whether this Reichardt-like mechanism can account for the perception of tactile speed and compare it to a rate based mechanism.

Title: Using optogenetics to probe neuronal excitability in mechanosensory afferents

Authors: *D. AL-BASHA[1,2], S. A. PRESCOTT[1,2];
[1]Neurosci. and Mental Hlth., The Hosp. For Sick Children, Toronto, ON, Canada; [2]Physiol., Univ. of Toronto, Toronto, ON, Canada

Abstract: Neurons rely on action potentials, or spikes, to transmit information. A certain amount of depolarization can evoke very different spike trains depending on the local spike generation properties. Those properties can vary across neurons, or even between different regions of a single neuron, based on the ion channels expressed in each neuron or region. We seek to understand spike generation in primary afferent neurons (PANs), which are responsible for the initial encoding of somatosensory stimuli. How exactly PANs encode information is still not clear because spike initiation in these neurons occurs at axonal terminals that are inaccessible to intracellular recording due to their extremely small size. To circumvent this problem, we developed an innovative approach that uses optogenetics to focally stimulate the axonal terminals while recording from the cell body. To this end, we expressed channelrhodopsin-2, a light-sensitive channel, in PANs in a mouse model. We first validated the use of light to probe neuronal excitability in vitro in the cell body. Using whole-cell recording to measure the excitability of these neurons in response to current injection and light, we show that photo-evoked spiking in the cell body is highly dependent on intrinsic excitability. We also show that PANs with large cell bodies, which correspond to low-threshold mechanoreceptors, had a high current threshold and spiked transiently in response to current injection and photostimulation. Next, we proceeded to test spike generation properties of axon terminals to compare these properties to that of the cell body. Using in vivo multiunit recording from PAN cell bodies while stimulating cutaneous axon terminals of low-threshold mechanoreceptors with light, we show that unlike the cell bodies, some axon terminals spike repetitively during sustained stimulation, highlighting differences in subcellular neuronal excitability.

Title: Whisker-mediated shape recognition in head-fixed mice

Authors: *C. RODGERS, P. CALAFATI, A. KHANNA, R. BRUNO;
Columbia Univ. Med. Ctr., New York, NY

Abstract: Rodents rely heavily on whisker-mediated touch to explore their environment. By sweeping their whiskers across objects, similar to the way in which we palpate objects with our fingertips, rodents can identify an object's location, texture, and shape. The "novel object recognition" task, widely used in psychiatric research, challenges freely moving rodents to identify unfamiliar objects; however, it is typically unclear which sensory modality and strategy they use to do so. In contrast, head-fixed behavioral paradigms for studying rodent somatosensation are generally used to study object location and texture, not shape. Therefore, we have developed a head-fixed behavioral paradigm for studying object recognition that is amenable to modern imaging and recording techniques. Mice learn to discriminate objects having different curvature. Preliminary results indicate that their performance correlates with degree of curvature and that multiple whiskers are required for good performance. We are presently recording activity in somatosensory cortex of mice performing this task. This paradigm is useful for examining the circuit activity underlying object recognition and how it relates to processing in other sensory systems.

Title: Neural encoding of raised gratings in vibrissal S1 during a head-fixed surface discrimination task

Authors: *B. R. ISETT, S. H. FEASEL, M. A. LANE, D. E. FELDMAN;
Helen Wills Neurosci. Inst., Univ. of California Berkeley, Berkeley, CA

Abstract: Rodents use facial whiskers to locate objects and discriminate textures, but little is known about how the whisker system encodes object shape. Shapes relevant to the whisker system might consist of features spaced at a scale accessible to the whisker tips during active sensation (1-10mm, “macrogeometry”). Therefore, we studied how tactile gratings at this scale are encoded by spiking of single units in whisker somatosensory cortex (S1). We trained mice to run on a rotary treadmill while raised grating stimuli (ridges of 2, 4, 8 or 10 mm spatial period mounted on a smooth cylinder), or the smooth cylinder alone, moved through the whisker field. Stimulus movement was yoked to the mouse’s locomotion to create a 1D tactile virtual reality, allowing us to study active sensation of stimulus features in a highly naturalistic regime. Animals learned to discriminate grating from smooth stimuli in a Go/No-Go paradigm, with only C1 and C2 whiskers intact (n=10 mice, d’= 1.4). Using high-speed imaging, we measured whisker position, speed, acceleration and phase. Gratings increased the rate of transient high-acceleration events (“stick-slips”), which clustered at grating bar edges. We recorded single-unit extracellular spiking to whisker kinematic- and stimulus-related features in L3-6 of the C1 or C2 column (n= 6 mice, 15 recording sessions, 458 single units). 69% of units fired faster on the stimulus cylinder than in air. The convex curvature of the stimulus cylinder drove multi-unit spiking maximally at the point on the cylinder closest to the whisker follicle. 27% of surface-excited units further increased firing rate on tactile gratings. Among the whisker kinematic features that occurred during stimulus exploration, stick-slips significantly modulated firing rate in 70% of S1 units in L3, L4, L5b and L6, and 50% in L5a. Bar edges drove pronounced acceleration transients, but modulated temporally precise spiking in only 10% of units. The majority of single units showed significant phase tuning, which was much stronger while contacting the stimulus wheel than during whisking in air. Most phase-tuned units were tuned to protraction phases. This phase preference facilitated responses to both stick-slip events and bar edges when they occurred

during the preferred phase. We hypothesize that single unit phase and stick-slip responses interact to build a robust spatiotemporal code of shape in S1.

Title: Conveying integrated whisker information through innate network and gamma oscillation in the sensorimotor cortex of mice

Authors: *H. LIM[1,2], E. BAEG[1], S. BAE[1,2], M. SUH[1,3];
[1]CNIR, Inst. For Basic Sci. (IBS), Suwon, Korea, Republic of; [2]Dept. of Biol. Sci., [3]Dept. of Biomed. Engin., Sungkyunkwan Univ., Suwon, Korea, Republic of

Abstract: Integration of whisker deflecting information is an initial important step not only in identifying object outside but in adequate motor execution. Here, we investigated how discrete sensory information is integrated and transferred within the barrel cortex and to the motor cortex. Voltage sensitive dye imaging from one hemisphere of slightly anesthetized mouse while stimulating one or two whiskers showed that time between stimulations and order of whisker deflections are critical factors in multi-whisker integration. Cortical activation was larger when two whiskers were stimulated simultaneously or with 5ms delay, compared to deflecting one whisker. In addition, spreading paths were different depending on the whisker that was stimulated first. Local field potentials, recorded from a principal and a surround barrel cortex, showed comparably larger supra-granular facilitative evoked potentials with the enhanced gamma oscillation when a whisker located in rostral or ventral position was deflected first. Electroencephalogram, obtained from the barrel and motor cortices, showed larger coherence in the gamma-frequency range. Our results suggest that discrete signal processing route and strength of responses encode integrated sensory information. Moreover, gamma oscillation transmits the integrated information to the other cortical areas for accurate sensing or attention.

Title: Spatio Temporal profile of neural activity in barrel cortex and perceptual decision

Authors: *J. CAMON, S. HUGUES, M. ERLANDSON, S. LAGOUN, E. MAROUANE, I. BUREAU;
Univ. Aix-Marseille, INMED, U901, INSERM, Marseille Cedex 09, France

Abstract: The vibrissal system has been intensively used in the recent years as a model to study the cortical activity underlying perceptual decision. Mice are trained to retrieve a reward when an object requiring a tactile exploration is presented to them or when their whiskers are passively deflected. Mice are trained over days or weeks and they may be subjected to thousands of trials during which the stimulation of their whiskers is paired with a reward. Sensory experience modifies networks and in particular pairing a tactile stimulus with an emotional contingency alters the whisker cortical map in barrel cortex. However, the plasticity of the whisker-evoked responses due to operant conditioning has little been explored beyond a single cortical column. To address this issue we developed a paradigm in which mice were freely moving and the whiskers C were deflected signaling to the mice the possibility to retrieve a reward. Then, we recorded the multi-unit activity (MUA) in the layers 2/3, 4 and 5 of barrel cortex evoked by the deflections of these whiskers and neighbors while mice were anesthetized. We found that training had profound effects on the size and temporal properties of the responses evoked by the C whisker outside of the C column. Their size was significantly correlated to the success rate of the mouse measured at the last training session. Moreover, the timing of these responses recorded in layer 4 and 5 correlated with the mouse reaction time in the arena almost perfectly. The MUA spiking rate and onset were not correlated. Our data suggest that behavioral conditioning organizes the feed-forward inputs sent by the trained whisker within a time window of ~ 20 ms and transmit them, directly or indirectly, to the “non-trained cortical columns” with a speed that is function of the perceptual decision delay. The temporal properties and the spiking rate of these late responses would code for two distinct aspects of the learned behavior: the primal reaction to the stimulus and the capacity of completing the task.

Title: Dendritic activity underlying angular tuning of barrel cortex neurons *In vivo*

Authors: *M. LAVZIN, L. GARION, U. DUBIN, J. SCHILLER;
Technion, Haifa, Israel

Abstract: It is a well-established finding that neurons in primary sensory cortical regions are selective to specific features of the stimulus. However, the mechanisms underlying this selectivity remain unclear.
Our recent work has shown that regenerative NMDAR currents play a significant role in shaping direction selective responses in layer 4 of the rat barrel cortex. However the spatial organization of these dendritic events and the synaptic inputs contributing to them is unknown. In the visual cortex of mice, it has been shown that spines showing different selectivity are distributed in the same dendritic branches of layer 2-3 neurons. However, it is unclear whether this is a general feature across different modalities, and what is the mechanism by which a specific dendritic branch determines its selectivity.
We used 2 photon calcium imaging combined with electrophysiological whole-cell patch-clamp recordings to directly visualize the activated spines and record the somatic sub- and suprathreshold voltage responses in barrel cortex neurons in an in-vivo anesthetized mouse preparation during angular stimulation of whiskers. We found that terminal dendritic branches show selectivity to angular stimulations. Furthermore, the angular tuning could differ between different dendrites.

Title: Muscle-based representation of reaching in macaque somatosensory cortex

Authors: *R. H. CHOWDHURY, J. GLASER, L. E. MILLER;
Northwestern Univ., Chicago, IL

Abstract: When we reach for a cup of coffee, we don't consider how our muscles are stretching. Rather, we perceive our limb state (the sense of proprioception) in terms of the position of the hand or overall posture of the limb. However, the most important proprioceptive sensors, muscle spindles and Golgi tendon organs, lie within muscles, sensing length and force. Thus, at some stage of processing, the brain transforms proprioceptive signals from an array of muscle sensors to an overall limb representation.

An interesting area to look for this transformation is area 2 of primary somatosensory cortex (S1), which both receives input directly from thalamus and communicates with other cortical areas involved in perception and reaching. Based on a small number of studies, we know that neurons in area 2 typically respond to arm movement in a "preferred" direction" (PD). These studies have all assumed that area 2 neurons encode limb state in egocentric hand coordinates. However, this assumption has not been explicitly tested. Here we present results suggesting that this transformation has, in fact, not yet occurred in area 2.

We have developed a visual motion tracking system using the Kinect v2 (Microsoft), a consumer-grade depth camera. We estimated the lengths of muscles by feeding these tracking data into a musculoskeletal model implemented in OpenSim. At the same time, we recorded neural responses from area 2 using a 96-channel Utah Electrode Array (Blackrock Microsystems). For small deviations around a given arm posture, hand-based and muscle-based coordinate systems are roughly linearly related. To disambiguate these relationships, we had the monkey perform a random target reaching task with its hand centered in either of two workspaces: ipsilateral and away from the body, or contralateral and near it. We found that most neurons responded strongly to hand movements in both workspaces, but often with different PDs. Additionally, in each workspace there appeared to be a bias in the distribution of PDs, causing them to be directed preferentially either towards or away from the body. Both of these results are inconsistent with a hand representation. To understand these results, we simulated neurons having neural activity that was a simple linear combination of muscle stretch velocity, a stimulus to which muscle spindles are highly sensitive. We found that the simulated neural discharge recreated both the bias and workspace dependence of the actual PDs. Thus, unlike previous assumptions about S1 representation of limb state, our results suggest that the transformation of muscle receptor signals to an egocentric sense of limb position has not yet been completed in area 2.

Abstract: Higher order sensory cortices, such as the posterior parietal cortex (PPC) have been implicated in a range of cognitive behaviors, ranging from navigation to multisensory integration and perceptual decision making. Only recently we have begun to explore the neural circuit dynamics in the PPC during such complex behaviors, over a large population of neurons and at single-cell resolution. Here we trained mice to perform a whisker-based texture discrimination task and report their decision by licking. Using genetically encoded calcium indicators (GECIs) and chronic cranial windows, we recorded the neural responses from excitatory neurons in layer 2/3 of the PPC of well trained mice during goal-directed behavior. We observed that some neurons displayed sensory evoked responses whereas others had task-outcome related activity that was present before behavioral report by licking. Another subset of neurons showed enhanced activity upon the omission of the texture stimulus, with all other cues present. Hence PPC neurons showed a spectrum of activity with temporal dynamics matching task epochs, along with a role in stimulus feature association. Finally optogenetic inhibition of the PPC during the task led to a decrease in performance. These findings demonstrate that neural activity in the PPC can influence task outcome, hence contributing to perceptual decision making.

Title: Active touch modulates cortical excitation and inhibition evoked by closed-loop optogenetic stimulation

Authors: *S. SUNIL, J. B. SCHROEDER, J. T. RITT;
Biomed. Engin., Boston Univ., Boston, MA

Abstract: Active sensing allows closed-loop behavioral selection of information during sensory acquisition. The rodent whisker system provides a well-characterized model, analogous to active touch in humans, for studying active touch. We developed a real time feedback system that delivers optogenetic stimulation to somatosensory cortex (S1), time locked to whisking as estimated through facial electromyography (EMG). Water-restricted mice were trained to alternately traverse a linear track to obtain a water reward. Once the behavior was learned, mice were implanted with custom chronic hyperdrives over left S1 for neural recording and stimulation, and with bilateral EMG electrodes in the whisker pad to estimate whisker position. A digital signal processor based system recorded activity in S1 and delivered optogenetic stimulation through an optical fiber using a blue (473nm) laser coupled to the implant. Protraction and retraction of the whiskers were defined using two manually identified thresholds. Stimulation of excitatory neurons in S1 lead to an increase in regularity of whisker motions, with effects on the next whisk following stimulation. Stimulation also induced a rapid increase in neural activity when timed with protractions, but not when timed with retractions. This cyclic modulation of S1 may suggest information is more likely encoded while the whiskers are in forward motion. We further investigated stimulation of inhibitory interneurons, which resulted in a decrease in neural activity during protractions, without significant change in neural activity during retractions. Taken with the previous experiment, these results suggest a cyclic modulation of both excitation and inhibition in S1 with each whisk, such that downstream areas may show preferential tuning to S1 timing relative to self-motion. Whisker motions did not show strong changes with recruitment of inhibition, possibly due to the local innervation of interneurons and a “window of opportunity” effect. Overall, sensory cortex likely plays a role in guiding sensory motions, in addition to encoding incoming information relative to self-motion.

Title: Does proprioceptive information contribute to illusory force sensation elicited by asymmetric vibration?

Authors: *S. TAKAMUKU[1], T. TESHIMA[2], T. AMEMIYA[1], H. GOMI[1];

Abstract: Asymmetric tangential vibration of a pinched vibrator induces an illusory sensation that sustained directional pulling force is applied to our fingertips. The illusion attracts wide interest not only in relation to its application in developing mobile force display devices, but also in relation to its implication on the mechanism of our force perception. Here, to specify the sensory substrate involved in the illusion force sensation, we systematically varied the state of contact with the vibrator and examined its effect on the clarity of the illusory sensation (i.e., detection rate of displayed force direction). In our first experiment, we examined the effects of vibration orientation, surface texture, and grip force (3-factors-repeated-measures-ANOVA). Pillar array with a diameter of 0.5 mm and gaps of 2.0 mm on vibrator surface significantly increased the correct rate (main effect of texture), suggesting a contribution of cutaneous receptors. Effect of grip force was also significant, but depended on orientation of vibration (significant interaction between factors of vibration orientation and grip force). Namely, correct rate dropped as increase in grip force when vibration was applied along the fingers (longitudinal vibration) but not when it was applied across the fingers (transversal vibration). The difference in the effect of grip force could reflect anisotropy of cutaneous sensory system and/or potential contribution of finger movements (finger movements are larger under transversal vibration due to anisotropy in musculoskeletal stiffness). To examine the latter possibility, in the second experiment, we had the participants pinch a vibrator with a flat surface while pulling the index finger with 2.5 N to minimize its adduction/abduction motion (repeated-measures ANOVA with orientation of vibration, application of bias force, and grip force as factors). Application of the pulling force significantly deteriorated the performance under transversal vibration with 2.0 N grip force. This suggests a possibility that not only the cutaneous mechanoreceptors around the fingertips but also sensory channels responding to finger motion contribute to the illusory force sensation experienced under the transversal vibration.

Title: GPU-accelerated calculation of an electric field generated by an electric fish and neural activities of the electrosensory system

Authors: *K. FUJITA[1,2], Y. KASHIMORI[2];
[1]Tsuyama Natl. Col. of Technol., Tsuyama-City, Okayama, Japan; [2]Univ. of Electro-Communications, Tokyo, Japan

Abstract: The purpose of this study is to accelerate calculation of electric stimuli and neural activities of the electrosensory system using a graphics processing unit. An electric fish can recognise object's parameters, such as material, size, distance and shape, in complete darkness. The ability to recognise these object's parameters is provided by fish's electrosensory system. The fish generates an electric field using its electric organ. An object around the fish distorts the electric field and make an electric image on fish's body surface. The fish can extract the object parameters from the electric image using its electrosensory system. However, features of the electric image representing object’s parameters and the neural mechanism to extract the parameters are not well known. To address this issue, we developed a realistic simulation model to obtain the detail of electric images generated by various objects and neural models of electrosensory system. However, the simulations to obtain the electric images and the neural activities require massive computational resource. In this study, we accelerated our simulations using a graphics processing unit that achieves massively parallelized computation.

Title: Frontal-posterior interactions in mouse neocortex during a texture discrimination task

Authors: *A. GILAD[1], J. CHEN[1,2], F. HELMCHEN[1];
[1]Brain Res. Inst., Zuerich, Switzerland; [2]Dept. of Biol., Boston Univ., Boston, MA

Abstract: The mammalian brain integrates behaviorally relevant sensory information by recruiting large parts of the neocortex to enable precise perception, apt decisions and adequate actions. The large-scale interactions and the distinct roles of the various neocortical regions, namely frontal motor-related areas and posterior sensory-related regions, remain poorly understood. Here, we aim to characterize how behavior-related activity is integrated throughout large parts of the cortex. Head-restrained transgenic mice expressing GCaMP6f in layer 2/3 excitatory neurons were trained on a 'go/no-go' S1-dependent texture discrimination task. On 'go' trials mice were required to lick for a water reward ('hit') when presented with a panel of one type of sandpaper; in 'no-go' trials they were supposed to withhold licking ('correct rejection') when presented with a differently graded sandpaper. In addition mice were required to delay their licking response on 'go' trials, enabling temporal segregation between "sensation" and "action". Different mice were trained on different 'go' textures. Using wide-field imaging, we simultaneously imaged large parts of the cortex, including frontal and posterior areas. We find that during sensation (i.e. texture touch) primary and secondary whisker somatosensory cortices displayed larger calcium transients during 'go' trials compared to 'no-go' trials, independent of texture type. During the delay period, we find that 'go' trials resulted in different activation patterns related to the state of the mouse: In 'go' trials where the mouse displayed high motor engagement (i.e. large body movements, during sensation), activity shifted to frontal areas, especially secondary motor cortex, whereas posterior sensory areas displayed suppressed activity. In contrast, on 'go' trials where the mouse displayed low motor engagement, activity was not present in frontal areas but rather remained elevated in posterior areas. The ratio between these two patterns varied across and within mice. These results highlight the importance of single trial analysis and may imply that different strategies may be used to reliably execute complex behaviors.

Title: Response of vibrissal-responsive trigeminal ganglion neurons to airflow

Authors: *P. KUMARAPPAN[1], N. E. BUSH[2], M. J. Z. HARTMANN[1,3];
[1]Biomed. Engin., Northwestern Univ., Evanston, IL; [2]Interdepartmental Neurosci. Program, Northwestern Univ., Chicago, IL; [3]Mechanical Engin., Northwestern Univ., Evanston, IL

Abstract: Studies of the rodent vibrissal (whisker) system primarily focus on understanding tactile perception and sensorimotor integration. Other whiskered mammals, the harbor seals and California sea lions, have been shown to use their whiskers to follow water currents, allowing them to catch prey using wakes. Given that some marine mammals can use their whiskers to sense fluid flow, it seems possible that rodents might also use their whiskers to gather sensory information about airflow.

Recent work in our laboratory [1] has characterized how whiskers respond in the presence of airflow. The whisker tends to bend in the direction of airflow and the magnitude of bending is related to the airflow speed. The whisker vibrates around its new (deflected) position at frequencies close to its intrinsic resonance modes.

Here, we recorded from vibrissal-responsive primary sensory neurons of the trigeminal ganglion (Vg) while presenting airflow stimuli to the whisker array. We performed extracellular recordings of single units from the Vg of anesthetized rats while independently varying the airflow speed and direction. We correlated the neural responses with airflow speed and direction, and compared the spike patterns to the calculated resonance modes that describe whisker vibration. Results are discussed in the context of a potential role of Vg neurons for encoding the airflow stimuli.
